Antiviral and cell growth inhibitory activities reside in the same glycoprotein of human fibroblast interferon

IT has been shown repeatedly that preparations of mouse interferon inhibit the growth of mouse cells *in vitro*[1–4]. In addition to inducing the antiviral state and inhibiting cell growth, preparations of mouse interferon stimulate interferon production by priming[5], enhance phagocytic activity[6], and potentiate in cells the toxic effect of double-stranded RNA[7]. All attempts with preparations of mouse interferon to separate the antiviral activity from the non-antiviral activities have been unsuccessful[3,5,8]. With human interferon few experiments have been reported, although the data available indicate inhibition of growth by preparations of human leukocyte interferon[9–11]. It has been claimed that the antiviral and cell growth inhibitory activities of human leukocyte interferon reside in different molecules and can be separated from each other by certain methods of fractionation[12]. In a more recent report[13], however, separation of the two activities could not be demonstrated even in drastic denaturing conditions. I have shown that both the antiviral and the cell growth inhibitory activity of human fibroblast interferon reside in the same glycoprotein.

Human fibroblast interferon was purified to homogeneity as described previously[14]. Before the final fractionate step on sodium dodecyl sulphate (SDS)-polyacrylamide gel the interferon was heated at 100 °C for 2 min in a buffer of 0.1 M Tris, *p*H 6.8, 0.1% SDS, 1% β-mercaptoethanol, and 5 M urea. The interferon was homogeneous and identical both biologically and chemically to the homogeneous interferon described in ref. 14. This homogeneous interferon was used in all experiments. Interferon was assayed on human fibroblast cells by a microassay technique[15] with vesicular stomatitis virus (VSV) as the challenge virus. All interferon units are expressed as international units (human standard reference 69/19). Human diploid fibroblasts between the twentieth and thirtieth doubling obtained from neonatal foreskin tissue were seeded into plastic flasks (25 cm^2) at 2×10^4–8×10^4 cells per flask. Cells were grown at 37 °C in 4 ml of Eagle's MEM supplemented with 10% foetal calf serum, 1.1 $g\,l^{-1}$ sodium bicarbonate 0.012 M HEPES buffer, 0.006 M Tricene buffer, and 50 $\mu g\,ml^{-1}$ gentomycin. The medium was changed every 5–7 d. In these conditions the cells grow with a doubling time of 35–40 h and to a final density between 1×10^6 and 2×16^6 cells per flask. The number of cells in each flask was counted in a haemocytometer after treatment of the cultures with a solution of 0.125% trypsin and 5×10^4 M versene in phosphate-buffered saline (PBS). Cell counts were performed every 24 or 48 h. Growth inhibition is defined as that inhibition which results in an increase of ⩾50% in the time for cell doubling.

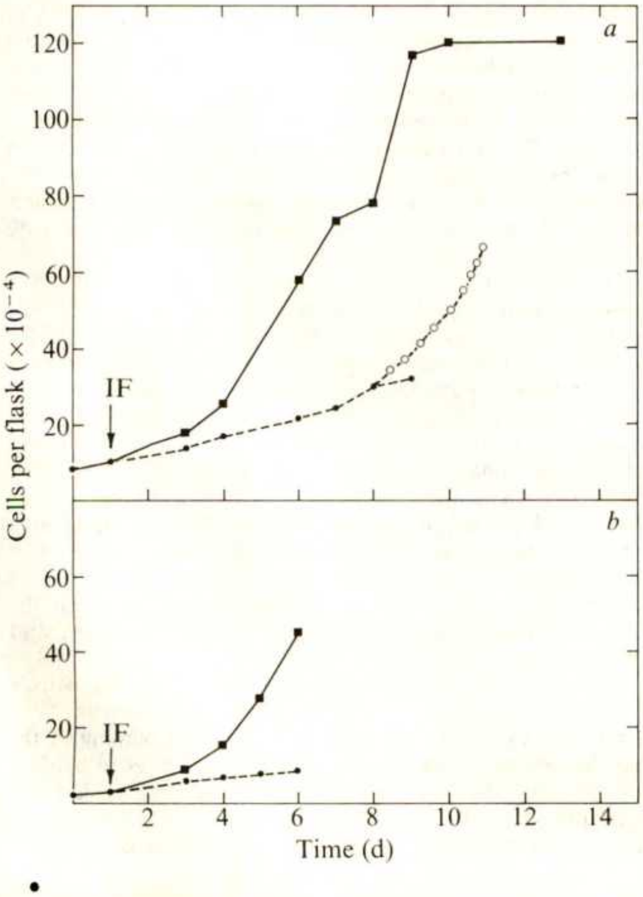
The effect of homogeneous human fibroblast interferon on the growth of fibroblast cells in culture is shown in Fig 1. With either 200 U ml^{-1} (Fig. 1*a*) or 500 U ml^{-1} (Fig. 1*b*) the rate of cell growth is inhibited appreciably. The growth inhibition could be reversed by removal of the interferon-containing medium, washing the cells once with MEM then allowing the cells to grow in MEM only (Fig. 1*a*). Cells whose growth had been inhibited by the homogeneous interferon showed no toxic effects for the duration of the experiment (6–10 d, Fig. 1). Cells were routinely observed for 6–10 d after the addition of interferon. Caution

Another cultured cell, the Daudi cell line, derived from a
pure preparations of interferon, for in an earlier exploratory experiment with a preparation of impure fibroblast interferon (1×10^6 U mg^{-1}) a growth-inhibitory, but also toxic, effect was observed. In this case the cells rounded and detached from the surface 2–4 d after the addition of the interferon preparation (E. K., Jr, unpublished).

I conclude that the antiviral and growth inhibitory activity of human fibroblast interferon reside in the same glycoprotein. This may represent a difference between human fibroblast and leukocyte interferons since preparations of leukocyte interferon are reported to contain the two activities in separate molecules[12]. This separation of activities in preparations of leukocyte interferon has not been confirmed by electrophoresis of the interferon on polyacrylamide gel in conditions of drastic denaturation[13]. In the purification of the fibroblast interferon, growth inhibitory activity has not been found with the absence of the antiviral activity nor has a partial separation of the two activities been observed.

The very potent growth inhibitory activity of preparations of purified mouse interferon has been shown previously[3]. With the fibroblast cells, significant growth inhibition is observed at 200 U ml^{-1}. A molar concentration can therefore be calculated for growth inhibition as has been calculated for the antiviral activity of fibroblast interferon[14]. Thus, from an interferon concentration of 200 U ml^{-1}, a molecular weight of 20,000, (ref. 14) and a specific activity of 2×10^8 U mg^{-1}, a concentration for a significant growth inhibition of human fibroblasts of 4×10^{-11} M is calculated.

Fig. 1 Inhibition of the growth of human diploid fibroblast cells by homogeneous interferon. Cells were seeded at 2×10^4–8×10^4 cells per flask in 4 ml medium. After 24 h the medium was changed in all flasks with half of the flasks getting medium containing interferon. *a*, Interferon, 200 U ml^{-1}; *b*, interferon, 500 U ml^{-1}. ●, With interferon; ○, interferon removed; ■, control.



Another cultured cell, the Daudi cell line, derived from a Burkitt's lymphoma[16], has been shown to be particularly sensitive to preparations of leukocyte interferon for growth inhibition[17]. The growth of Daudi cells can be significantly inhibited at 1–5 interferon units per ml (refs 13 and 17).

There is an extensive list[18] of polypeptide hormones which regulate cell growth both *in vivo* and *in vitro* but unlike interferon most of the polypeptide hormones stimulate cell growth. For instance, insulin stimulates DNA synthesis in resting 3T3 cells at 3×10^{-9} M[19]. Fibroblast growth factor shows measurable stimulation of DNA synthesis in 3T3 cells at 4×10^{-11} M and maximum stimulation at 1×10^{-10} M (ref. 20). Cell growth inhibition has been reported for adrenocorticotropin (ACTH)[21] and factors such as 'chalones'[22].

I thank Dr R. Z. Lockart, Jr for discussions and suggestions, Miss Diana Fahey for technical assistance and Mr. N. Ferreira for preparing the interferon.

Direct measurement of membrane motion and fluidity by electron microscopy

THE mobility of cell membrane components[1] has been measured either in the light microscope scale (by visual labelling[2] and by the recovery of fluorescent bleaching[3,4]) or at the molecular level (by nuclear magnetic resonance (NMR)[5] and spin label EPR[6] methods). In this report, a new method, using electron microscopic techniques to measure membrane motion, is described. This method reduces the spatial and temporal averaging processes inherent in many other methods, and extends the resolution limit of observation to the nanometer scale. The main difficulty in applying electron optical techniques to kinetic measurement had been the requirement that the specimen be placed in a vacuum. The recent development of environmental stages[7] has partly overcome this problem. The direct observation of reaction kinetics in an electron microscope is now possible. The application of this technique to biological research enables biological reactions to be observed at high resolution in a physiological environment.

For model membrane studies, various molar mixtures of cholesterol, dipalmitoyl phosphatidylcholine and natural phosphatidylserine (extracted from bovine brain)[8] were used. The chloroform solution of the lipids were spread as monomolecular layers on the surface of the liquid subphase in a Langmuir trough. The subphase solution contained 5 mM Tris-HCl buffered to various *p*Hs. Polystyrene latex spheres (Dow) of sizes 0.237 μm or 0.088 μm were introduced into the subphase at a concentration of 0.005% solid. The charged latex spheres were electrostatically attached to the polar head group of the phospholipids at appropriate *p*H values. When bilayers were formed from the monolayers of the lipid mixtures as previously described[9], the latex spheres adhered to the hydrophilic surface of the bilayers. They served as membrane markers when the unsupported single bilayer was viewed in an electron microscope in a hydration stage[10]. The marked bilayers were kept fully hydrated at all experimental temperatures. The electron beam current was kept below 10^{-4} A cm^{-2} at the specimen level, the beam being deflected from the area of interest between photographing periods. Electron micrographs were recorded on Kodak No-Screen X-ray film. The images of the unsupported bilayer membranes were extremely dim at the low beam current. Focusing was made on an area adjacent to the area of interest. Time-lapse micrographs of several second intervals, as well as timed exposures of several seconds, were taken.

Two types of particle motion were observed. The fast, random motion of the particles was best described as a two-dimensional Brownian motion. The loci of the particles consisted of zig-zag tracks of random walk, as shown in Fig. 1. The mean square displacements $\overline{\Delta}^2$ were measured from the micrographs of exposure time τ, and the two-dimensional lateral diffusion coefficients D of the membranes were deduced from Einstein's equation: $\overline{\Delta}^2=4D\tau$. For a bilayer of an equimolar mixture of dipalmitoyl phosphatidylcholine and cholesterol at 15 °C, the r.m.s. displacement of 20 labels was 0.54 μm in 5 s. This value gave a diffusion coefficient D to be $(1.4\pm0.3)\times10^{-10}$ $\mathrm{cm}^2\ \mathrm{s}^{-1}$, the error being the standard deviation. This value is to be compared with those of bilayers of 4:1 molar mixtures of egg lecithin and cholesterol at 40 °C, that is 1.9×10^{-9} $\mathrm{cm}^2\ \mathrm{s}^{-1}$ and 1.5×10^{-7} $\mathrm{cm}^2\ \mathrm{s}^{-1}$ respectively from NMR[5] and spin label EPR[6] experiments. A recent measurement by fluorescent labelling method (W. W. Webb, personal communication) on egg lecithin and cholesterol bilayers also yielded a value of D in the range of 10^{-8} $\mathrm{cm}^2\ \mathrm{s}^{-1}$. Our low value was probably a result of the large size of the labelling spheres, which were expected to cover thousands of lipid molecules. The motion of the labels represented the collective motion of many lipid molecules attached to the labels, instead of the diffusion of a single molecule. The grouping of lipid molecules by the labels was expected to impede the fast diffusion motion of individual molecules. The higher cholesterol content, saturated hydrocarbon chains and the lower temperature of our specimens, may also have accounted for some of the discrepancies. Detailed measurements of D as functions of temperature and composition by this method will be published elsewhere.

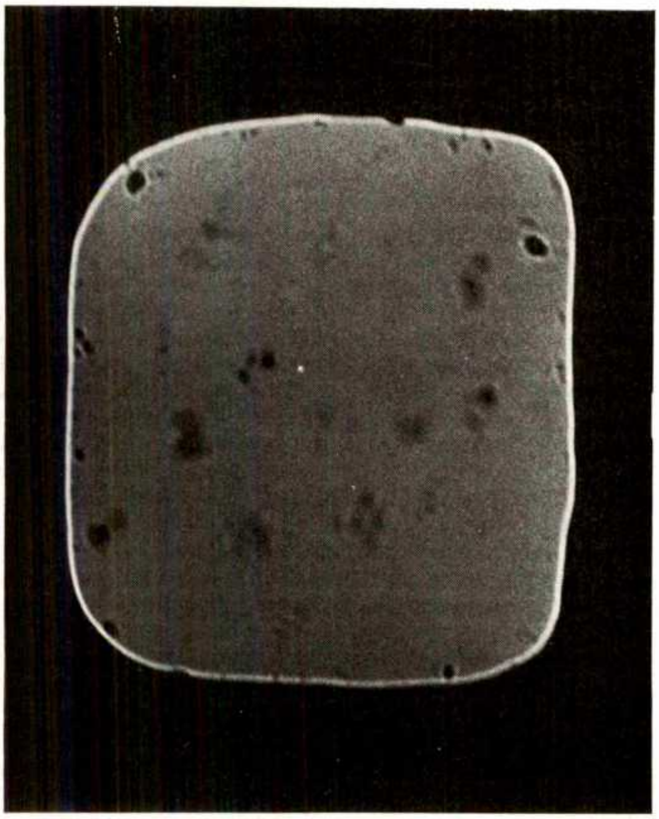

Fig. 1 Electron micrograph of the movement of 0.088-μm polystyrene latex microspheres attached to an unsupported bilayer of an equimolar mixture of dipalmitoyl phosphatidylcholine and cholesterol at 15 °C in saturated water vapour. The exposure time is 5 s. The loci of the movement of the micrographs appear as blurred patches, with darkened spots indicating points of changing direction of the path of random walk. Bright fringes are caused by defocusing of the objective lens for contrast enhancement (magnification ×7,480).

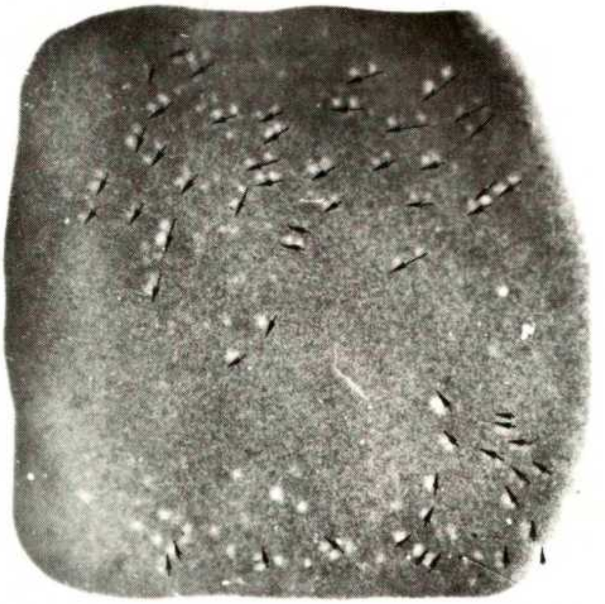

Fig. 2 The superposition of two negatives from consecutive electron micrographs of a microsphere-labelled bilayer of an equimolar mixture of dipalmitoyl phosphatidylcholine and cholesterol at 4 °C in saturated water vapour. The micrographs were taken 5 s apart. Arrows adjacent to the white sphere images indicate the relative positions of the microspheres from the first to the second micrograph (magnification ×6,528).

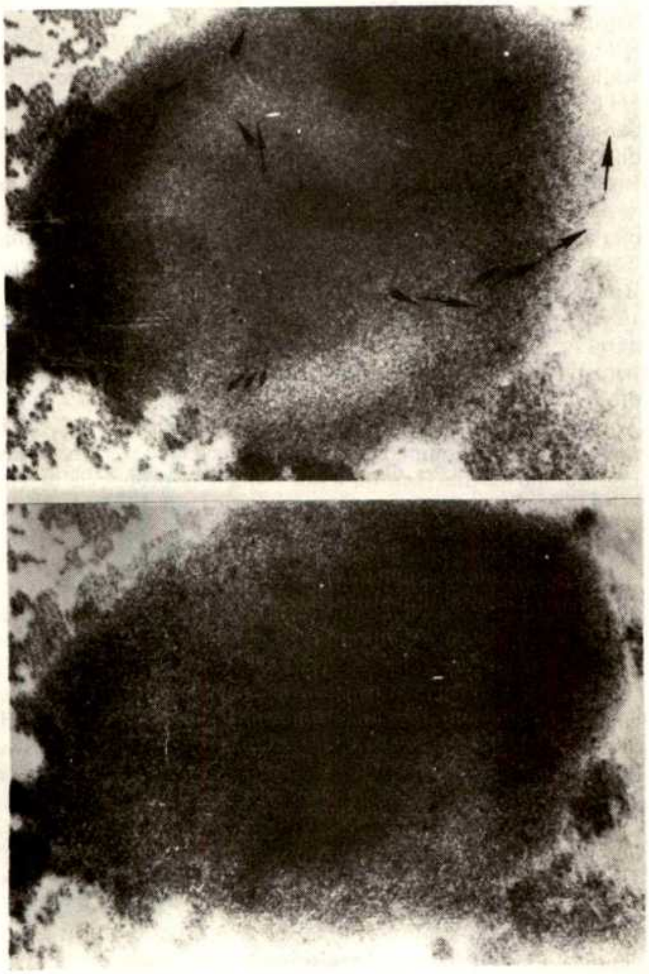
As the temperature of the specimen was lowered below the transition temperature of the bilayer membrane, the fast random motion was reduced. Time-lapse photographs of 10 s or more apart showed a convective movement of particles; the neighbouring particles often drifted along similar directions. Figure 2 shows the drift or marker particles. The mean drift velocity was 3×10^{-6} cm s^{-1}. If this is taken to be the "diffuse" velocity, the apparent value of D would be 10^{-11} $\mathrm{cm}^2\ \mathrm{s}^{-1}$, in rough agreement with NMR line shape measurement[11]. The coordinated drifting of particles indicated that the whole area moved as one patch. The boundaries between patches were discernible in the micrograph. The existence of patches or domains below the transition temperature agreed with the observations by electron microscopy[12,13] and diffraction[9], and with much indirect evidence[6].

Human erythrocyte membranes were prepared by the method of Jung[14]. The ghost membranes were labelled with latex microspheres of mean diameter 0.126 μm. The binding of the charged spheres to the ghost membranes was checked by dark field light microscopy. The ghost membrane suspension was either placed on the Formvar–carbon coated grids or directly on uncoated fine mesh (1,500 CPI) grids. Excess liquid on the grids was removed and the grids were viewed in the hydration stage. When uncoated grids were used, the labelled ghosts were seen to drift freely with the thin liquid film formed over the fine mesh holes. The movement of the marker particles in this case represented both the relative motion on the membrane, and the rotation and tumbling motions of the membranes as a whole. The latter type of motion was eliminated if the membrane sacs were deposited on Formvar–carbon substrates. An example of the marker movement on a ghost sac supported by Formvar–carbon substrate is shown in Fig. 3. The motion of the labels seemed to be more convective than diffusive even at 37 °C. (If the displacement of the labels was treated as diffusive, the apparent value of D would be in the order of 10^{-11} cm^2 s^{-1}.) A fluorimetric study[15] of the erythrocyte ghost membrane gave an upper limit of D to be 3×10^{-12} cm^2 s^{-1}. Both results suggested that the diffusive motion in human erythrocyte ghost membrane was damped. It should be interesting to note that the apparent D values in 3T3 cell membranes, measured by a similar collective labelling method using a light microscope[2], were the order of 10^{-11} cm^2 s^{-1}. A similar value was obtained from mouse L cell membranes by a fluorimetric study[4].

By using an electron microscope, the size of the marker particles can be reduced below the resolution limit of light microscopes (~0.5 μm), and the microscopic motion of the membrane can be followed in greater detail. Smaller labels are now being tested. The membrane motion observed in the submicrometre scale is the result of the collective behaviour of membrane molecules, rather than the motion of the individual molecules. The detailed movement of the membrane in this scale has vital biological significance[1]. By studying membrane motion in this scale, one can bridge the knowledge obtained from measurements in the single molecular level[5,6] and that from bulk viscosity measurement[2]. Observation of movements of microdomains as well as specific sites on the cell surface such as anionic sites, antigens and lectin receptors may now be possible with specific labelling techniques.

Fig. 3 Electron micrographs of microsphere-labelled human erythrocyte ghost membrane taken 4 s apart. The membranes are kept fully hydrated at 37 °C. The arrows on the first micrograph indicate the direction of movement of the labelling microspheres to the positions on the second micrograph. The spheres appear as dark on the hydrated membrane sac. Large, dark patches are liquid (magnification ×9,640).



This work was supported by a US grant from the National Cancer Institute. I have appreciated discussions with Dr D. F. Parsons. Lipid specimens were provided by Dr D. Papahadjopoulos. I am the recipient of a career development award from the NCI.

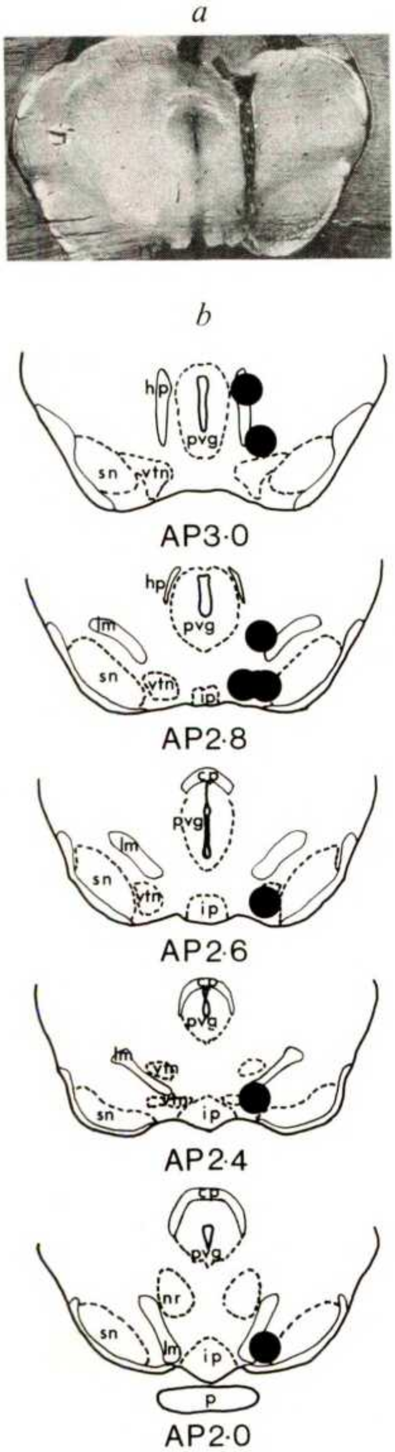
Potentiation of central reward by localised perfusion of acetylcholine and 5-hydroxytryptamine

THERE is considerable evidence that the ascending catecholaminergic systems of the brain[1] are involved with behaviour that is contingent on reward. Much of this evidence concerns the variables which influence intracranial self-stimulation behaviour[2]. Because the anatomical and neurochemical correlates of self-stimulation are specified, evaluation of the catecholamine hypothesis should ideally involve the manipulation or measurement of neurochemical activity within restricted regions of the brain. We have made a first step in determining the neurochemical code of the excitatory input to the dopaminergic systems which originate in the ventral mesencephalon (VM) and which are thought to play a part in intracranial self-stimulation[3]. A technique well suited for this purpose is push–pull perfusion with which exogenous putative neurotransmitters can be administered to discrete regions of the brain by way of the perfusion medium. Using this technique it was possible to establish dose–response relationships between self-stimulation of the medial forebrain bundle (MFB), through which fibres of the catecholaminergic systems pass, and perfusion of 5-hydroxytryptamine (5-HT) or acetylcholine (ACh) in the VM.

In each of eight male Norwegian hooded rats (250–350 g) a monopolar stimulating electrode (diameter 0.25 mm) and a stainless steel guide cannula (20 gauge thin wall) were stereotaxically implanted according to the coordinate system of De Groot[4]. The electrode was placed in the MFB (AP, 4.4; L, 1.7; HV, −9.0); and the guide cannula was positioned so that its tip rested 2–4 mm above the sites intended for perfusion (AP, 3.0–2.0; L, 1.0–1.5; HV, −5.0).

Five to seven days after surgery the rats were taught to depress a lever in a Skinner box in order to receive intracranial electrical stimulation. The stimulation parameters were individually adjusted for each rat so that a rate of lever pressing approximately 50% of maximum was obtained. Training continued until response rates were stable over a period of 90 min. Subsequently, that period was divided into three consecutive periods of 30 min which were designated pre-perfusion, perfusion and post-perfusion. The electrical stimulation parameters were identical for each of these three periods. The average frequency of lever pressing for the pre- and post-perfusion periods was determined. The frequency of lever pressing for the perfusion period was then expressed as a percentage deviation from this value.

Fig. 1 *a*, A histological section of rat brain showing a lesion made by the push–pull cannulae. The section was obtained from the brain of one of the animals used in this study. *b*, Representative frontal sections of rat brain modified from the stereotaxic atlas of Pelligrino and Cushman[3] indicating the confirmed placement of perfusion sites. cp, Posterior commissure; hp, fasciculus retroflexus; ip, interpeduncular nucleus; lm, medial lemniscus; nr, red nucleus; p, pons; pvg, central grey substance; sn, substantia nigra; vtn, Tsai's ventral tegmental nucleus.



Because push–pull systems available at present often cause excessive traumatisation of brain tissues[5] a modified system was developed for use in the present study. Briefly, this system comprises the addition of a calibrated monitor tube to the pull side of the normally closed push–pull system. The level of fluid in this tube indicates the pressure in the pull line and gives immediate notice of any obstructions occurring within the brain. This facility prevents the inadvertent induction of expansion lesions and experimental hydrocephalus.

At the start of the "perfusion period" a concentric push–pull cannula assembly[6] was lowered through the guide cannula until its tip extended 2-4 mm beyond that of the guide. The rate of perfusion was between 0.6 and 1.7 μl min^{-1}. The perfusion was continued during the second experimental period and was continuously monitored for blockages occurring within the pull line. In the event of a blockage the cannulae were temporarily removed, flushed clear and replaced.

The perfusion medium was an artificial cerebrospinal fluid (CSF) consisting of: NaCl, 127.7 mM; KCl, 2.5 mM; $CaCl_2$, 1.3 mM; $MgCl_2$, 0.9 mM; $NaHCO_3$, 21.0 mM; Na_2HPO_4, 2.5 mM and glucose 3.4 mM. To this stock solution the required amounts of 5-hydroxytryptamine, creatine sulphate or acetylcholine chloride were added immediately before each experiment.

Each of six animals was tested with four doses of ACh, while each of four animals was tested with four doses of 5HT. The four dose levels, as well as a CSF vehicle control condition for both ACh and 5HT, were administered in a different random order for each animal. Successive perfusions with a given animal were separated by at least 24 h.

After completion of all behavioural testing, the position of the electrode tip and the site of perfusion in each animal were verified according to normal histological procedures. Brain tissue was fixed by an intracardial perfusion of a 10% formal saline solution after which it was embedded in paraffin wax. Serial sections of 8 μm were cut and stained with haematoxylin using the modified Weil–Weigert method of Wolf[7].

All electrodes were found to be located in the MFB region within 0.5 mm of the stated stereotaxic coordinates. Fig. 1*a* shows the type of lesion which is produced by the present push–pull perfusion technique, and Fig. 1*b* represents the loci of all perfusion sites.

The mean percentage changes (± s.e.) in MFB self-stimulation of four rats, when different doses of 5-HT were perfused in local areas of the VM, are shown in Fig. 2*a*. 5-HT increased self-stimulation in each of the four rats, an effect which was statistically significant ($P<0.02$, Kruskal–Wallis one-way analysis of variance[8]) for the group as a whole. In two of the animals the facilitatory effect of 5-HT disappeared at the two highest doses of 5-HT. Also in two animals, the effects of 5-HT on self-stimulation were accompanied by marked contraversive turning behaviour.

Figure 2*b* illustrates the mean percentage changes (± s.e.) in MFB self-stimulation of six rats when different doses of ACh were perfused in the VM. Following a significant increase in self-stimulation behaviour ($P<0.02$, Kruskal–Wallis one-way analysis of variance) response rates were depressed below baseline levels as the concentration of ACh in the perfusate was increased. Facilitation of self-stimula-

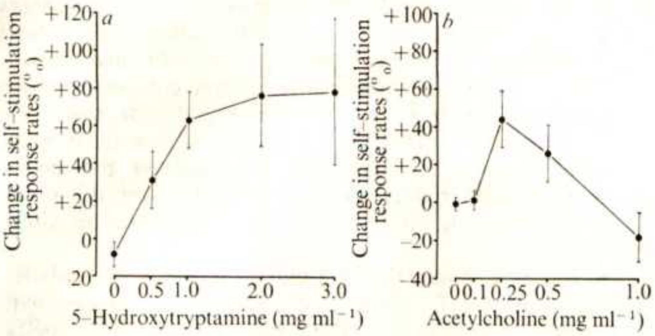


Fig. 2 *a*, Illustration of the mean percentage changes (± s.e.) in MFB self-stimulation of four rats when different doses of 5-HT were perfused in the ventral mesencephalon. *b*, Illustration of the mean percentage changes (± s.e.) in MFB self-stimulation of six rats when different doses of ACH were perfused in the ventral mesencephalon.

tion by ACh was observed in each of the six animals at the dose of 0.25 mg ml^{-1}.

The present results show that a given animal can be perfused repeatedly with the modified push–pull system without causing excessive physical trauma to the brain. The push–pull perfusion was used in preference to the intracranial microinjection technique for two reasons. First, the push–pull perfusion provides a degree of temporal control over chemical stimulation of the brain which is impossible to replicate with microinjections. Secondly, the continual replacement of fresh ACh from the push syringe obviates the need for substitute cholinergic agonists or cholinesterase inhibitors.

The finding that MFB self-stimulation was potentiated by localised perfusions of 5-HT in the VM is contrary to the inhibitory influence of 5-HT on self-stimulation suggested by Wise *et al.*[9] and by Poschel *et al.*[10]. The position adopted by these authors was based on experiments which involved the administration of pharmacological or neurotoxic agents either systemically or by way of the cerebral ventricles. These procedures will affect neurochemical activity in large areas of the brain. In contrast, the present results were obtained by perfusing 5-HT within restricted regions of the VM. The differences between the general and specific manipulation of 5-HT systems suggests an anatomical coding of brain function in which 5-HT may be used at different morphological locations in order to achieve opposite or competing behavioural or physiological effects.

The favoured explanation of the present results is that 5-HT and ACh may be exciting, directly or indirectly, the dopaminergic cell bodies known to be present in the VM. Supporting this view is, first, the fact that in some animals, marked contraversive rotation was observed in response to 5-HT. Dopaminergic systems in the VM have been strongly implicated in mediation of this behaviour[11]. Second, a pathway originating in the serotonergic cell group of the median raphe, from which self-stimulation can be obtained, terminates in the ventral mesencephalic tegmentum[12]. Third, self-stimulation of the serotonergic cell bodies of the median raphe can be modified by drugs which affect mainly catecholaminergic systems of the brain[13]. This implies that activity initiated in the median raphe might be relayed postsynaptically by way of catecholaminergic systems. The results of the present experiments suggest a possible anatomical substrate for the proposed interaction between serotonergic and catecholaminergic systems involved in central reward. Fourth, acetylcholinesterase has been localised within the dopamine-containing neurones of substantia nigra[14], presumably this is to inactivate ACh released from neurones afferent to the substantia nigra. Although the proposed explanation of the present results may be satisfactory for those perfusion sites located in or near areas containing the dopaminergic cell bodies[1], further investigation will be needed to clarify the role of 5-HT and ACh at the more dorsally located perfusion sites.

We acknowledge the expert assistance with the histology of Miss Gill Dolman. P. R. is supported by the Science Research Council.

Stimulation of cerebral histamine H_2 receptors by clonidine

CLONIDINE (2-[(2,6-dichlorophenyl)amino]-2-imidazoline) is a potent antihypertensive agent whose site of action is believed to be in the central nervous system[1] but its mechanism of action is far from clear. Because of its effects on peripheral tissue, it has been generally accepted that the drug stimulates alpha-adrenergic receptors[1]. A recent report has, however, challenged this view: far from stimulating the receptors responsible for the accumulation of cyclic AMP in rat cortex, the drug seems to act as a potent alpha-adrenergic antagonist[2]. On the other hand, clonidine has been reported to stimulate gastric secretion by activation of histamine H_2 receptors[3]. It was therefore of interest to check whether clonidine could also act on H_2 receptors in brain tissues where they have been characterised[4–6]. We now report that clonidine strongly stimulates the accumulation of cyclic AMP in slices from guinea pig brain through activation of H_2 receptors.

Male Hartley guinea pigs (300 g; Janvier, Le Genest) were killed by decapitation and slices were prepared from the hippocampus and incubated according to Baudry *et al.*[4]. The hippocampus was selected because of the strong stimulation of adenylate cyclase elicited by histamine in this region[6]. Cyclic AMP was assayed at the end of 15-min incubations by the protein kinase binding method and proteins were determined by the method of Lowry *et al.* with bovine serum albumin as standard[4].

As shown in Fig. 1, clonidine induced a concentration-dependent accumulation of cyclic AMP. The half maximal stimulation was obtained with 50 μM and the maximal effect, representing a fivefold increase, was achieved by 500 μM.

The nature of the receptors involved in the effect of a supramaximal concentration of the drug was investigated with different kinds of antagonists.

Neither phentolamine, an alpha-adrenergic antagonist, nor timolol, a specific blocker of beta-receptors, nor mepyramine, a histamine H_1 antagonist, had any effect,

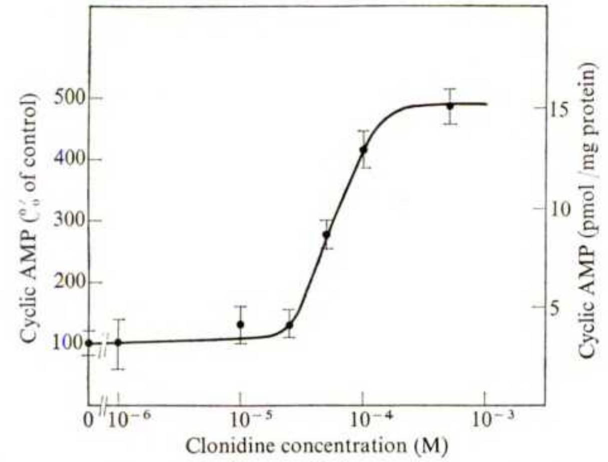

Fig. 1 Effect of increasing concentrations of clonidine on cyclic AMP accumulation in slices from guinea pig hippocampus. Each value represents the mean ± s.e.m. of three to four experiments.

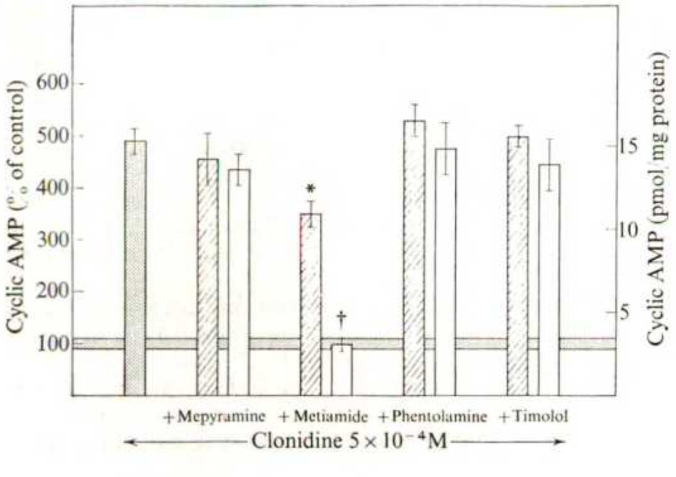
even at 100 μM, on the clonidine-induced stimulation. On the other hand, the action of clonidine was partially inhibited by 1 μM of the H_2 antagonist, metiamide[7] and totally blocked at 100 μM of this agent. Furthermore, the stimulation elicited by 100 μM clonidine and 100 μM 4-methylhistamine, an agonist of H_2 receptors were not additive (Y.A., A.V., and J.S., to be published).

Taken together these results clearly indicate that clonidine stimulates histamine H_2 receptors in brain tissues, as already demonstrated in stomach[3] and heart[8]. In fact clonidine seems to be one of the most potent agonist of H_2 receptors available: both the EC_{50} and the maximal stimulation of cyclic AMP accumulation were of the same magnitude as for 4-methylhistamine (Y.A., A.V., and J.S., to be published).

It is not clear whether this action of clonidine on cerebral histamine receptors is related to its hypotensive properties. Since this drug exerts its cardiovascular effects at very low dosage (in the range of 100 μmol kg^{-1}), its strong efficacy *in vivo* hardly seems compatible with the EC_{50} determined in our *in vitro* system. In this respect, the blockade of adrenergic alpha-receptors in slices from rat brain occurs at a much lower concentration[2]. In addition, very little information is available concerning the possible involvement of histaminergic neurones in the central control of blood pressure. It has only been demonstrated[9] that the intraventricular administration of histamine elicits tachycardia and hypertension in several species; however this action seems to be mediated by way of H_1 receptors and the effects of a selective stimulation of cerebral H_2 receptors remain to be assessed.

Fig. 2 Effect of antagonists of H_1 or H_2 histaminergic and alpha- or beta-adrenergic receptors on the accumulation of cyclic AMP elicited by a supramaximal concentration of clonidine. None of the agents affected the basal level of cyclic AMP. Each value is the mean ± s.e.m. of four experiments. The width of the horizontal line represents the s.e.m. of unstimulated controls. Blank areas, 10^{-4} M; hatched areas, 10^{-6} M. $^*P < 0.005$. $^\dagger P < 0.0005$.



On the other hand, the high magnitude of the stimulation of the cyclic AMP system that we observe, together with the almost complete inhibition by intraventricular metiamide of the clonidine-induced hypotension which has been recently reported by Karppanen *et al.*[10] lend strong support to the idea that histamine H_2 receptors in brain could be involved in the action of clonidine.

We thank Professor H. Schmitt for helpful discussions.

Synaptic vesicle cytochemistry changes when cultured sympathetic neurones develop cholinergic interactions

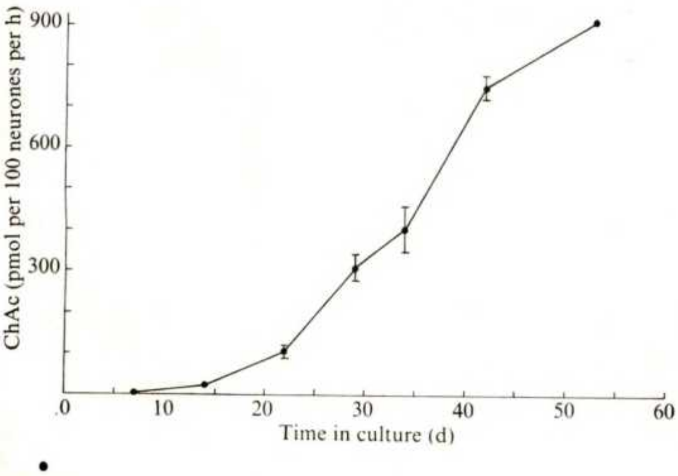
THE principal neurones of the rat superior cervical ganglion (SCG) can be established as dissociated cells in long term cultures[1] without the survival of the small intensely fluorescent "interneurone" normally found in the animal. These isolated sympathetic neurones (SCGN) exhibit certain expected adrenergic characteristics such as the synthesis and accumulation of catecholamines[2–4]. They also specifically take up exogenous noradrenaline and demonstrate Ca^{2+}-dependent release of this transmitter during induced depolarisation[5]. When these neurones are cocultured with thoracic spinal cord explants, they receive a typical cholinergic preganglionic input[6]. When cultured with the appropriate target of brown fat, the SCGN will provide characteristic noradrenergic contacts with the fat cells[7]. The interpretation of these generally expected results is confounded by the following observations: (1) cultures of dissociated sympathetic neurones form numerous synaptic contacts with each other[8–10]; (2) cytochemical studies of these synapses show that they contain predominantly dense-cored vesicles and thus appear to be noradrenergic[8–11]; and (3) physiological studies clearly indicate that synaptic signals between these cultured neurones are nicotinic–cholinergic[7,11]. In addition, dissociated SCGN will provide cholinergic innervation to striated muscle in culture[12]. Only one type of neurone, however, has been described in these cultures. We have investigated whether synaptic endings with the morphological characteristics of noradrenergic terminals were the only synaptic type to be found in cultures where cholinergic interactions between neurones were readily demonstrable. If, as previously reported, only synapses with noradrenergic cytochemical characteristics were found, it would strongly suggest that one synaptic type was handling both noradrenaline (NA) and acetylcholine (ACh). If two synaptic types were found it would suggest that two types of neurones were present in these cultured networks, thus providing a possible explanation for the paradoxical results discussed above.

We established sympathetic neuronal networks by dissociating the SCG from perinatal rats by a method previously described[9], but without antimitotic agents to suppress non-neuronal cell growth. In these conditions a substantial number of non-neuronal cells are present although these do not develop to the point of forming a confluent monolayer. We chose these conditions that foster cholinergic mechanisms (discussion in ref. 13) although we have observed cholinergic transmission in cultures entirely free of supporting cells[7]. All results presented here derive from one group of 60 cultures that was established simultaneously from one group of foetuses and maintained in an identical manner. After initial settling on to 24-mm Aclar dishes, each culture contained about 2,000 neurones, a number which remained essentially constant throughout the experiment. The use of a gridded culture dish assisted in counting the number of neurones per dish. Less extensive studies of previous culture series confirmed the results. The methods used for anatomical, biochemical and physiological analyses are given in the figure legends.

Choline acetyltransferase (ChAc) activity, which was very low in these cultures when first established, increased with age. ChAc activity in SCGN, expressed relative to number of neurones, increased more than 1,000-fold between one and 7.5 weeks (Fig. 1). The increase in ChAc activity during the development of SCGN *in vitro* probably reflects increased biosynthetic capacity for the production of ACh. The presence of this enzyme is considered a reliable indicator of the presence of cholinergic mechanisms[14–16]. During the same period acetylcholinesterase and dopa decarboxylase activities increased 30- and 20-fold, respectively, in this same culture series (our unpublished observations).

Physiological recordings indicated that nicotinic–cholinergic (hexamethonium-sensitive) synaptic interactions between the SCGN increased in potency and complexity with age in culture (Fig. 2*a* and *b*). In young cultures (20–33 d) only single responses (Fig. 2*a*), often with high failure rates, were observed. Reciprocal connections, frequent suprathreshold responses, and repetitive discharges (Fig. 2*b*) were first seen after 36 d in culture. The increased efficacy of synaptic transmission with age *in vitro* correlated with increased probability of finding interactions (Fig. 2*c*).

Fig. 1 Increase in ChAc activity with time in culture. ChAc activity was assayed radiometrically at 37 °C in homogenates of cultures by a modification[18] of existing methods[19,20]. Enzyme activity for each culture was expressed relative to the number of neurones in that culture. Values for time points between 7 and 53 d are means ± s.e.m. of activities in eight, eight, three, three, three, four and two cultures, respectively. The average number of neurones per culture was 2,160 ± 92 ($n = 31$). ChAc activities at 7 and 14 d were 0.83 ± 0.1 and 23.9 ± 3.7 pmol ACh produced per 100 neurones per h, respectively.



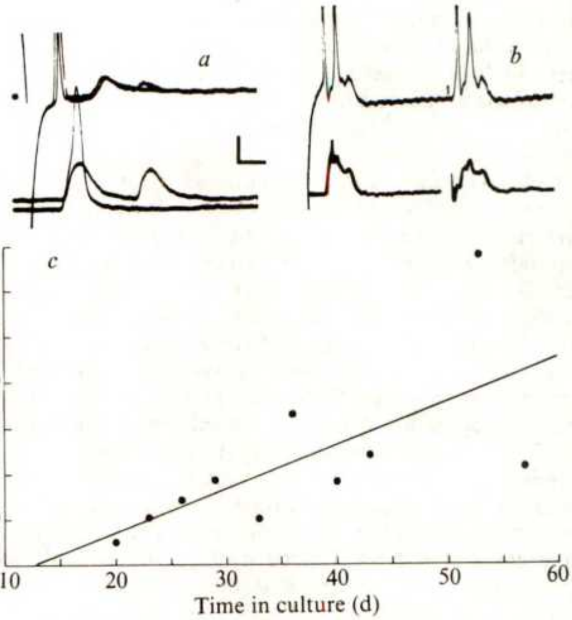


Fig. 2 Development of synaptic interactions as a function of days in culture. Intracellular recordings were obtained with 1M potassium citrate electrodes from SCGN that were maintained with a continuous perfusion of Eagle's MEM supplemented with antibiotics or with medium containing 10^{-4} M hexamethonium[6]. Evoked synaptic potentials were sought by sequentially stimulating, with anode break excitation, each of a pair of simultaneously impaled neurones. Examples of recordings taken from a 33- and 53-d culture are shown in *a* and *b*, respectively. *a*, Two superimposed stimulus trials of the cell shown in the upper trace (L9) evoked short latency subthreshold or suprathreshold responses in the cell shown in the lower trace (R6). Electrical stimulation of R6 did not reveal reciprocal connections to L9. The first subthreshold potentials in L9 (upper trace) were due to recurrent connections; late potentials occurring concurrently in both neurones were due to spontaneous activation from some unknown source. *b*, Direct stimulation of cell shown in upper trace (L3) from a 53-d culture evoked a short latency abortive action potential, followed by multiple subthreshold potentials, in cell shown in lower trace (R3) as well as recurrent suprathreshold plus multiple subthreshold responses in L3. Stimulation of R3 (shown as break in lower baseline) evoked a reciprocal suprathreshold response in L3 which, in turn, elicited the same complex sequence of responses seen when L3 was stimulated electrically. Only single responses were seen in young cultures (20–33 d) whereas repetitive and suprathreshold activation was frequently observed in older cultures (36–57 d). In more than 25 pairs of cells studied pharmacologically, hexamethonium reversibly blocked the synaptic activity. Calibration: *a*, 10 mV, 20 ms and *b*, 10 mV, 50 ms. *c*, Plot of the ratio of cells synaptically driven to number of cells stimulated as a function of age in culture. Each dot based on recordings from an average of 50 cells (range 40–60) from a single culture. Positive slope of linear regression line ($r = 0.66$ with $P < 0.05$) suggests that the probability of finding synaptically coupled neurones increases with age in culture.

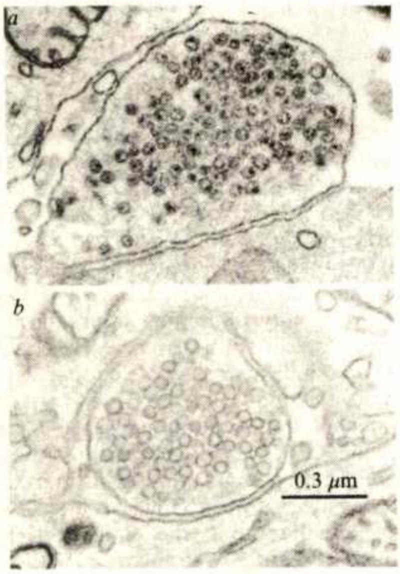
Detailed morphological studies were carried out on these SCGN cultures at 1 and 8 weeks. Preloading with NA and $KMnO_4$ fixation techniques were used specifically to demonstrate catecholamine-containing dense-cored synaptic vesicles (see legend to Fig. 3). Figure 3 illustrates examples of synaptic profiles in contact with neuronal somata and proximal dendrites after 1 week (Fig. 3*a*) and 8 weeks (Fig. 3*b*). The vesicle population in the endings in the 1-week culture was predominantly dense-cored with few clear vesicles. In contrast, the synapse shown from the 8-week culture contained mainly clear vesicles. Less than 10% of the population of synaptic vesicles was clear in most terminals examined after 1 week, whereas by 8 weeks most terminals contained more than 80% clear vesicles (Fig. 4). But some profiles after 8 weeks retained a high percentage of dense-cored vesicles (as in Fig. 3*a*) with a low proportion of clear vesicles. On one neuronal soma from an 8-week culture, eight synaptic profiles contained principally clear vesicles and one profile showed a predominance of vesicles containing dense cores. Occasionally at 8 weeks, endings containing a large number of clear vesicles had several vesicles with striking dense cores. Some profiles consisted of two to three connected varicosities each of which contained the same predominant type of synaptic vesicle. Studies in progress indicate that the shift in type within the synaptic vesicle population may occur as early as 2 weeks *in vitro*.

These results indicate that acetylcholine synthesis, cholinergic transmission and synaptic terminals containing clear vesicles develop with time in culture, a critical change occurring around 2 weeks *in vitro*. This development is gradual and not total since profiles containing principally dense-cored vesicles are still present at 8 weeks. As the number of neurones per culture dish remains stable after 1 week, these results suggest that one neurone type maintains two distinct synaptic endings and neurotransmitter enzyme systems or, alternatively, that two different neuronal types are present after 2 weeks *in vitro*. The critical question now centres on the source of the large numbers of cholinergic neurones present in older cultures. The small number (about 5%) of cholinergic neurones which may be present in the normal rat SCG[17] could not explain the accumulation of the large number of cholinergic "driver" cells found in late cultures (Fig. 2). Are these cells gradually evolving in culture from one originally undetermined multi-potential precursor population or from a differentiated noradrenergic neurone whose properties are altered in the culture environment? We anticipate that an extensive characterisation of the types of synaptic profiles present during successive weeks *in vitro*, together with additional biochemical and physiological experiments, will resolve this issue.

Fig. 3 Electron micrographs of synaptic endings found on SCG neurones after 1 week (*a*) and 8 weeks (*b*) in culture. Dissociated neurones of the SCG dissected from perinatal rats were established in culture as described before[1]. Instead of a Leibovitz-based medium, a standard feed containing 65% Eagle's MEM with glutamine added, 25% human placental serum, 10% chick embryo extract, 3% 1.1 M glucose and nerve growth factor was used. At weekly intervals from 1 to 8 weeks the cultures were rinsed in Leibovitz medium (L-15) and incubated for 30 min in freshly prepared 10^{-5} M noradrenaline in Leibovitz to which ascorbic acid (0.2 mg ml^{-1}) was added. The *p*H was adjusted to 7.2–7.3 before incubation. A rinse in L-15 was followed by fixation with 3% $KMnO_4$ in Krebs' Ringer phosphate (*p*H 7.1, 4 °C) and by *en bloc* staining with 1% uranyl acetate in maleic acid buffer (*p*H 5.2, 4 °C). Embedding in Epon–Araldite followed dehydration. As expected with this fixation, postsynaptic densities are not demonstrated. Both (*a*) and (*b*) are at the same magnification.



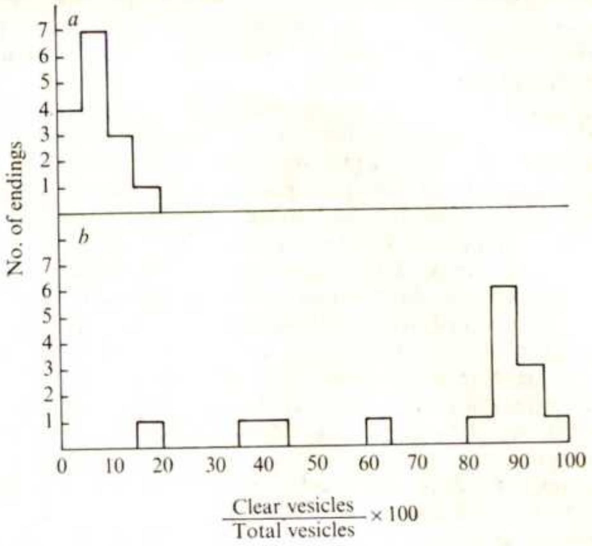


Fig. 4 Number of endings (ordinate) containing listed percentages of clear vesicles (abscissa) after 1(*a*) and 8(*b*) weeks *in vitro*. Consecutive endings found on the neuronal somata and proximal dendrites (as illustrated in Fig. 3) were photographed and printed at a standard magnification to count and classify vesicles measuring 40–70 nm as dense-cored or clear. Fifteen total endings at both 1 and 8 weeks are illustrated. Total vesicles ranged from 18 to 162 and 26 to 163, respectively.

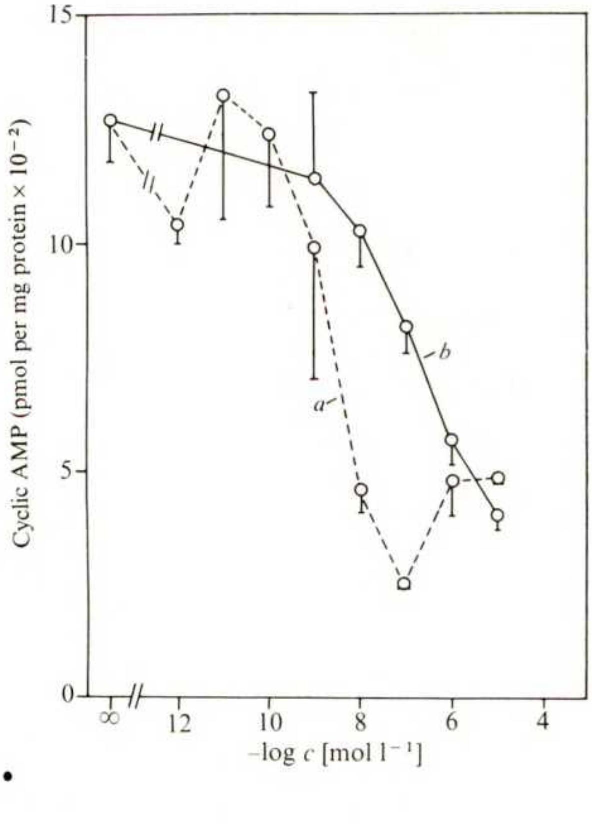
Enkephalin regulates the levels of cyclic nucleotides in neuroblastoma x glioma hybrid cells

NARCOTICS do not normally occur *in vivo*. "Opiate receptors" must therefore have evolved to recognise endogenous ligands, which are mimicked by the opiates[1]. Indeed such compounds have been isolated[2-5] and their structure elucidated as that of the two pentapeptides leucine- and methionine-enkephalin[6]. Neuroblastoma × glioma hybrid cells 108CC15 display many properties characteristic of neurones[7]. In these cells morphine and other narcotics[8-10] prevent the increase in the level of cyclic AMP that is caused by prostaglandin E_1 (PGE_1)[11]. The opiates also increase the level of cyclic GMP in the hybrid cells[12]. On long term incubation with morphine, the hybrid cells show phenomena which can be interpreted as biochemical correlates of morphine tolerance, dependence and withdrawal[9,13].

Fig. 1 Leu-enk (*a*) and levorphanol (*b*) inhibit the elevation by PGE_1 (0.3 μM) of the level of cyclic AMP in the neuroblastoma × glioma hybrid line 108CC15. 2.5 ± 10^5 viable cells were seeded on to replica plates (85 mm in diameter) containing 20 ml of growth medium[11]. The cells were grown for 4 d before the medium was removed. The cells were first washed and then incubated with 5 ml of incubation medium[14] and the various additions at 37 °C for 10 min. Leu-enk was added as a 100-fold concentrated solution in water. 1.9 million viable cells per plate, 90% viability (exclusion of nigrosin), passage number 17. After the incubation the cellular content of cyclic AMP was determined as described[14], with the exception that the columns for the purification of cyclic AMP were modified[12] and that the nucleotide was eluted with 5 ml of 0.05 M HCl. Each value is the mean ± s.d. of data obtained from three parallel incubations. Leu-enk was synthesised by conventional methods coupling Z–Tyr–(BZL)–Gly–Gly–OH[15] and H–Phe–Leu–OH[16] by the mixed anhydride procedure to yield Z–Tyr–(BZL)–Gly–Gly–Phe–Leu–OH (melting point 181–183 °C $(\alpha)^{20}_{546}$ −25.8 ° and $(\alpha)^{20}_{D}$ −21.7 °, c, 1.06 in dimethylformamide). Hydrogenolytic removal of the protecting groups led to chromatographically and sequentially homogeneous leu-enk (melting point 197–199 °C (dec.); $(\alpha)^{20}_{546}$ +35.3 ° and $(\alpha)^{20}_{D}$ +29.1 °, c, 1.15 in water; amino acid ratios in acid hydrolysate: Tyr 1.00 (1), Gly 1.95 (2), Phe 1.00 (1), Leu 1.00 (1); ultraviolet maximum (water) 274.5 nm, $\varepsilon = 1,350\ M^{-1}\ cm^{-1}$).



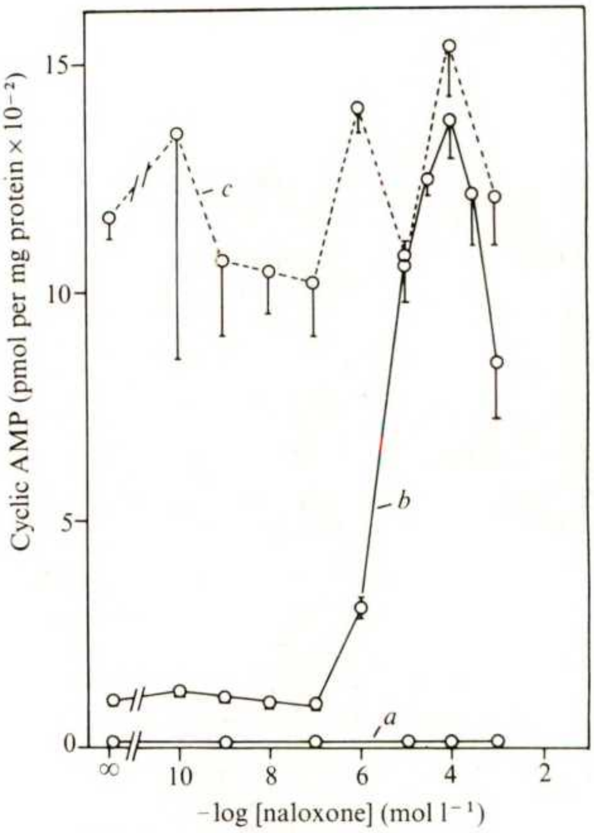


Fig. 2 Naloxone prevents the inhibition by leu-enk of the PGE_1-induced increase in the level of cyclic AMP. *a*, Absence of PGE_1 and leu-enk; *b*, Presence of 0.3 μM PGE_1 and 0.1 μM leu-enk; *c*, Presence of PGE_1. 2.3×10^6 viable 108CC15 cells per plate, viability 92%, passage number 16. Other details as in Fig. 1.

Here we report that leucine-enkephalin (leu-enk) has effects like those of opiates on the hybrid cells.

PGE_1 strongly elevates the level of cyclic AMP in the hybrid cells[11]. Increasing concentrations of leu-enk progressively prevent this increase (Fig. 1*a*) until maximal inhibition is observed at 0.1 μm (concentration at which 50% inhibition takes place, IC_{50}, 3 nM). In the range 0.1–1 μM leu-enk the curve rises again, but there is no further increase between 1 and 10 μM leu-enk (Fig. 1*a*). In several independent experiments the same results were obtained. Such an increase in the level of cyclic AMP was also observed at concentrations above 0.1 mM of morphine and its congeners[8]. Levorphanol (Fig. 1*b*) is a less potent inhibitor of the PGE_1 elevation of cyclic AMP than leu-enk. Its IC_{50} value (0.3 μM), which is identical to that reported[9], is approximately 2 orders of magnitude higher than that of leu-enk. In the absence of PGE_1 1 μM leu-enk maximally lowers the level of cyclic AMP from 19.8 ± 2.6 to 9.6 ± 1.4 pmol mg^{-1} protein. As is the case with morphine[10,17,18], the action of leu-enk is due to an inhibition of the formation of cyclic AMP and is not associated with an increase in cyclic AMP phosphodiesterase activity. The increase from 796 ± 176 in the presence of PGE_1 to $4,940 \pm 220$ seen in the presence of PGE_1 and the phosphodiesterase inhibitor isobutylmethylxanthine is partially suppressed to $2,590 \pm 60$ pmol cyclic AMP per mg protein if 0.1 μM leu-enk is included in the incubation medium.

Naloxone completely prevents the inhibition by leu-enk of the PGE_1-induced rise in the level of cyclic AMP (Fig. 2*b*). In the absence of leu-enk (Fig. 2*c*), or of PGE_1 and leu-enk (Fig. 2*a*), naloxone has no effect.

As is the case with morphine[12] (Fig. 3*a*), leu-enk (Fig. 3*b*) causes an elevation of the intracellular level of cyclic GMP. The half-maximal stimulating concentrations (EC_{50}) of morphine and leu-enk are around 0.1 μM (Fig. 3*a*) and 0.3 nM

(Fig. 3*b*), respectively. From one experiment to another these EC_{50} values vary considerably, but they seem to change in parallel with one another.

Naloxone prevents the increase in the level of cyclic GMP that is elicited by leu-enk (Fig. 4*a*). Its IC_{50} value is 20 pM. Up to a concentration of 10 nM, naloxone alone causes no effects of its own on the level of cyclic GMP. At more elevated concentrations it raises the level of cyclic GMP even in the absence of leu-enk (Fig. 4*b*).

The influence of leu-enk or opiates on the levels of cyclic nucleotides are strongly dependent on the presence of high concentrations (154 mM) of Na^+, as used in the present experiments. In the absence of Na^+, leu-enk at pM concentrations elevates the level of cyclic AMP (these authors, in preparation). This phenomenon may be related to the observation that opiate agonist binding is favoured at low, and antagonist binding at high concentrations of sodium ions[19,20].

Besides the short-term effects of leu-enk, long term effects similar to those reported for morphine[9,13], can be observed. If the hybrid cells are preincubated for 6 h with 1 μM leu-enk, the level of cyclic AMP that is reached during the subsequent main incubation (10 min) with 0.3 μM PGE_1 rises from 830±40 to 1,190±130 pmol cyclic AMP per mg protein. If 1 μM leu-enk is added at $t = 0$ and 3 h of the 6 h preincubation period, the subsequent stimulation by PGE_1 raises the level of cyclic AMP to 1,830±140 pmol per mg protein. Details of these experiments will be published elsewhere (our results, in preparation).

The data presented demonstrate an analogous influence on the hybrid cells of opiates and leu-enk. The opiates and leu-enk both depress the rate of formation of cyclic AMP and cause an increase in the level of cyclic GMP. The effects are all blocked by naloxone. Data almost identical to these for leu-enk were obtained with methionine-enkephalin. The similarity in the actions of opiates and leu-enk is paralleled by their structural similarity (J. R. Smythies, personal communication, and refs 21 and 22). The physiological meaning of the increased levels of cyclic GMP remains to be discovered. The short term action of opiates, that is, the depression of the formation of cyclic AMP, is probably correlated with its analgesic effect[23,24]. From analogy then, one may conclude that the enkephalins are neurohormones that, in the brain, suppress the sensation of pain. From studies on animals[25] and the neuroblastoma × glioma hybrid cells 108CC15 (refs 9 and 13) it could be deduced that the phenomena of tolerance, withdrawal and dependence seen after long term influence of morphine are connected with increased formation of cyclic AMP. The fact that one does not become addicted to one's endogenous enkephalins is probably due to the degradation of the material[3]. In contrast, with the cell culture system, long term effects do occur. This extends the analogy between opiates and the enkephalins to their long term effects. It leads to the prediction that an inhibitor of the degradation of enkephalin, if applied properly to an animal, may cause opiate tolerance and dependence. The long term effects on the hybrid cells also suggest that breakdown of leu-enk in the culture does occur, although at a moderate rate.

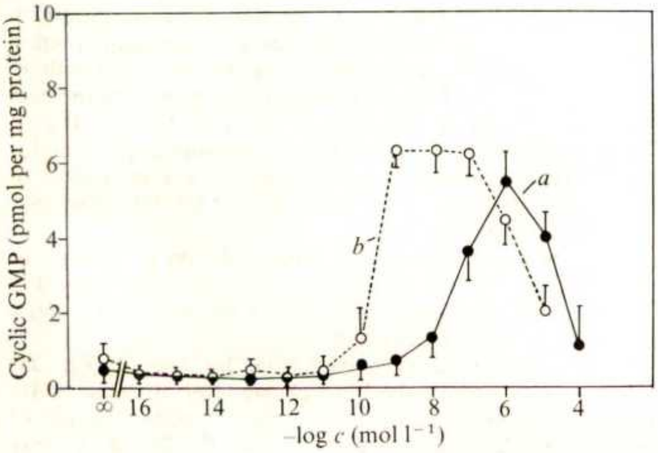

Fig. 3 Morphine (*a*) and leu-enk (*b*) elevate the levels of cyclic GMP in hybrid cells 108CC15. 1.0 × 10^6 viable cells per plate, viability 95%, passage number 17. The cells were incubated in incubation medium for 30 s and their content of cyclic GMP was determined as described[12].

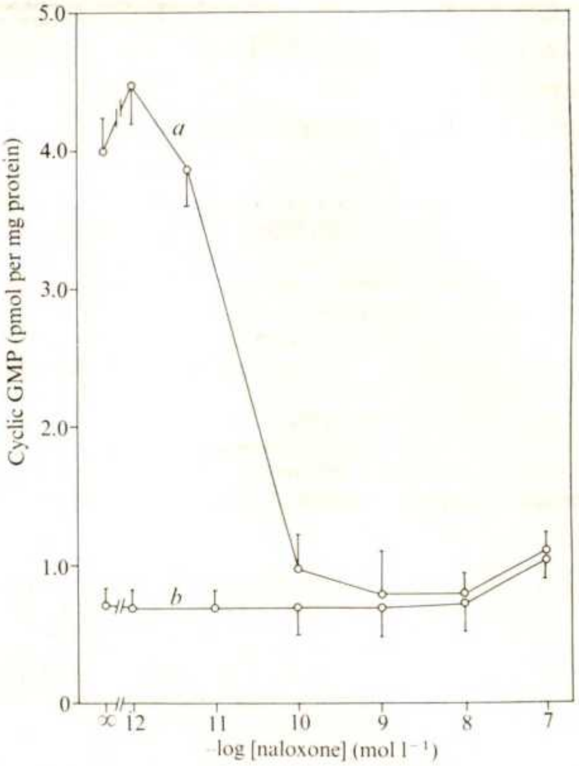

Fig. 4 Naloxone inhibits the increase in the level of cyclic GMP caused by leu-enk. *a*, Presence of 0.1 μM leu-enk; *b*, absence of leu-enk. 1.2 × 10^6 viable cells, viability 97%, passage number 14. Other details as in Fig. 3.

Enkephalin and opiate narcotics increase cyclic GMP accumulation in slices of rat neostriatum

SEVERAL recent studies suggest that cyclic nucleotides are involved in the cellular actions of the opiate narcotics[1-6]. Following the observation by Collier and Roy[1] that low concentrations of morphine inhibited prostaglandin E_1 (PGE_1)-stimulated adenylate cyclase activity in rat brain, Traber *et al.*[2] showed that morphine acted similarly to block the rise in intracellular 3′,5′-adenosine monophosphate (cyclic AMP) induced by PGE_1 in cultured neuroblastoma, or in a hybrid cell line of neuroblastoma × glioma with a high density of opiate receptor binding sites. Sharma *et al.*[3] found that morphine inhibited basal adenylate cyclase activity in this cell line and Gullis *et al.*[4] observed that morphine increased the 3′,5′-guanosine monophosphate (cyclic GMP) and reduced the cyclic AMP content of these cells. Racagni *et al.*[5] have also demonstrated that injection of analgesic doses of morphine *in vivo* to rats also increased cyclic GMP concentration in the neostriatum. These effects have generally been found to be stereospecific and blocked by the opiate receptor antagonist drug naloxone, suggesting that they are mediated through specific opiate receptors. We have extended these observations to *in vitro* studies on slices of rat neostriatum, an area with a very high density of opiate receptor binding sites[6], and have also examined the effects of enkephalin on this system.

Slices of rat neostriatum were incubated for 15 min at 37 °C in Krebs–Ringer bicarbonate buffer containing 1 mM isobutylmethylxanthine (IBMX) (a potent phosphodiesterase inhibitor) and added drugs, as previously described by Forn *et al.*[7] (see legend to Fig. 1). Cyclic AMP and cyclic GMP in boiled tissue extracts were determined by sensitive protein binding and radioimmunoassay techniques (see legend to Fig. 1).

Morphine (10^{-7}–10^{-5} M) increased the accumulation of cyclic GMP in rat striatal slices to a maximum of 200% of control values (Fig. 1). The tissue content of cyclic AMP was concomitantly decreased to about 80% of control, although this effect did not always attain statistical significance. Very similar control and morphine-stimulated values were obtained after isolation and separation of the two cyclic nucleotides by ion-exchange chromatography (Fig. 1 legend). The half-maximum response for both cyclic nucleotides occurred at a morphine concentration of about 3×10^{-8} M. The dose–response curve for morphine was bell-shaped and higher morphine concentrations (10^{-4}–10^{-3} M) caused no significant changes in the tissue content of either cyclic nucleotide. Naloxone (10^{-6} M) completely blocked the effects of morphine (10^{-6} M) on the accumulation of both cyclic nucleotides (Table 1). Indeed, although naloxone alone had no action, in the presence of morphine and naloxone the accumulation of cyclic GMP was significantly reduced below control values (Table 1), although the tissue content of cyclic AMP was unaffected. Levorphanol, an active congener of morphine at concentrations from 10^{-8} to 10^{-3} M mimicked the actions of morphine on cyclic nucleotide accumulation although the reduction in tissue cyclic AMP was not significant, whereas the inactive enantiomer dextrorphan tested at the same concentrations had no effect (Table 1). The latter observations suggest that the actions of morphine on cyclic nucleotide accumulation in rat striatal slices are due to an interaction with specific opiate receptors in this tissue.

The enkephalins are pentapeptides, isolated from porcine brain and characterised by Hughes *et al.*[8], which seem to be specific opiate receptor agonists. Two similar

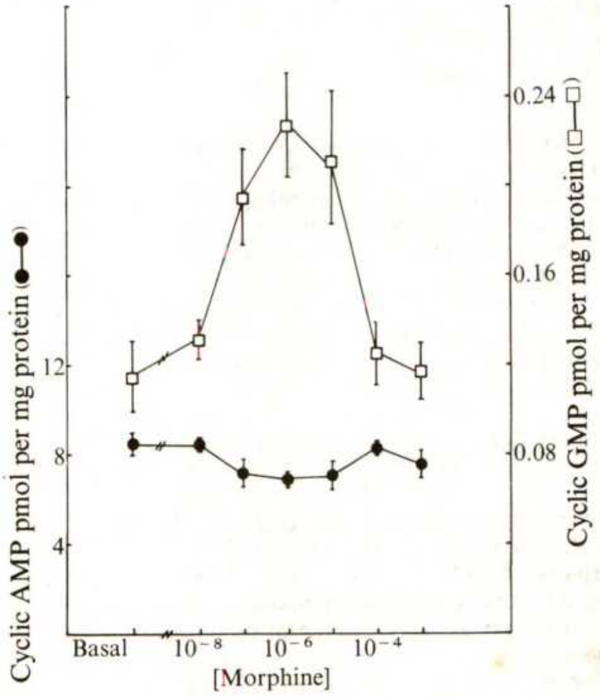

Fig. 1 Effect of morphine on cyclic nucleotide concentrations in slices of rat neostriatum. The tissue preparation, incubation and extraction procedues were as described by Forn *et al.*[7]. After preincubation for 60 min at 37 °C, samples of neostriatal slices (260 × 260 μm; total 10 mg wet weight) were incubated for a further 15 min in the presence of various concentrations of morphine hydrochloride. Tissue extracts were prepared by boiling and centrifugation, 50 μl was taken for cyclic AMP determination by the method of Brown *et al.*[11]; and 100 μl was taken for determination of cyclic GMP by radioimmunoassay. The remaining tissue was dissolved in 1 ml 1 N NaOH and protein was measured by the method of Lowry *et al.*[12]. The cyclic GMP radioimmunoassay antiserum and method were provided by Dr J. Albano and will be described in detail elsewhere. The radioimmunoassay procedure was briefly as follows: 100 μl supernatant was added to 100 μl ^{3}H-cyclic GMP (0.02 μCi, 1.0 pmol) in 50 mM Tris-HCl (*p*H 7.4) containing 2 mM theophylline and 6 mM β-mercaptoethanol. Antiserum (100 μl) diluted in the same buffer was added and the tubes left at 2–4 °C for 6–18 h. The antibody complex was separated by membrane filtration; filters were washed with 5 ml of buffer and dissolved in 4 ml ethoxyethanol; 10 ml of 0.4% butyl PBD in toluene added and radioactivity determined. A standard curve for displacement of bound ^{3}H-cyclic GMP was determined using non-radioactive cyclic GMP. The sensitivity of the assay was 0.02 pmol cyclic GMP in 100 μl. Known amounts of both cyclic AMP and cyclic GMP added either separately or together as internal standards were quantitatively recovered, and the amount of each cyclic nucleotide measured was linearly related to the volume of supernatant used for assay. Cyclic GMP did not interfere with cyclic AMP determinations when present in up to a tenfold excess; cyclic AMP did not interfere with cyclic GMP when present in up to a 500-fold excess. In some experiments incubations were terminated by the addition of 1 ml 5% trichloroacetic acid, the tissue was homogenised and the cyclic nucleotides were isolated and separated by the method of Matsuzawa and Nirenberg[13]. All incubations were performed in quadruplicate, and the data are expressed as means ± s.e.m.

Table 1 Effect of specific opiate narcotics and naloxone on cyclic nucleotide levels in slices of rat neostriatum

Drug	Cyclic AMP (pmol per mg protein)	Cyclic GMP (pmol per mg protein)
Control	9.1±0.84	0.15±0.014
10^{-6} M morphine	7.4±0.26*	0.28±0.037†
10^{-6} M naloxone	9.2±0.31	0.14±0.016
10^{-6} M morphine + 10^{-6} M naloxone	9.1±0.51	0.10±0.010*
10^{-6} M levorphanol	8.0±0.71	0.26±0.036*
10^{-7} M levorphanol	7.6±0.17	0.29±0.036†
10^{-6} M dextrorphan	9.2±0.87	0.16±0.016
10^{-7} M dextrorphan	9.1±0.28	0.17±0.019

All values are means ± s.e.m. for four separate incubations, see Fig. 1 legend for details.

peptides exist, one with leucine as the C-terminal amino acid (leu-enkephalin) and one with methionine as the C-terminal amino acid (met-enkephalin). The addition of either of these compounds at concentrations up to 10^{-4} M did not affect cyclic AMP or cyclic GMP accumulation in slices of rat neostriatum (Table 2). This result was, however, not unexpected, since both forms of enkephalin are rapidly inactivated in tissues at 37 °C (ref. 9). We also tested the effects of these substances in the presence of a peptidase inhibitor, bacitracin[10], (30 μg ml^{-1}) (Sigma Chemical Co.). At this concentration, bacitracin did not by itself significantly affect cyclic nucleotide levels nor did it interfere with the cyclic GMP response elicited by morphine (Table 2). In the presence of bacitracin, both leu- and met-enkephalin (10^{-4} M) increased cyclic GMP accumulation in rat striatal slices to an extent similar to that seen with morphine (Table 2), and this effect was blocked by naloxone. Cyclic AMP accumulation was also decreased to a level similar to that observed in the presence of morphine (Table 2).

The effects of morphine on cyclic nucleotide accumulation in rat striatal slices are strikingly similar to those observed previously in neuroblastoma × glioma hybrid cells[4], although the EC_{50} for morphine is approximately one order of magnitude lower in striatal slices than in cell cultures, and the effect on both nucleotides is relatively greater in the cultured cells. Morphine displays a bell-shaped dose–response curve in both systems and in each case the presence of morphine and naloxone significantly decreases cyclic GMP below control levels.

Table 2 Effect of leu- and met-enkephalin on cyclic nucleotide levels in slices of rat neostriatum

Drug(s)	Cyclic AMP (pmol per mg protein)	Cyclic GMP (pmol per mg protein)
Control	8.1±0.42	0.14±0.006
10^{-6} M morphine	6.7±0.91	0.23±0.014†
10^{-4} M leu-enkephalin	8.1±0.40	0.15±0.016
10^{-4} M met-enkephalin	8.2±0.43	0.14±0.011
30 μg ml^{-1} bacitracin	7.7±0.29	0.15±0.015
10^{-6} M morphine + 30 μg ml^{-1} bacitracin	6.8±0.32*	0.22±0.024*
10^{-4} M leu-enkephalin + 30 μg ml^{-1} bacitracin	6.7±0.81	0.22±0.028*
10^{-4} M met-enkephalin + 30 μg ml^{-1} bacitracin	6.6±0.12†	0.25±0.011†
10^{-4} M leu-enkephalin + 30 μg ml^{-1} bacitracin + 10^{-6} M naloxone	8.0±0.18	0.14±0.014
10^{-4} M met-enkephalin + 30 μg ml^{-1} bacitracin + 10^{-6} M naloxone	7.5±0.26	0.13±0.025

All values are means ± s.e.m. for four separate incubations, see Fig. 1 legend for details.
*$P < 0.05$.
†$P < 0.01$ compared with control values.

The potency of enkephalins (both leu- and met-) in displacing the specific binding of radiolabelled ligands from opiate receptors and on isolated test tissues is similar to that of morphine[8]. The fact that much higher concentrations of enkephalins are necessary to increase cyclic GMP levels in rat striatal slices probably reflects the instability of these substances in mammalian tissues and an incomplete inhibition of brain peptidases in our experiments. Higher concentrations of bacitracin were tested, but were found to interfere with the opiate response. It is, therefore, not yet possible to compare the true potencies of enkephalin and the opiate narcotics in this system. Nevertheless, the fact that the naturally occurring peptides, leu- and met-enkephalin increase cyclic GMP accumulation in rat striatal slices in the presence of a peptidase inhibitor raises the possibility that this response may also occur *in vivo*, and that it may represent a mechanism by which the actions of these substances, as well as those of morphine and other exogenously applied opiate narcotics are mediated at the cellular level.

We thank Dr J. Albano for the generous gift of cyclic GMP antiserum and Dr R. Miller for suggesting the use of bacitracin. Leu- and met-enkephalins were generously provided by Dr G. Metcalf, Reckitt and Colman Ltd, Hull, England; morphine, levorphanol and dextrorphan by Roche Products Ltd and naloxone by Endo Laboratories. K.P.M. is a graduate fellow of the US National Science Foundation.

A sequential *in vivo–in vitro* study of carcinogenesis induced in the rat brain by ethylnitrosourea

THE processes which occur between exposure to a chemical carcinogen and the appearance of a gross tumour, the latent period, are still largely unknown. One approach to investigating how the biological properties of cells are altered during this time is to monitor the behaviour of cells cultured from target organs at different times after carcinogen treatment. A system in which a single dose of a chemical results in a high yield of tumours is a good starting point for such experiments. When pregnant rats are injected with ethylnitrosourea (ENU) almost every one of the progeny develops tumours of the nervous system[1], of which macro- and microtumours of the brain constitute ~ 60% (predominantly cerebral gliomas[2]). To investigate the pro-

Table 1 Agar growth and tumorigenicity of cultures derived 138–145 d after exposure to ENU or buffer

Culture	Passage level	Average no. of colonies per 10^4 cells plated	Plating efficiency in agar (%)	Passage level	No. of animals with tumours/ No. injected	Average time before killed (d)
22E	10	10	0.1	11	7/7	57.7
22A	10	286	2.9	10	8/8	44.6
23A	13	0	0	13	0/6	>265
23C	10	0	0			(1)

To initiate cultures the brain tissue was sliced, chopped into small pieces (about 1 mm^3) and incubated in 10 ml of dissociating medium (0.05% collagenase and 5% foetal calf serum in phosphate-buffered saline without divalent cations) at 37 °C for 20 min with occasional agitation. The suspension was dispersed with 10 or more excursions in a 10-ml pipette, centrifuged and resuspended in Dulbecco's modification of Eagle's medium with 15% foetal calf serum. The medium was changed on the following day to remove debris and unattached cells. Subculturing took place at weekly intervals soon after the cultures became confluent. To test for growth in agar, cells were plated at up to 10^4 in 1 ml of 0.3% Bacto-agar in Dulbecco's medium and 15% foetal calf serum. The base layer was 0.6% agar made up in the same medium. Two to four plates were prepared for each culture. Colonies of 22E and 22A were counted 2–4 weeks after plating, by which time many were macroscopic. The control cultures were observed for up to 3 months with feeding and were negative throughout. To test for tumorigenicity, cells were injected subcutaneously at 1×10^6–2×10^6 per newborn animal (< 5 d old). Animals were examined three times each week and killed when the tumours were about 1 cm in diameter (1): 23C was injected a number of times but due to cannibalism only one animal survived from experiments at comparable passage levels. (It had no tumour at 104 d.) There was a large number of successful injections at later passages and these animals, together with those injected with 23A cells, are still under observation. Preliminary histological observation has indicated that the tumours formed by 22E and 22A are not fibrosarcomas, and have features of glial tumours. A more extensive examination is in progress and details will be published elsewhere.

cess of carcinogenesis during the latent period, cultures have been prepared from ENU-induced gliomas and from ENU-treated animals at different times before the appearance of such tumours.

Pregnant rats of the BD–IX inbred line were injected intraperitoneally with ENU at 40–50 mg per kg body weight on days 15 or 16 of pregnancy. The average latent period for brain tumours was 246 d. Cultures prepared from cerebral gliomas consisted mainly of cells resembling glia and cells with thin cytoplasm, indistinct boundaries and often what looked like incipient processes. We have called the latter type "basal layer cells"[3,4]. These are likely to be morphologically undifferentiated glia because they formed processes in response to dibutyryl adenosine cyclic monophosphate[3], and because clones with a similar morphology have many of the characteristics of astrocytes[4,5]. The tumour cultures grew in 0.3% agar and were tumorigenic[4].

For the initial set of experiments to investigate the latent period, cultures were prepared from a group of animals 138–145 d after transplacental exposure to either ENU or buffer. The cerebra of five ENU-treated and two buffer-treated animals were cultured. Two of the former cultures (22E, 22A) contained islands of cells resembling basal layer cells and associated glia characteristic of tumour cultures. There was no sign of a visible tumour during the slicing and chopping of brain tissue in either case. The two cultures were further investigated. The tumour-like cells which were initially in a minority, gradually became predominant on passaging. Both cultures contained cells which grew in agar and formed tumours in animals (Table 1). The cultures from buffer-exposed animals (23A, 23C) did not contain cells resembling cultured tumour cells, did not grow in agar and have not so far produced tumours (Table 1).

To investigate cells very early in the latent period, a culture was prepared from the pooled brains of an entire litter of foetuses 2 d after transplacental exposure to ENU or buffer. The primary cultures from ENU-treated (BE10) and control (BE11) foetuses were morphologically indistinguishable. Tests for growth in agar and in animals were negative after many passages. At the 40th passage level, however, the BE10 culture formed small colonies, several weeks after plating in agar.

At later transfers macroscopic colonies developed in 2–4 weeks; the result of one experiment is given in Table 2. Further, two clones of BE10, BE10-13 and BE10-7 grew in agar and were tumorigenic (Table 2).

The culturing of cells shortly after treatment of an animal with a chemical as we have done in one set of experiments has been suggested as a test for carcinogens[6]. The method has also been used to ensure that target cells are affected by the ultimate carcinogen[7,8], a situation not necessarily obtained by *in vitro* treatment of cultured cells. Kidney cells cultured 20 h to 7 d after the injection of rats with dimethylnitrosamine showed several transformed properties, but were not tumorigenic[7]. Laerum and Rajewsky[8] have reported that brain cultures made 20–90 h after transplacental exposure to ENU went through a series of changes. They describe the formation of piled-up foci of cells or 'nodules' which were washed off and cultured. These gave rise to cells which grew in 0.15% agar and became tumorigenic after a total of about 200 d in culture. Their control cultures died out before nodule formation so that no measure of spontaneous transformation could be made. The formation of foci which we have called 'clusters' has been observed in both ENU-treated and control cultures. These have been washed from the BE10 and BE11 cultures and maintained separately. There are some differences in the two cultures, for example, that from BE10 has a higher plating efficiency in agar (0.4–0.5 %) than that from BE11 (0.01–0.1 %) depending on passage level. Moreover, some of the animals injected several months before with the former have recently been found to have tumours. All four cultures

Table 2 Agar growth and tumorigenicity of cultures derived 48 h after treatment with ENU or buffer

Culture	Passage level	Average no. of colonies per 10^4 cells plated	Plating efficiency in agar (%)	Passage level	No. of animals with tumours/ No. injected	Average time before killed (d)
BE10	57	$354/10^4$	3.5	60		(1)
BE11	57	$<1/10^4$	<0.01	60		(1)
BE10-7	24	$360/10^3$	36	28	8/8	95.1
BE10-13	32	$54/10^4$	0.5	34	5/5	40

BE10-13 was derived at the 10th and BE10-7 at the 20th transfer of BE10. This was before the earliest time at which cluster formation was observed in BE10. Other experimental details as in Table 1. (1) These animals are still under observation. The tumours formed by BE10-7 and BE10-13 are not fibrosarcomas and have glial features. Further histological observations are in progress and the results will be published elsewhere.

are being maintained and tested to estimate the extent of spontaneous transformation.

It seems, therefore, that at a time equivalent to about 3/5 of the average latent period, ENU-treated animals, have cells which, in culture, behave in a manner indistinguishable from tumour cells. These are not readily detected in cultures taken very early in the latent period. The results so far, however, suggest that there are cells present at 48 h with the potential to become tumorigenic, and that this potential is revealed after prolonged culturing. Experiments are in progress to try to detect these cells without such extensive culturing and to define the time at which committed cancer cells can first be readily detected in culture. It has recently been found that histological changes were first observed about 9 weeks after exposure of the foetuses to ENU (P. L. Lantos, personal communication). The combined *in vivo–in vitro* method used at a series of times in the latent period thus seems to be a valuable approach to investigating the process of carcinogenesis.

We thank Professor P. N. Magee for gifts of ENU and for discussions, and Miss S. L. Davies for technical assistance. The work was supported by a grant from the Cancer Research Campaign.

Native collagen formation by liver parenchymal cells in culture

IN normal supporting tissue and repair tissue of animals collagen is usually considered to be produced by cells of mesenchymal origin. Little is known, however, about the type of cell which synthesises collagen in organs which undergo diffuse fibrosis without known physical trauma, such as in cirrhosis of the liver. Tissue culture has shown, however, that epithelial cells[1], including cancer cells[2] and smooth muscle cells[3], can synthesise collagen. We report here that an epithelial clone, originating from the liver cell line of rat forms a considerable amount of native collagen in culture.

An epithelial cell line from the liver of a JAR-2 suckling rat[4] was established as before[5]. The culture medium consisted of 0.5% lactalbumin hydrolysate medium (LE) supplemented with 10% calf serum (CS). After 200 d of culture the cells dispersed with 0.25% trypsin were seeded in 60-mm plastic Falcon plates for cloning. Inocula varied between a high of 1×10^3 and a low of 3×10 cells per plate, and the 1×10^3 plate yielded colonies derived from single cells. Two colonies which were cytologically distinguishable from each other were picked out and cultured continuously. One consisted of rather small roundish cells and the other of larger polygonal cells. They were designated clones BB and BC, respectively. Both clones have been maintained by serial passages for 4 yr and 3 months in culture flasks containing Ham's F 12 medium and 10% CS or foetal bovine serum (FBS). The cell replication cycle of these clones was 20–31 h after 21 generations. Plating efficiency was 35–55% after 19 generations. The cells were epithelioid, proliferated as monolayers, and achieved contact inhibition.

To detect liver-type metabolic activities of the cells, assays

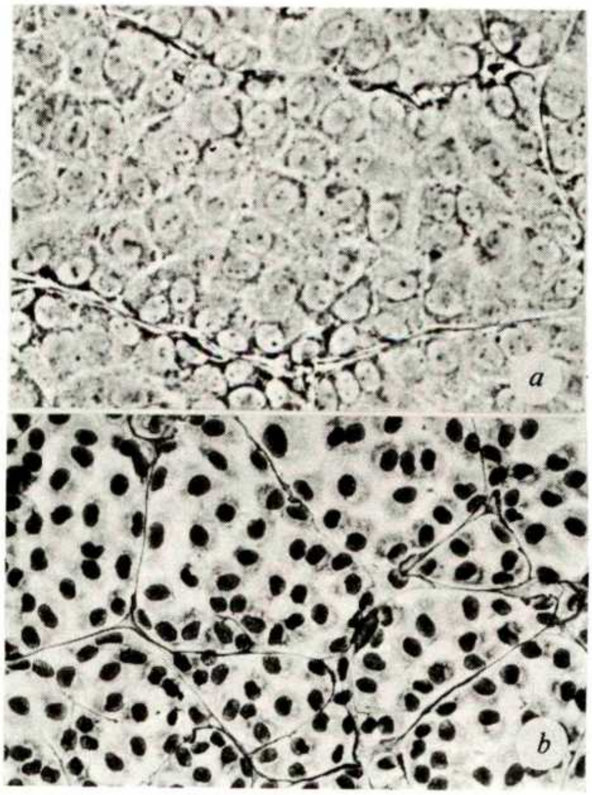

Fig. 1 Micrographs of a cloned liver cell line BC cultured on cover slip for 28 d without transfer. *a*, Unfixed, phase-contrast illumination(× 587); *b*, fixed with absolute methanol, stained by silver impregnation. Collagen fibres stained purple-brown situated between cells (× 293).

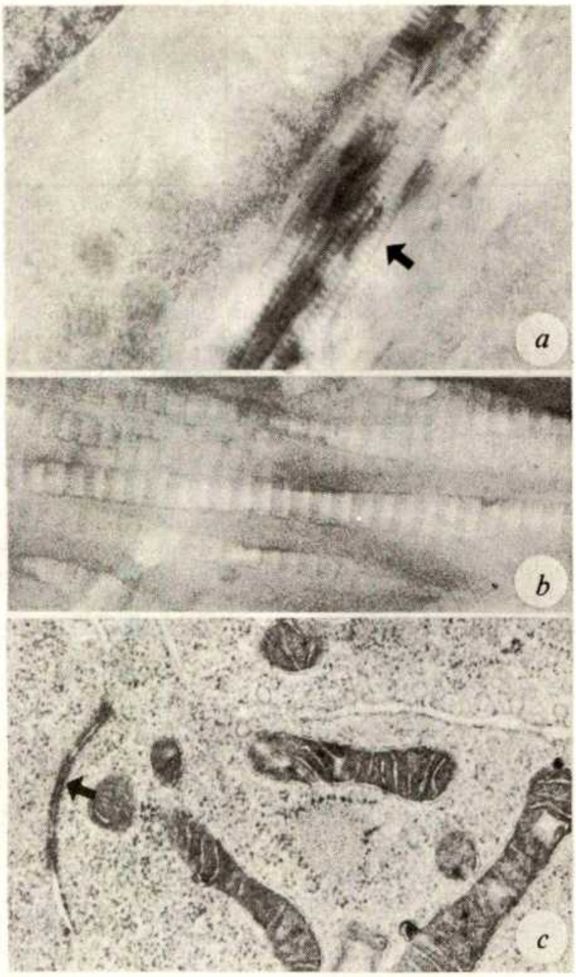

Fig. 2 Electron micrographs of BC cells grown in the same conditions as described for Fig. 1. *a*, Bundle of collagen fibrils in the extracellular space (arrow), negatively stained with 20% phosphotungstic acid by the method of Kushida *et al.*[10] (× 18,182); *b*, higher magnification of collagen fibrils shown in *a*, demonstrating the banding pattern and periodicity of 640 Å (× 45,455); *c*, the portion of two adjacent cells illustrating the desmosome (arrow) and typical small inpocketings of the plasma membrane, stained with uranyl acetate and lead citrate (× 20,545). Fixation, dehydration and embedding in Epon were as in the original plastic culture plates by the published procedure[9].

of rat serum albumin (Al), α-foetoprotein (AFP), and transferrin (trans.) in the culture fluid were performed after eight to 43 generations. Table 1 shows that these clones produced all three serum proteins, indicating that they were clones of rat liver parenchymal cells.

Although there was some difference in cytological appearances of the two clones, a particularly noticeable feature developed under the phase contrast microscope in BC cells left as a full sheet for more than 3 weeks without transfer. Thin fibre-like intercellular structures appeared, increased with time, began to enclose a portion of the culture, and finally divided the whole culture into multiple nodular areas (Fig. 1*a*). This process was usually complete within 6 weeks in our culture conditions.

To identify these structures we used silver impregnation, Mallory-Azan, resorcin-fuchsin, and periodic acid-Schiff. These staining methods, especially the former two, gave the characteristic colour reactions of collagen fibres (Fig. 1*b*). There was no collagen reaction in BB cells. Electron micrographs of BC cells revealed fibrils of characteristic collagen periodicity, deposited in broad intercellular spaces which separated the cells from each other (Fig. 2*a* and *b*). Where cell perimeters were in contact they were connected tightly to desmosomes, arranged in a direction in which collagen fibrils were rearely found (Fig. 2*c*).

To preclude the possibility of contamination of fibroblasts in the original BC clone, we recloned it. Three subclones, BC.S1, BC.S2, and BC.S3, were obtained from plates seeded with 1×10^2 cells by the same procedure as before. The subclones were morphologically similar to the parent clone. For quantitative proof of these findings a hydroxyproline assay of the cell layers maintained for 21 d without subculture was performed by the method of Prockop and Udenfriend[11]. Table 2 shows that values obtained from clone BC and its subclones were more than five times greater than that from the mouse fibroblast line 3T3 (Table 2), for which electron microscopy had shown evidence of production of collagen in extremely small amounts[9].

To see whether the cells had undergone spontaneous malignant transformation, we tested colony-forming capacity in soft agar, tumorigenicity in the cheek pouches of golden hamsters treated with antithymocyte serum, and chromosome number between 48 and 53 generations. No colony developed in soft agar, nor did the cheek pouches of the hamsters reveal any sign of tumours. The predominant mode of chromosome number was 59, indicating hypotriploidy.

† A mouse fibroblast line[12].

‡ A cloned subline of HeLa, human uterine cancer cell line[13]. Assay for this cell line was exceptionally performed after 10 d in culture.

Our data demonstrate the production of native collagen by one of two clonal lines of rat liver cells. Both had synthesised *in vitro* three proteins which are regarded as the differential products of liver parenchyma in early culture generations.

The question arises whether collagen synthesis is a normal function of liver parenchymal cells. It is widely believed that collagen fibres in the liver are formed by the sinusoid lining cells and the fibroblasts of Glisson's capsule.

There are, however, data suggesting that liver parenchymal cells participate in collagen synthesis *in vivo*[14]: 100 times more protocollagen proline hydroxylase activity was reported in the parenchymal cell fraction than in the mesenchymal cell fraction, both of which were isolated from the same adult rat liver. Our results support these findings. They also enable us to speculate that liver parenchymal cells produce the collagen fibres found in the space of Disse, overproduction of which is normally controlled by a homoeostatic mechanism. We suggest that the marked increase of collagen fibres in liver cirrhosis represents a failure of this mechanism.

We thank Dr T. Tachikawa for assistance with electron micrography. This work was supported by a grant in aid

of cancer research from the Ministry of Education, Science and Culture, Japan.

Identification of medicarpin as a phytoalexin in the broad bean plant (*Vicia faba* L.)

THE analysis of phytoalexin induction has been proposed as a dynamic approach to plant systematics[1]. It has also been pointed out that production of the furanoacetylene wyerone acid[2] by *Vicia faba* is an intriguing anomaly to the more general accumulation of isoflavanoid phytoalexins by members of the Leguminosae. In our studies on phytoalexin production by *V. faba*, three related furanoacetylenes (Fig. 1), wyerone acid (*a*), wyerone (*b*)[3] and wyerone epoxide (*c*)[4], have been identified as the major components of the multiple phytoalexin response of the broad bean plant to fungal infection[5]. In addition to these phytoalexins other minor inhibitors were detected in bioassays of thin layer chromatograms of methanol extracts of infected tissues[5]. Only one of these inhibitors reacted with *p*-nitroaniline[6] to give an orange coloration indicating phenolic character. No anti-fungal compounds were detected in extracts of healthy tissues. Here we report the identification of the phenolic inhibitor as medicarpin (3-hydroxy-9-methoxy pterocarpan) (Fig. 1*d*), a phytoalexin present in a wide range of leguminous species[1].

Table 1 Yields of phytoalexins from *V. faba* pod endocarp tissue bearing limited lesions caused by *B. cinerea* 4 d after fungal inoculation

Phytoalexin	Yield (μg per g fresh tissue)
Wyerone	217
Wyerone acid	219
Wyerone epoxide	30.7
Medicarpin	19.5

Yields are the mean of results from two experiments. Samples (about 4 g) of infected tissue were macerated in diethyl ether and the ether extract subjected to thin-layer chromatography (TLC) on precoated plates (Merck 5715). Wyerone acid was isolated after TLC in ether–methanol (6:1) and like other wyerone derivatives was recognised by its blue fluorescence under ultraviolet light (366 nm) at R_F 0.53. TLC of extracts in hexane–acetone (2:1) followed by chloroform–petrol (2:1) enabled purification of wyerone (R_F 0.6), wyerone epoxide (R_F 0.53) and medicarpin (R_F 0.31); the latter quenched the fluorescence of silica gel under ultraviolet light (254 nm). After elution in methanol concentrations of the phytoalexins were recorded by ultraviolet spectrophotometry[2,4].

Pod endocarp tissue (2.5 kg) bearing limited lesions caused by *Botrytis cinerea* was collected 5 d after fungal inoculation[7]. Diethyl ether extracts of the infected tissue[3] were subjected to preparative layer chromatography (PLC) on silica gel (Merck GF254 type 60) using hexane–acetone (2:1) followed after drying with chloroform–petroleum spirit 60–80 °C (2:1) as solvents. The band giving a positive *p*-nitroaniline test (R_F 0.34) was eluted and the phenolic compound repurified by PLC in chloroform (R_F 0.35) and finally chloroform–methanol (10:1).

After elution from R_F 0.6 the inhibitor (7 mg) was crystallised from ether–hexane. Proton magnetic resonance spectra of the crystalline product in deuteriochloroform were consistent with structure *d* in Fig. 1. Recorded optical activity ($[\alpha]_D^{20} - 214°$ $c = 0.19$, chloroform, melting point 129–130 °C); and ultraviolet absorption spectrum λ_{max} (ethanol) 287 (log $\varepsilon = 3.94$), 282 (3.88), 226 (4.14), 210 nm (4.53) were virtually identical to those published for medicarpin[8]. Identification was confirmed by comparison of the mass spectra obtained for our sample and authentic medicarpin.

To date *Vicia faba* seems to be unique in its *de novo* production of chemically unrelated compounds which act as phytoalexins. Much lower concentrations of medicarpin than of wyerone derivatives accumulated within infected tissue (Table 1). This suggests that medicarpin is probably not of great significance to the inhibition of growth of invading fungal hyphae. Medicarpin biosynthesis in *V. faba* may represent the expression of a primitive resistance response which has been largely superseded by the accumulation of the furanoacetylenes. Preliminary examination of the production of wyerone derivatives in pod tissues of different species of *Vicia* in response to infection by *B. cinerea* indicated that the more primitive[9] *V. cracca*, *V. sativa*, *V. sepium* and *V. sylvatica* do not produce wyerone or wyerone acid. These inhibitors, however, were induced in pods of *V. galilea* and *V. narbonensis*, two species closely related to *V. faba*.

Our results provide further support for the proposal that analysis of phytoalexin induction may become an invaluable approach to plant systematic and phylogenetic relationships. It should prove worthwhile to examine medicarpin and furanoacetylene induction within the genus *Vicia*. Note, however, that in our experience, investigation of phytoalexin accumulation within infection droplets[1] does not provide a complete picture of phytoalexin induction. It is only by thorough analysis of infected tissue that the more subtle relationships are likely to be discerned. For example, we have detected only trace amounts of medicarpin and wyerone within infection droplets containing conidia of *B. cinerea* incubated on leaves or pod seed cavities of *V. faba*.

We thank Dr V. J. Higgins (University of Toronto) for a sample of authentic medicarpin and Dr P. H. Davis (University

of Edinburgh) for seed of *V. galilea*. J.A.H. was supported by the ARC.

Initiation inhibition and reinitiation of the synthesis of heterogeneous nuclear RNA in living cells

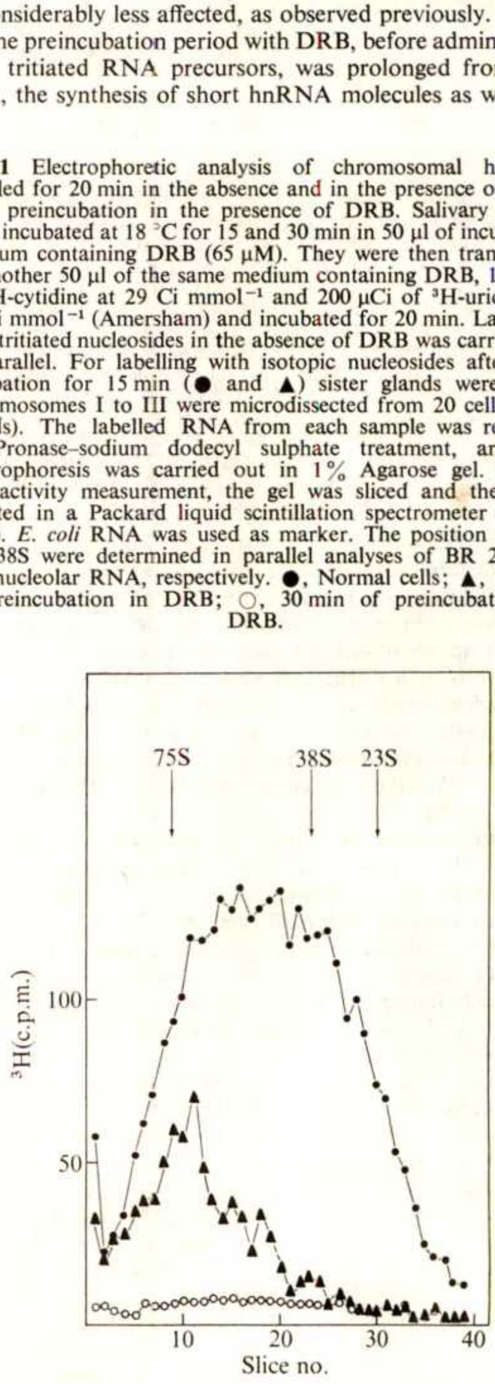
THE nucleoside analogue 5,6-dichloro-1-β-D-ribofuranosylbenzimidazole (DRB) inhibits the synthesis of heterogeneous nuclear RNA (hnRNA) at the initiation level in explanted salivary glands of *Chironomus tentans*, but does not interfere with the synthesis of ribosomal RNA and transfer RNA (refs 1–4). When the radioactive RNA precursors and the inhibitor are coincidently added to the glands the labelling of hnRNA transcripts produced by smaller transcriptional units is suppressed before that of the larger ones[2,3]. If, however, the glands are pretreated with DRB, and the time of preincubation is sufficiently long, labelling of small as well as large hnRNA transcripts is equally eliminated, and the DNA template becomes depleted of nascent hnRNA chains[2–4]. Important questions, arising from these findings, are whether DRB can be washed out from the cells, and whether a reinitiation of hnRNA synthesis can subsequently be achieved. This paper presents data which show that the initiation of the RNA synthesis resumes when glands pretreated with DRB are washed and replenished with inhibitor-free medium.

A reversal of transcription inhibition by DRB should result in a preferential labelling of hnRNA chains in the lower molecular weight ranges, if the incubation period after removal of DRB is brief enough (< 15–30 min). Labelled molecules in the 75–100S range could be expected only around 30 min (calculated synthesis time of the largest hnRNA molecules) after transferring inhibited glands to a DRB-free medium. A reversal of the effect of DRB on polyinosinicpolycytidylic acid-induced interferon production in a strain of diploid human fibroblast has been reported[5]. The superinducing action of DRB was promptly abolished by removing DRB from the cells. The reversibility of the transcription by DRB also increases its usefulness as a tool in studies of transcription mechanism and metabolism of hnRNA in living cells.

In an attempt to examine whether DRB is a reversible inhibitor of the synthesis of chromosomal hnRNA and to record the sequence of hnRNA events after a possible reinitiation of the transcription, explanted glands were preincubated with DRB in 50 μl of Cannon's modified insect medium for 30 min at 18 °C (refs 6 and 7). The glands were then washed and replenished with inhibitor-free medium supplied with ^{3}H-cytidine and ^{3}H-uridine and were incubated for different periods. Fixation of glands, microdissection of chromosomes, extraction and electrophoresis of RNA and the measurement of radioactivity were carried out as described elsewhere[2-4,8]. The RNA of chromosome IV, dominated by Balbiani ring 1 and 2 RNA, shows labelling kinetics different from those of chromosomes I to III (refs 2–4), and therefore the present analyses of chromosomal RNA do not include RNA from chromosome IV.

To demonstrate the effect of DRB on the initiation of hnRNA synthesis in chromosomes I to III, explanted glands were preincubated with DRB for 15 and 30 min before labelling for 20 min with tritiated cytidine and uridine in the continued presence of the analogue (Fig. 1). The control glands were labelled in similar conditions, but without inhibitor. The electrophoretic profile of labelled chromosomal hnRNA from control cells shows an heterogeneous distribution of molecules in the 16–100S range as described earlier[2,3,9]. When DRB was added to the incubation system 15 min before isotopic nucleosides, there was an almost complete disappearance of label in the 23–38S range of hnRNA, but incorporation into the 75–100S region was considerably less affected, as observed previously. If, however, the preincubation period with DRB, before administration of the tritiated RNA precursors, was prolonged from 15 to 30 min, the synthesis of short hnRNA molecules as well as of

Fig. 1 Electrophoretic analysis of chromosomal hnRNA labelled for 20 min in the absence and in the presence of DRB after preincubation in the presence of DRB. Salivary glands were incubated at 18 °C for 15 and 30 min in 50 μl of incubation medium containing DRB (65 μM). They were then transferred to another 50 μl of the same medium containing DRB, 100 μCi of ^{3}H-cytidine at 29 Ci mmol^{-1} and 200 μCi of ^{3}H-uridine at 44 Ci mmol^{-1} (Amersham) and incubated for 20 min. Labelling with tritiated nucleosides in the absence of DRB was carried out in parallel. For labelling with isotopic nucleosides after preincubation for 15 min (● and ▲) sister glands were used. Chromosomes I to III were microdissected from 20 cells (four glands). The labelled RNA from each sample was released by Pronase–sodium dodecyl sulphate treatment, and the electrophoresis was carried out in 1% Agarose gel. Before radioactivity measurement, the gel was sliced and the slices counted in a Packard liquid scintillation spectrometer (Model 3380). *E. coli* RNA was used as marker. The position of 75S and 38S were determined in parallel analyses of BR 2 RNA and nucleolar RNA, respectively. ●, Normal cells; ▲, 15 min of preincubation in DRB; ○, 30 min of preincubation in DRB.



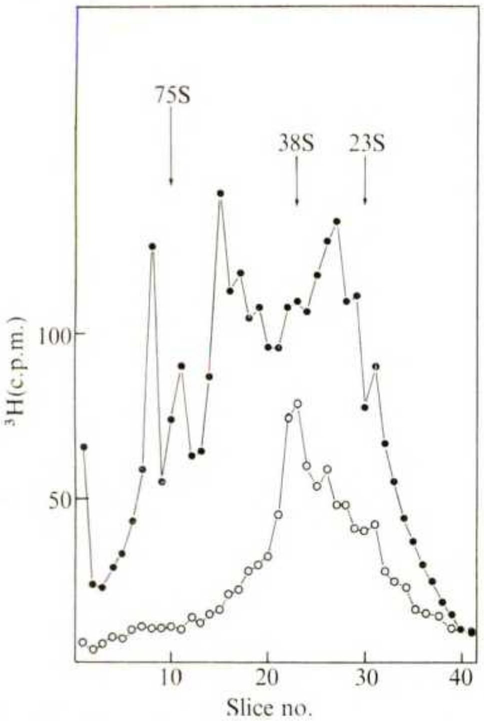


Fig. 2 Electrophoretic analyses of chromosomal hnRNA labelled for 15 min without preincubation in DRB, and after preincubation in DRB followed by removal of DRB from the cells before addition of isotopic nucleosides. Four glands were incubated at 18 °C for 30 min in 50 µl of incubation medium containing DRB (65 µM). The glands were then transferred to an inhibitor-free medium, and were rinsed 3 times each in a volume of 0.5 ml. They were then placed in 50 µl of DRB-free medium containing 100 µCi of ^{3}H-cytidine and 200 µCi of ^{3}H-uridine and incubated for 15 min. For labelling with tritiated nucleosides without preincubation with DRB (control glands), the sister glands were used in an otherwise parallel procedure. Chromosomes I to III were dissected from 20 cells (four glands). For other data see the legend to Fig. 1. ●, Normal cells; ○, DRB-treated cells.

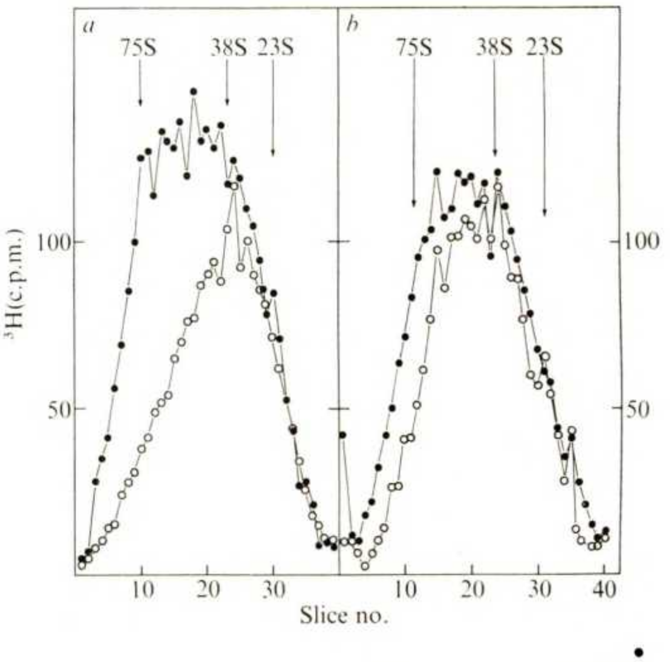
long molecules was equally interrupted, though 5–10% of the labelled material, distributed evenly over the whole spectrum, survived the drug treatment. On the basis of these and previous observations[2-4], it seems likely that the DNA segments which serve as template for hnRNA synthesis are essentially cleared of nascent RNA chains 30 min after addition of DRB.

An efficient reinitiation of transcription after inhibition by DRB is conditional on first, that the intracellular DRB concentration is rapidly reducable to a level not being inhibitory; and second, that the interference of DRB or DRB metabolite (presumably a DRB triphosphate) with the initiation mechanism is reversible after removal of the compound from the cells. Experiments were designed to clear the DNA template of nascent hnRNA chains by blocking the initiation of new chains with DRB for 30 min, and then to reverse the inhibition of initiation simply by washing out DRB from the cells. After rinsing in excess volumes of incubation medium lacking the inhibitor (3×0.5 ml), the glands were incubated for 15 min in a drug-free medium supplemented with tritiated cytidine and uridine (Fig. 2). The control glands were incubated for the same period but without DRB throughout. Although the electrophoretic analysis of hnRNA derived from control cells shows heterogeneous distribution of label in the 16–100S range[2,3], the corresponding analysis of hnRNA from DRB-pretreated and washed glands shows essentially one broad and somewhat asymmetric peak in the 23–38S region. It has a rather steep slope on the high molecular weight side, but is less steep on the other side. Thus, 15 min after removal of DRB from pretreated glands, transcription inhibition seems to be reversed, and a reinitiation of hnRNA synthesis has been taking place. The maximum sizes of hnRNA chains initiated and elongated after removal of inhibitor are, however, significantly less than that of hnRNA produced by cells with an uninterrupted and continuous initiation of transcription. Most of the labelled chains have a molecular size not exceeding that of the 38S marker, although there is also some label in the 38–100S range. This latter material can probably be attributed to radioactivity associated with growing chains which were not eliminated during pretreatment with DRB (refs 1, 2 and Fig. 1). Such uninhibited RNA chains of the larger transcriptional units are then able to produce labelled hnRNA molecules in the 38–100S range immediately after administration of labelled RNA precursors irrespective of whether or not reinitiation is taking place.

To follow the sequence of hnRNA events after drug treatment and replenishment with drug-free medium, isotopic nucleosides were added to the glands 5 min (Fig. 3*a*) and 30 min (Fig. 3*b*) after removal of DRB, and the incorporation continued for 20 min. Control glands were incubated in a similar way but in the absence of inhibitor throughout incubation. The electrophoretic profile of chromosomal hnRNA, derived from glands to which tritiated nucleosides were introduced 5 min after removal of DRB, agrees reasonably well with that of hnRNA extracted from control cells in the range below the 38S marker (Fig. 3*a*). The amount of labelled material in the 38–100S range, however, is lower in treated cells, decreasing gradually from the 38S region towards the 100S range. In the 75–100S region, it comprises 30–40% of the radioactivity level found in the normal pattern. Considering that escape labelling of hnRNA during DRB treatment constitutes not more than 5–10% of the uninterrupted RNA labelling, it seems probable that reinitiated 75–100S RNA molecules have attained their maximum size (finished transcripts) 25 min after reversal of inhibitory action. It should be observed, however, that even though reinitiated hnRNA chains in the 75–100S range have been completed 25 min after removal of DRB, the amount of labelled

Fig. 3 Electrophoretic analyses of chromosomal hnRNA labelled for 20 min without preincubation in DRB, and after preincubation in DRB followed by removal of DRB from the cells before addition of isotopic nucleosides. In each experiment four glands from four different animals were incubated at 18 °C for 30 min in 50 µl of incubation medium containing DRB (65 µM). The glands were then transferred to an inhibitor-free medium and rinsed 3 times each in a volume of 0.5 ml and placed in 50 µl of fresh medium for *a*, 5 and *b*, 30 min. Next, 100 µCi of ^{3}H-cytidine and 200 µCi of ^{3}H-uridine were introduced to the medium and the glands were labelled for 20 min. For labelling with tritiated nucleosides without preincubation in DRB (control glands), the sister glands were used in an otherwise parallel procedure. Chromosomes I to III were dissected from 20 cells (four glands). For other details see the legend to Fig. 1. ●, Normal cells; ○, DRB-treated cells.



RNA in this part of the spectrum is, still 60–70% lower than that in untreated cells. This may be because: (1) transcription initiation is not restored to normal efficiency after replacement of medium containing DRB with inhibitor-free medium (partial reinitiation); and/or (2) finished hnRNA molecules accumulate after their completion on chromosomes I to III. The latter would imply that chromosomal RNA extracts from control cells contain a larger quantity of finished molecules than that from cells which were pretreated with DRB for 30 min and incubated in inhibitor-free medium for 25 min after removal of DRB (Fig. 3*a*).

The finding that hnRNA molecules migrating faster than 38S display a normal rate of labelling if isotopic nucleosides are added 5 min after transferring glands to drug-free medium (Fig. 3*a*) argues against inefficiency in transcription reinitiation. Previous observations that hnRNA on the chromosomes I to III attains maximum specific activity after 45–90 min of incorporation[2], whereas the labelling of Balbiani ring RNA of similar size reaches a plateau value after 20 min of labelling[10] are compatible with an accumulation of hnRNA molecules on the chromosomes I to III after their completion. Therefore, to restore the rate of labelling and accumulation of chromosomal 75–100S RNA to the normal condition after removal of DRB from inhibited cells, incubation for 20 min or longer would be required before the addition of radioactive RNA precursors. In the experiment shown in Fig. 3*b*, the interval between washing and replenishing DRB-treated glands with drug-free medium and administration of isotopic nucleosides was prolonged to about 30 min. As predicted, the electrophoretic patterns of chromosomal hnRNA derived from inhibited and washed cells and from untreated cells display a reasonably good agreement, although absolute equality cannot be claimed. The results in Fig. 3 strongly indicate that 25 min of incubation after washing out DRB from cells (5 min in the absence plus 20 min in the presence of radioactive nucleosides) pretreated with the drug for 30 min, is sufficiently long to reinitiate, elongate and complete hnRNA chains migrating as 75–100S RNA. To bring the rate of the synthesis (accumulation) of the largest hnRNA molecules on the chromosomes I to III to a level similar to that before exposure to transcription inhibition, however, incubation in inhibitor-free medium for at least 30 min is demanded after removal of DRB. The principal reason for that is probably the accumulation of newly made hnRNA on chromosomes I to III rather than, or in addition to, an inefficient reinitiation of the transcription.

I thank Agneta Askendal and Amina Ossoinak for skillful technical assistance. The investigation was supported by the Swedish Cancer Society and Karolinska Institutet (Reservationsanslaget).

Inactivation of parathyroid hormone mRNA by treatment with periodate and aniline

TRANSLATION of parathyroid hormone (PTH) mRNA in extracts of wheat germ[1] or Krebs II ascites cells[2] produces a polypeptide which contains the structure of PTH but which is larger than either PTH or its biosynthetic precursor proparathyroid hormone[3,4] (proPTH). In the wheat germ system, this cell-free protein, designated pre-proparathyroid hormone (pre-proPTH) contains a methionine at the amino terminus[5] derived from initiator methionyl-tRNA[6]. Although this observation suggests that initiation of the synthesis of pre-proPTH is normal in the cell-free system, it is possible that *in vitro* initiation occurs at a codon that codes for an internal methionine *in vivo*. Such an artefact could be due to a degraded mRNA in which the *in vivo* initiator codon is lost or inactivated.

Recent studies on the structure of mRNA have suggested a method for demonstrating that an isolated mRNA is intact at the 5′ end and thus that the proper initiator codon is present. Many mRNAs of viruses and eukaryotic cells have been shown to be blocked at the 5′ end by a 7-methlyguanosine linked through its 5′ hydroxyl by way of a triphosphate or pyrophosphate to the 5′ hydroxyl of the penultimate nucleoside[7]. This 5′–5′ linked structure is necessary for the translation of mRNAs of vesicular stomatitis virus, reovirus, and haemoglobin[8,9] and mRNA from brine shrimp[10]. The 7-methylguanosine can be removed from the mRNAs by oxidation with periodate followed by a β elimination reaction catalysed by aniline[9]. I have compared the effects of periodate and aniline treatment on the activity of PTH mRNA with the effects on the activities of haemoglobin mRNA which has a blocked 5′ terminus and with satellite tobacco necrosis virus (STNV) mRNA which does not contain a methylated blocked 5′ terminus[11,12] and is actively translated in the wheat germ cell-free protein synthesising system without being methylated (J. M. Clark, Jr, personal communication).

Treatment with periodate followed by aniline inhibited the translation of PTH and haemoglobin mRNAs by 90% or more, compared with controls incubated in the same manner without periodate and aniline (Fig. 1*a* and *b*). In contrast, the activity of STNV mRNA was inhibited only about 15% by this treatment, an inhibition similar to that observed in the control incubated with aniline alone (Fig. 1*c*). Treatment with periodate alone substantially reduced the activity of haemoglobin and PTH mRNA but had no inhibitory effect on STNV RNA. The resistance of STNV RNA to this treatment minimises the possibility that the periodate inhibition is a nonspecific effect. The inhibition may be due to spontaneous β elimination of the oxidised mRNA, or the oxidation of the sugar moiety on methylguanosine may alter the 5′ end enough to decrease the efficiency of initiation. The present data do not allow us to distinguish between these two possibilities. Rao *et al.*[13], however, have shown that periodate treatment alone completely inhibits the activity of rat liver mRNA and have concluded that the unoxidised ribose is required for activity. It is not clear why they observed nearly 100% inhibition after periodate oxidation and I observed only a 50% inhibition.

The effect of aniline treatment alone on the activity of the mRNAs was somewhat variable. The activity of haemoglobin mRNA was not reduced by aniline treatment while PTH mRNA and STNV RNA were inhibited by about 50 and 15%, respectively. Steinschneider and Frankel-Conrat have reported that aniline treatment alone reduced the infectivity of tobacco mosaic virus RNA by 50% and that some aniline was tightly bound to the RNA and could not be removed by extensive washing[14]. Thus, different mRNA may be differentially sensitive to treatment by aniline.

Although treatment with either periodate or aniline alone reduced the activity of PTH mRNA, the inhibition after treatment with both chemicals was more than simply a summation of the two individual inhibitions. In the experiment shown in Fig. 1*a*, the sample treated with aniline and periodate should have been about 25% of control if the effects of aniline and periodate were additive instead of the observed 4% of control. In another experiment the

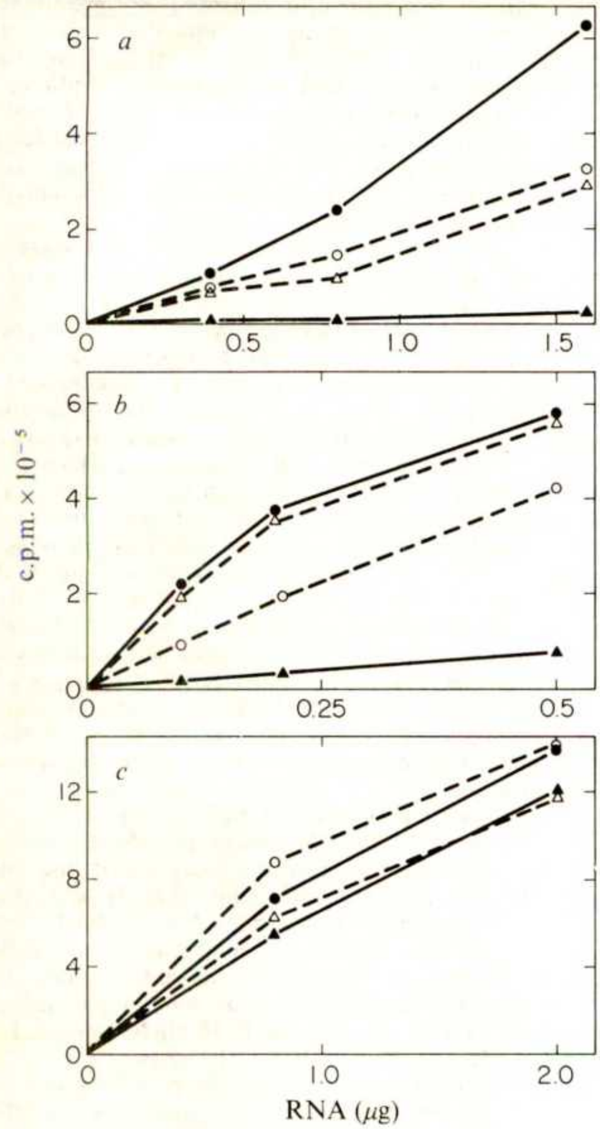

Fig. 1 Translation in wheat germ extracts of PTH (*a*), haemoglobin (*b*) and STNV (*c*) mRNAs after treatment with periodate and aniline. Haemoglobin mRNA was isolated as described by Labrie[15]. Parathyroid RNA sedimenting between 8S and 14S (designated PTH mRNA in this report) was isolated as described previously[1] with modifications. Bovine parathyroid glands were obtained at the time of slaughter and were stored in liquid nitrogen. About 1 g of glands was sliced and then homogenised for 1 min in a Waring blender in 5 ml of phenol, 5 ml of chloroform containing 4% isoamyl alcohol and 2 ml of 10% sodium dodecyl sulphate. 5 ml of buffer (0.01 M Tris-HCl, *p*H 7.4, 0.1 M NaCl, 0.001 M EDTA, 0.1% sodium dodecyl sulphate) was added and RNA was extracted by shaking with phenol–chloroform as described previously[1]. DNA and low molecular weight RNA were extracted from the sample with 3 M sodium acetate, *p*H 6.0, 7.5 mM EDTA[16] and the RNA sedimenting on a sucrose gradient from 8S to 14S was isolated from the high molecular weight RNA as before[1]. The mRNAs were incubated with periodate and aniline as described by Steinschneider and Fraenkel-Conrat[14] and modified by Mayer *et al.*[17]. 10 μg of haemoglobin or STNV mRNA or 4 μg of PTH mRNA were incubated in 50 μl of 0.1 M sodium acetate, *p*H 5.3, 1 mM EDTA containing 1 mM sodium periodate for 2 h at room temperature in the dark. Glucose was added to 10 mM, 150 μl ethanol were added and RNA was precipitated overnight at −20 °C. The RNA was centrifuged in a Brinkman microfuge, washed with ethanol, dried under vacuum and dissolved in 50 μl of 0.33 M aniline HCl. After incubation for 2 h at room temperature in the dark, NaCl was added to 0.3 M and 150 μl of ethanol were added. The samples were left overnight at −20 °C, and the RNA was centrifuged, washed twice with ethanol, dried under vacuum and dissolved in 25 μl of H_2O for translation in the wheat germ extracts. Controls were incubated in the same manner except that either aniline or periodate or both were not added. Conditions for the translation of the mRNA in the wheat germ cell-free system have been described[1]. 5–10 μCi of ^{35}S-methionine (300 Ci $mmol^{-1}$, Amersham Searle) were added to each reaction of 25 μl. Total trichloroacetic acid-insoluble radioactivity was determined in 1- or 2- μl aliquots of the reaction. The amounts of radioactivity and RNA indicated in the figure are the c.p.m. and μg, respectively, in a reaction of 25 μl. The amount of radioactivity (*a*, 0.43×10^5 c.p.m.; *b*, 0.26×10^5 c.p.m.; and *c*, 0.45×10^5) incorporated into protein if mRNA was not added to the reaction was subtracted from each of the plotted values. ●, Incubated without aniline or periodate; △, incubated with aniline and without periodate; ○, incubated with periodate and without aniline; ▲, incubated with periodate and aniline.

treatment with aniline and periodate was reversed. The samples treated with either periodate or aniline alone were 73% and 85% of control, respectively. The sample treated in reverse order with aniline and periodate was 54% of control, near the 62% expected as a result of simple additive effects, while the sample treated with periodate and then aniline was 19% of control. The inhibition was less in this experiment than that shown in Fig. 1, probably because 0.27 M aniline was used instead of 0.33 M aniline. This synergistic action suggests that the effect of the periodate/aniline treatment is the result of a β-elimination reaction which would be expected if PTH mRNA has a nucleoside in 5′–5′ linkage at the 5′ end.

Analysis of the products of the translation of the mRNAs in the wheat germ extracts by sodium dodecyl sulphate slab gel electrophoresis is shown in Fig. 2. Each of the mRNAs directs primarily the synthesis of the expected protein products. If STNV RNA is mixed with either PTH mRNA or haemoglobin mRNA, both the RNAs in the mixture direct the synthesis of their respective proteins (Fig. 2*b* and *g*) but after treatment of the mixture with periodate and aniline, essentially only STNV proteins are observed (Fig. 2*c* and *h*).

These experiments demonstrate that inactivation of mRNAs by treatment with periodate and aniline is an effective means of determining whether mRNAs contain a 5′–5′ linked nucleoside at the 5′ terminus, particularly with an impure preparation of mRNA such as that used in this report for PTH mRNA when direct chemical analysis is not possible. The inactivation of haemoglobin and PTH mRNAs by this treatment supports studies with other mRNAs indicating that the blocked 5′ end is required for maximal activity of mRNA[8-10]. Simply demonstrating that periodate–aniline treatment causes inhibition of mRNA activity is not sufficient to conclude that a particular mRNA contains such a 5′–5′ linked nucleoside since treatment with aniline or periodate alone can cause substantial inhibition. The controls of treatment with aniline or periodate alone are thus essential to interpreting the results. Furthermore, addition of a mRNA without a blocked 5′ terminus to the reaction as in the experiment in Fig. 2 can control other nonspecific factors such as RNase activity or physical loss of the mRNA during the procedure. For the many mRNAs that contain polyadenylic acid, the demonstration of a blocked 5′ end by this method, combined with the demonstration that polyadenylic acid is present at the 3′ end, will be useful criteria for establishing that a mRNA has not been partially degraded during isolation.

The data presented indicate that PTH mRNA contains a blocked 5′ terminus and thus is probably intact at the 5′ terminus. If this is true, then the normal initiator codon *in vivo* is present and it is unlikely that the translation of PTH mRNA *in vitro* is the result of false initiation at an internal codon. This further strengthens the contention that pre-proPTH represents all of the information present in PTH mRNA that is translated into protein.

I thank Dr John M. Clark, Jr for providing STNV RNA and for helpful discussions and Calihan and Co., Meats, Peoria, Illinois, for the bovine parathyroid glands. This

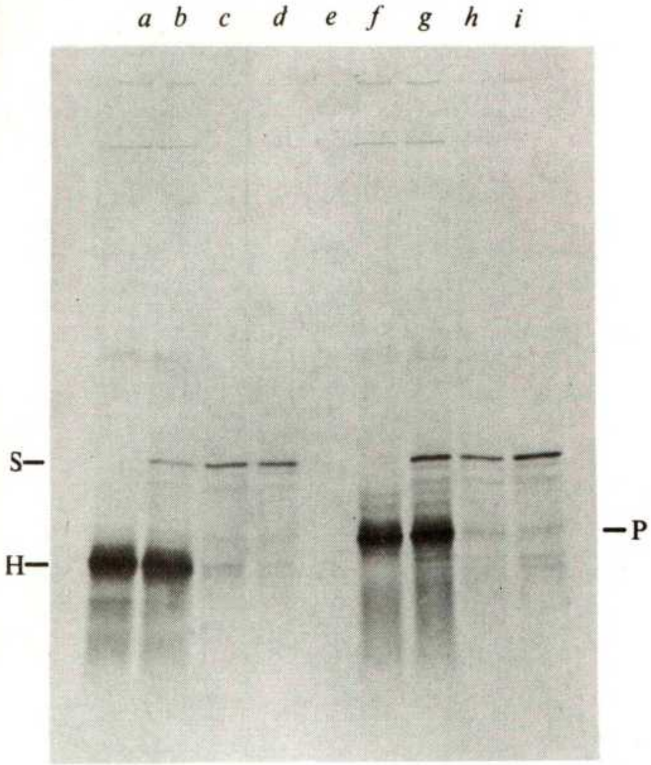

Fig. 2 Analysis by sodium dodecyl sulphate gel electrophoresis of the radioactive proteins synthesised in the wheat germ extracts. Translation of mRNA was as described in the legend to Fig. 1 and 5 µl of the reactions were analysed on 15% acrylamide slab gels according to Laemmli[18] as described previously[6]. The autoradiogram was prepared by exposing the dried gel to Kodak RP Royal X-ray film for 18 h. RNA added to each reaction of 25 µl was: *a*, 0.2 µg haemoglobin mRNA; *b*, 0.2 µg haemoglobin mRNA+0.4 µg STNV mRNA; *c*, same as *b* after treatment of the mixture with periodate and aniline; *d*, 0.4 µg STNV RNA; *e*, none; *f*, 1.6 µg PTH mRNA; *g*, 1.6 µg PTH mRNA+0.8 µg STNV mRNA; *h*, same as *g* after treatment of the mixture with periodate and aniline; *i*, 0.8 µg STNV mRNA. The positions of haemoglobin, STNV coat protein and pre-proPTH are indicated by H, S, and P, respectively.

Aqueous glasses as matrices in freeze-fracture electron microscopy

FREEZING is an important technique in the preservation of the morphology of biological materials for electron microscopic examination. Methods relying on freeze-fracturing, sometimes followed by etching, have been developed and have led to advances in the interpretation of biological ultrastructure[1]. Other, related applications of freezing are for the preservation of biological activity[2] and the preparation of biological specimens for microanalysis of low molecular weight components[3]. The freezing of cells and tissues can, like all other methods of fixation, give rise to artefacts, although probably to a lesser extent than the more traditional methods. The most important factors governing the quality of biological freezing include the size distribution of the ice crystals, the extent of supercooling and the possibility of osmotic dehydration and shrinkage of cells. Very high cooling rates are considered essential to minimise the deleterious effects of ice crystals, and to overcome excessive osmotic shrinkage of cells by extracellular ice formation, the use of cryoprotective agents is common. It is believed that an effective, penetrating cryoprotectant must diffuse into the cell without, at the same time, interfering with its morphology. Glycerol and dimethylsulphoxide fulfil these conditions and are widely used as cryoprotectants, although it is known that they can interfere with the physiological functions of some cells[4].

The available evidence suggests that, in the appropriate conditions, the cell contents are readily supercooled[5], and so it should be possible to protect cells from freeze damage by controlling the formation and growth of ice nuclei in the extracellular fluid, even in the absence of penetrating cryoprotectants. We have achieved this using water-soluble synthetic or modified natural polymers.

In favourable conditions, suitable polymers in aqueous solution can be made to yield vitreous states which are devoid of ice crystallites at low temperatures. The experimental requirements are a combination of high viscosity (that is,

Fig. 1 50% PVP solution quenched, freeze-fractured and subsequently etched for 5 min at 173 K. (× 19,440)

high molecular weight and adequately high concentration) and fast cooling. Even where, for practical reasons, complete vitrification is not possible and submicroscopic ice nuclei develop during quenching, these are prevented from growing at the temperatures normally used for freeze-fracturing (120–170 K) by the very low diffusion rates in the embedding polymer solution. One of the main advantages of polymeric cryoprotectants is their inability to penetrate the cell, so they are less likely to interfere with the physiological functions, or alter the morphology. Also, by virtue of their high molecular weights, they cause hardly any osmotic flow of water from the cell.

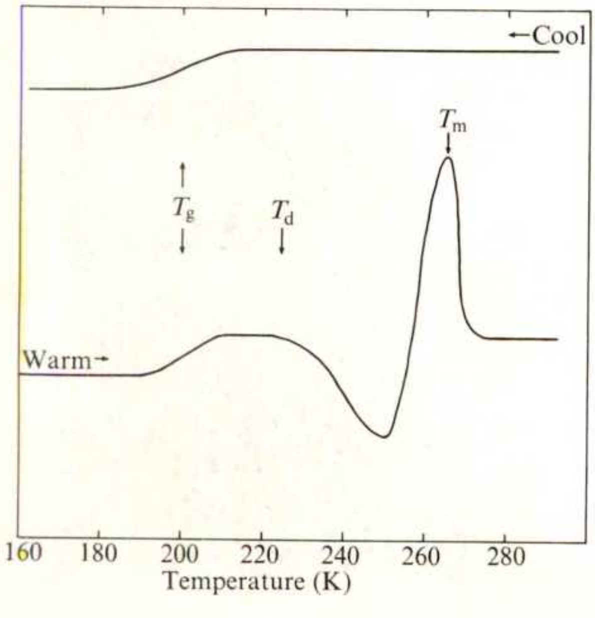
The polymers which are most effective for the achievement of vitreous states are those with a large water-binding capacity, for example, polyvinyl pyrrolidone (PVP), polyvinyl alcohol, dextran and polyethylene glycol. Several others, such as modified starches and celluloses, although interacting strongly with water, do not yield sufficiently concentrated solutions at the molecular weights normally obtainable. Most of our exploratory work has been with PVP of average molecular weights 44,000 and 700,000, used at concentrations of 25 and 50 weight %. The aqueous solution of the polymer was quenched in melting Freon 22 and then transferred to liquid nitrogen. It was freeze-fractured (Balzer BA 360 M Freeze Etching Unit) at 173 K, some specimens subsequently being etched at this temperature. Tungsten/tantalum replicas backed with carbon were prepared and examined by transmission electron microscopy.

Figure 1 shows an electron micrograph of a quenched 50% PVP of average molecular weight 44,000. At the magnification used there is no evidence of any ice crystals, and the largest structural units are ~ 10 nm in diameter. Figure 2 represents two differential scanning thermograms (Perkin Elmer DSC.2) obtained by cooling and heating the same solution. Although the fastest cooling rate which could be achieved in the calorimeter was only 80 K min^{-1}, the cooling trace shows the complete suppression of ice formation; instead a vitrification (T_g) is indicated at 200 K. The same T_g is seen in the warming trace (10 K min^{-1}), followed by a devitrification (T_d) at 220 K, and finally by melting (T_m). These transition temperatures are in reasonable agreement with those reported previously[6].

A 25% PVP solution, treated in the same way showed (Fig. 3) general structural features similar to those in Fig. 1, but ice nucleation sites which have given rise to spherulitic crystallites of micrometre dimensions are indicated. Raising the temperature and maintaining it at 200 K for 2 h did not, however, lead to a further crystal growth.

These processes in the 25% solution could not be monitored by scanning calorimetry, because even the fastest cooling rate which could be achieved in the calorimeter was too slow to prevent the total freezing of the solution. This confirms a

Fig. 2 Differential scanning thermogram obtained by heating a 50% PVP solution. T_g, Glass transition; T_d, devitrification; T_m, melting point.



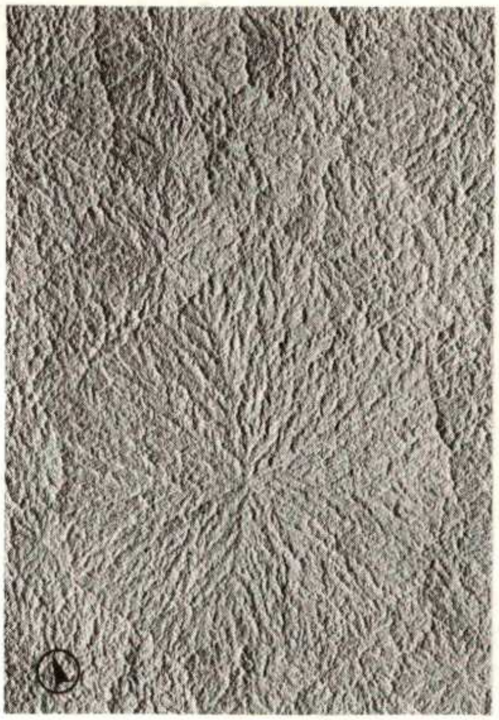


Fig. 3 25% PVP solution treated as for Fig. 1. (× 19,440)

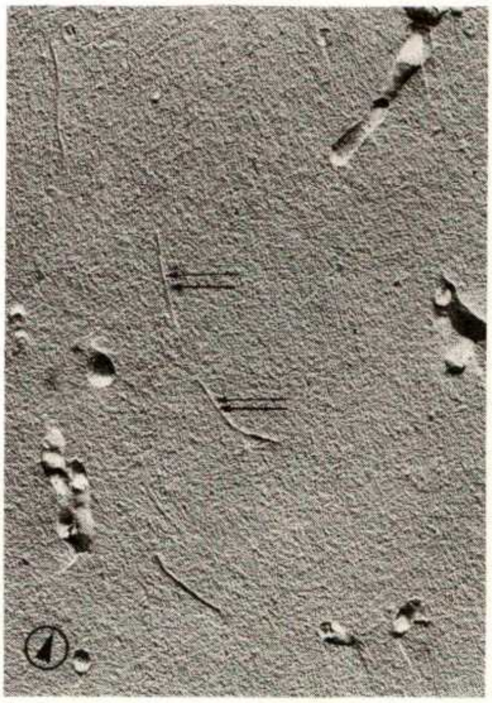
Fig. 4 Nerve cell from the interganglionic connective from the cockroach (*Periplaneta americana*) central nervous system. Freshly dissected tissue was incubated in buffered 50% PVP for 30 min before quenching. Microtubules (arrows) can be distinguished clearly in the cytoplasmic background, showing the absence of ice damage. (× 18,000)



previous observation[6], made using a calorimeter especially designed for much faster cooling, where it was not possible to identify T_g, because ice developed during sample cooling.

Experiments were also carried out in which PVP solutions containing single cells and tissues of animal and plant origin were similarly quenched and fractured. In all cases, extracellular medium had the appearance shown in Fig. 1 and no ice crystals could be detected in the cytoplasm. Figure 4 shows an example taken from the central nervous system of the cockroach. The cell shown comes from the centre of the tissue which is ~ 1 mm thick and the absence of ice in the cytoplasm suggests that intracellular cryoprotection is afforded even when the cell is not in direct contact with the medium containing the polymer.

Further work is in progress to investigate the influence of different polymer systems and different experimental conditions on the morphological details of quenched cells and tissues. A more detailed report will be published elsewhere.

We thank Mr W. M. Lee for technical assistance with the freeze-fracturing and Mr R. Hemming for performing the scanning calorimetry.

The hinge-bending mode in lysozyme

A COMPLETE description of an enzyme requires a knowledge of its structure and the dynamics of its function. From the crystal structures of enzymes and enzyme–inhibitor complexes and the known chemistry of model systems, it has been possible in some cases to draw reasonable inferences concerning the mechanisms of enzyme-catalysed reactions. Little has been done so far, however, to supplement such essentially static results by an investigation of the reaction dynamics. This requires an understanding of the internal motions of the enzyme, as well as those of the substrate, since both are likely to be essential to the function. Here we present a theoretical study of a low frequency vibration involving the two globular lobes of lysozyme between which the cleft containing the active site is located[1]. Any motion involving this cleft could play a part in the catalytic activity; in fact, atom displacements of up to 0.75 Å found in a comparison of the free enzyme and the enzyme–inhibitor complex indicate that the cleft has closed down in the latter[2]. The force constant for the low frequency bending vibration corresponding to the opening and closing of the cleft is obtained from empirical energy functions[3]. Because the protein surface moves appreciably during the vibration, damping effects resulting from the viscous dissipation in the solvent are included in the calculation[4,5].

To model the hinge-bending mode, the lysozyme molecule is assumed to be composed of two essentially rigid lobes (lobe 1: residues 5–36 and 98–129; lobe 2: residues 40–94), connected by a hinge region consisting of the amino-terminal end (residues 1–4) and two short polypeptide chain segments (residues 37–39, 95–97) running from one lobe to the other[1]. A natural axis parallel to the cleft is obtained for the bending motion by passing a line through $C_\alpha 38$ and $C_\alpha 97$, an excellent view of the cleft and the chosen axis can be obtained from diagram L4 of Dickerson and Geis[6].

The bending motion of lysozyme in the presence of solvent is determined by the Langevin equation for a damped harmonic oscillator[7], which has the form

$$I\frac{d^2\theta}{dt^2} + f\frac{d\theta}{dt} + k\theta = N_r(t) \qquad (1)$$

Here, θ is the angular displacement from the equilibrium position, I the effective moment of inertia, f the friction coefficient, and k the force constant associated with the relative motion of the lobes; $N_r(t)$ represents a randomly fluctuating torque characteristic of Brownian motion. The properties of a system governed by equation (1) are well known[7]. To apply the results to the present case, it is necessary only to determine the parameters I, f, and k.

The force constant k was estimated from an empirical energy function that expresses the total conformational energy as a function of the Cartesian coordinates of the heavy atoms[3]; it includes terms associated with bond lengths, bond angles, dihedral angles, hydrogen bonds and non-bonded interactions. To obtain an equilibrium starting structure, the real space refined coordinates of lysozyme[8] were subjected to 200 steps of steepest-descent energy refinement. The potential function for bending was then determined by rotating residues 39–96 rigidly about the chosen axis and computing the conformational energy of the distorted protein as a function of the bending angle. To obtain a more realistic potential function, the same rigid rotations were performed, but at each bending angle there followed a 100-cycle energy minimisation which allowed for adiabatic relaxation of the protein[3]. The bending angle was kept fixed during the relaxation by imposing constraints on residues distant from the hinge in the interior of each lobe (residues 44–51, 61 and 65–73 in lobe 2, residues 109–122 in lobe 1). The results of the two calculations are shown in Fig. 1; a parabolic fit to the points yields the force constants $k_r = 4.1 \times 10^{14}$ erg rad^{-2} mol^{-1} (rigid), and $k_a = 3.3 \times 10^{13}$ erg rad^{-2} mol^{-1} (adiabatic). Total moments of inertia about the bending axis were computed for residues 38–97 (I_2) and for the rest of the molecule (I_1); the values are $I_2 = 1.01 \times 10^{-10}$ g cm^2 mol^{-1} and $I_1 = 1.08 \times 10^{-10}$ g cm^2 mol^{-1}. Water molecules associated with the protein were ignored in this calculation. The friction coefficient was estimated by a modified Stokes law[9] appropriate for the hydrodynamic interaction of two spheres of radius 10 Å separated by a gap of 5 Å, undergoing small relative motions about an axis 20 Å from the sphere centres; the resulting value is $f = 5.7 \times 10^2$ g cm^2 s^{-1} mol^{-1}.

If hydrodynamic effects are neglected, equation (1) reduces to the equation for a simple harmonic oscillator. With the approximation $I = (I_1 I_2/I_1 + I_2)$, the resulting frequencies are $\omega_r = 15$ cm^{-1} and $\omega_a = 4.2$ cm^{-1}. These very low frequencies result from a balance between the large force constant and the large moment of inertia associated with the bending motion. The effective CCN bending force constant for an α carbon is 2×10^{12} erg rad^{-2} mol^{-1}, less than 1/10 of k_a. The additional contributions to k_a come from a large number of non-bonded contacts (20–50, depending on the bending angle), involving atoms in the hinge region and in the lobes (for example, for closing, Leu 56 O . . . Trp 108 N_{ε_1}, Trp 63 C_{η_2} . . . Asp 101 O_{δ_2} and for opening His 15 N_{ε_2} . . . Thr 89 O_{γ_1}, His 15 C_{δ_2} . . . Thr 89 O_{γ_1}). The large difference between k_r and k_a arises from small atomic displacements ($\leqslant 0.5$ Å) that alleviate the close non-bonded contacts produced by the rigid motion.

Introduction of the hydrodynamic terms in equation (1) demonstrates that for an aqueous medium the inequality

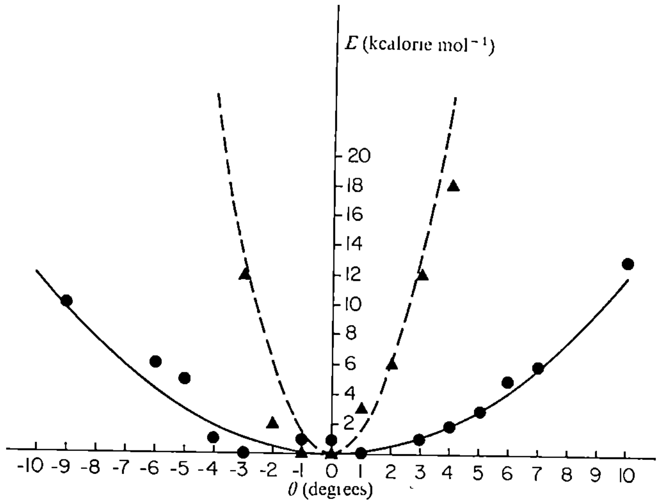

Fig. 1 Change in conformational energy produced by opening ($\theta<0$) or closing ($\theta>0$) the lysozyme cleft. Calculated values are for the rigid bending potential (▲), and for the adiabatic bending potential (●); the curves are parabolic fits to the points. The $\theta=0$ value corresponds to the minimum energy geometry for each of the potentials; the adiabatic minimum corresponds to an energy 34 kcalorie mol^{-1} below the rigid curve and is displaced toward a more open configuration by 5°.

($f^2 > 4Ik$) is satisfied so that the motion is 'overdamped'; that is, rather than vibrating periodically with the calculated frequency, the two lobes move relative to each other in a diffusive manner in accord with the Smoluchowski equation[7]. Quantitatively, the inertial effects decay rapidly, with a time constant $\tau_I = (I/f) \simeq 10^{-13}$ s, and the relaxation time for displacements from equilibrium is $\tau_\theta \simeq f/k_a \simeq 2\times10^{-11}$ s; this latter value is to be compared with the undamped vibration period, $\tau = 8\times10^{-12}$ s.

The time constant τ_θ for the diffusional displacement of the lobes is sufficiently large to justify the use of the adiabatic potential; that is, the local torsional and bending motions required to remove the repulsive contacts have vibrational periods that are much shorter than τ_θ.

It is possible that the cleft motion involving the active site cleft has a significant effect on the rate constants for substrate binding to lysozyme. The time required for a molecule the size of glucose to diffuse freely 5 Å is $> 5\times10^{-10}$ s at 300 K, and, thus, substantially $> \tau_\theta$. Since opening or closing fluctuations on the order of twice the root mean square value ($\langle\theta^2\rangle^{1/2} \simeq 1.6°$) correspond to displacements of over 1 Å in the outer part of the cleft region, the coupling between substrate binding and the cleft vibrational mode requires a more detailed study taking into account the enzyme–substrate interaction; for example, the motion could be significantly perturbed by the presence of the substrate.

It is important also to note that the lobe motion examined here is so rapid, compared with the transport phenomena usually considered for biopolymers (such as diffusion and sedimentation), that the traditional approximations of incompressible and quasi-steady flow used in determining f have to be questioned. In particular, the Reynolds number, which measures the deviation from quasi-steady flow[10], $=R^2/\eta\tau_\theta$, is 0.1–0.2 (R is the lysozyme radius and η is the kinematic viscosity) and the Mach number, which measures the deviation from incompressible flow[11], $=R/c\tau_\theta$, is 0.1 (c is the speed of sound in water). Thus, the present treatment is valid only as a first approximation. Moreover, a more detailed molecular approach to the solvent behaviour (for example, the water in the cleft) might be appropriate, although computer studies indicate that bulk water responds in a viscous manner to shearing forces on the molecular scale for times greater than 5×10^{-13} s (ref. 12).

The method used and the results obtained for the diffusive behaviour of the hinge-bending mode of lysozyme may be of wider interest in the theory of biopolymers. Active site clefts are found in many enzymes[13] and their opening and closing may be generally involved in the substrate-binding step. Also, the relative displacements of domains or subunits, which are linked by flexible hinges (as in the immunoglobulins[14–16]) or interact only by non-bonded forces (as in the haemoglobin tetramer[17]) are likely to require similar considerations, in which the balance between internal forces and hydrodynamic damping effects are essential. Finally, any experiments designed to observe such motions[18,19] will have to take account of the results obtained here (for example, preliminary calculations indicate that the Raman band associated with the lysozyme bending mode will be damped out in solution, although binding of an inhibitor could lead to underdamped motion and an observable Raman band).

We thank John Deutch for discussions and the NSF and NIH for support. The lysozyme coordinates were provided by R. Diamond.

Structure of bilirubin

THE biological breakdown of haem proceeds through a series of intermediates of which the orange-yellow bile pigment, bilirubin, the chromophore responsible for coloration in the various forms of jaundice, is a key member. In the adult human, for example, erythrocytes have a lifetime of about 3 months and their destruction produces about 300 mg bilirubin each day[1,2]. Although there were some early doubts (arising from the possibility of a cyclisation between the C18 vinyl group and the oxygen function at C19)[3], the gross chemical structure (Fig. 1) for bilirubin has been beyond reasonable dispute for

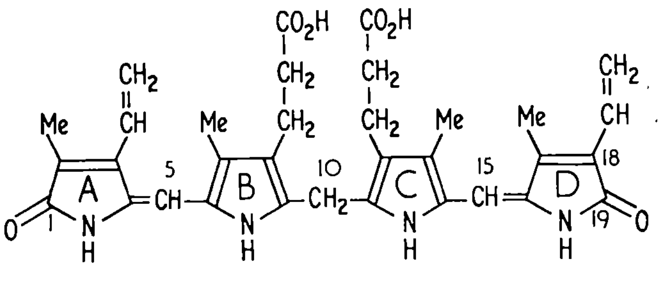

Fig. 1 Gross structure of bilirubin (also called bilirubin IXα).

many years[4]. There remain, however, considerable structural uncertainties with respect to (1) stereochemistry, the geometry around bridges 5 and 15 being unknown, and represented variously as *E* or *Z* in the current literature. (The two configurations, *E* and *Z*, have been recognised in a model pyrromethanone system, however, (see ref. 5 and Fig. 2)); (2) tautomerism, although spectroscopic evidence favours the lactam formula for rings A and D (shown in Fig. 1) over the lactim[6-9]; and (3)

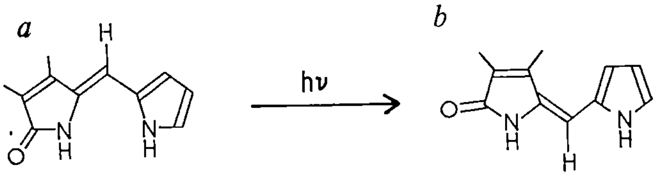

Fig. 2 *a*, *Z* configuration; *b*, *E* configuration.

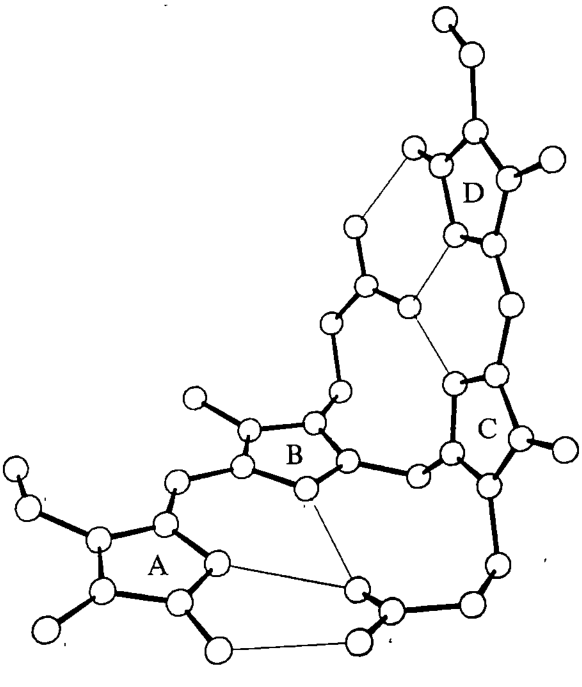
conformation, although several speculations, supported by spectroscopic evidence and model making, are available[10-17]. We report the X-ray analysis of bilirubin—the first such analysis of a naturally occurring linear tetrapyrrole—which shows that bilirubin has the *Z* configuration at the C4–C5 and C15–C16 bonds, and possesses in the crystal a ridge tile conformation with considerable intramolecular hydrogen bonding.

Crystals of bilirubin were grown by allowing diethyl ether to diffuse slowly (isothermal distillation technique, room temperature, dark) into a solution of bilirubin in anhydrous pyridine containing a trace of anhydrous ammonia. Crystals were mounted in glass capillaries in the presence of mother liquor. Crystal data: $C_{33}H_{36}N_4O_6$, molecular weight 584; crystal class triclinic; space group $P\bar{1}$; $a = 19.439$, $b = 11.707$, $c = 15.500$ Å; $\alpha = 97.19°$, $\beta = 100.22°$, $\gamma = 118.20°$; $V = 2{,}969$ Å^3 $\rho_{calc} = 1.31$ g cm^{-3} for $Z = 4$.

Fig. 3 Structure of bilirubin. Hydrogen bonds are indicated by fine lines.



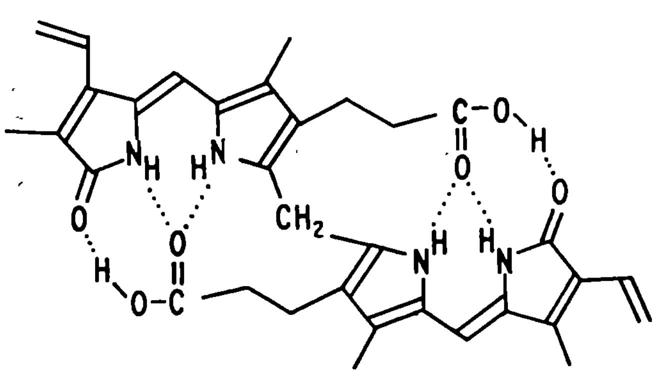


Fig. 4 Structure shown in Fig. 3 in simplified form.

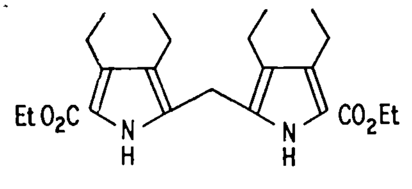
X-ray diffraction patterns recorded from these crystals generally revealed that reflections with odd *h* indices were diffuse, indicating disorder in the *x* direction. (It seems likely that this disorder may have frustrated previous attempts to determine the structure.) The amount of this diffuse scatter varied from crystal to crystal: in some cases the *h*-odd reflections were so diffuse that the triclinic cell seemed to be halved ($a = 9.720$ Å, $Z = 2$). In the crystal selected for detailed examination, the *h*-odd reflections had initially been somewhat diffuse, but had gradually sharpened during maturation (5 weeks, room temperature, dark). The diffraction pattern then contained virtually no diffuse effects.

Two complete sets of data were collected from this crystal: a set of photographic Weissenberg data collected about two axes ([010] and [111]) and scanned using the SRC Microdensitometer Service at Harwell; and a set of counter-data collected using a Nonius CAD4 diffractometer. The photographic set contained 1,323 unique observed reflections (37% of the possible number of unique reflections to a limit of $2\theta(\mathrm{CuK}_\alpha) = 80°$); and, of the 6,095 reflections measured by the diffractometer, only 1,408 obeyed the condition $F_{obs} > 3\sigma F_{obs}$. This serious lack of data arose because the average intensity of the X-ray reflections rapidly decreased with increasing scattering angle: few reflections were found above $2\theta(\mathrm{CuK}_\alpha) = 70°$.

The structure was solved using the diffractometer data and a computer program written by Dr G. M. Sheldrick (Cambridge), which uses a multisolution procedure incorporating negative quartets. Details of this solution will be published elsewhere. Full matrix constrained-bond length refinement of the photographic data (which proved the better set for refinement purposes) with hydrogen atoms in geometrically calculated positions has given $R = 12.5\%$. Because of the small number of observed reflections the structure is not an accurately

Fig. 5 Model compound 3.



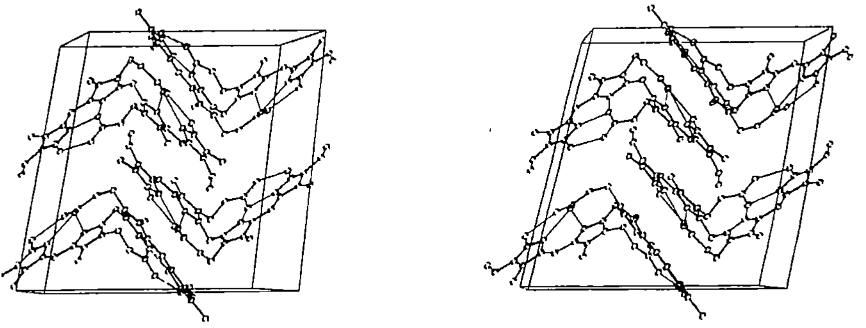


Fig. 6 Packing of bilirubin molecules in the unit cell. The *b* axis is approximately perpendicular to the page, and the *c* axis is horizontal.

determined one: estimated standard deviations of individual bond lengths were generally in the range 0.02–0.05 Å.

The two independent molecules of bilirubin in the asymmetric unit of the structure both have the conformation shown in Fig. 3 and represented in a simplified way in Fig. 4. The molecule takes the form of a ridge tile, the ridge being along the line $C8^1$–C10–$C12^1$. Thus rings A and B lie in one plane, and rings C and D in another, the interplanar angle being about 98°. Six intramolecular hydrogen bonds (two sets, each involving a carboxylic acid group, a pyrrole-imino hydrogen, and a terminal lactam system) stabilise this conformation. The average $N \cdots O$ and $O \cdots O$ distances in these hydrogen bonds are 2.70 and 2.53 Å, respectively. There is no evidence for intermolecular hydrogen bonds: the low solubility of bilirubin in water, which has important biological consequences, can readily be understood in terms of this pattern of hydrogen bonding. Although the hydrogen bonding, and therefore the conformation, may well be altered in very polar solvents (such as dimethylformamide and methanolic ammonia), it seems likely that in less polar solvents (such as chloroform) the conformation with six hydrogen bonds (Fig. 3) will be retained. Unfortunately, the X-ray data are neither sufficiently numerous nor sufficiently accurate to allow determination of the position of the hydrogen atoms in these hydrogen bonds and we are not able to make a clear cut assignment of either the lactam or the lactim formulations.

The X-ray result provides independent proof of the correctness of the gross chemical structure assigned to bilirubin by Fischer *et al.*[4] The stereochemistry about the double bonds at the *meso*-bridges (C5 and C15) is frequently, even in modern work[18,19], represented as *E*. The *Z* configuration (Fig. 4) is now shown to be correct. This type of structure seems to have been first portrayed by Blauer and King[14]; the first discussion in detail was by Kuenzle *et al.*[15].

The observed bond lengths suggest that delocalisation over an individual conjugated system of two pyrrole rings (that is, A+B or C+D) is rather limited since C4–C5 and C15–C16 seem to be essentially double bonds (average 1.30 Å) whereas C5–C6 and C14–C15 resemble single bonds (average 1.48 Å). This supports the view that bilirubin can be regarded as a 2,2′-dipyrrolylmethane (that is, rings B+C) with conjugating substituents at the α positions (compare with the model compound shown in Fig. 5)[18].

The packing of the four bilirubin molecules in the unit cell is shown in Fig. 6. Taking the original analogy further, we now have a stack of ridge tiles interleaved with a similar but inverted stack. Figure 6 suggests an explanation for the diffuse *h*-odd reflections observed in the diffraction patterns of most of our crystals: enantiomeric conformations of bilirubin (related by inversion centres) have very similar ridge tile shapes and the orientation of any ridge tile is virtually unaltered by a rotation of 180° about a direction approximately parallel to the a^* axis (vertical in Fig. 6). On the basis of Fig. 6, it is not difficult to imagine disordered structures which would give an apparent halving of the *a* axis. We have, indeed, collected a third set of data from a disordered crystal, and successfully refined it to $R = 19.7\%$ by assuming that either enantiomer may occupy any molecular site, the packing of the ridge tiles remaining constant.

We thank Dr S. Neidle and Dr J. C. M. Stewart for an earlier attempt on this problem; Dr G. M. Sheldrick (Cambridge) for assistance; Dr M. Elder and his staff at the SRC Microdensitometer Service for measuring the Weissenberg films; and the MRC for financial support.

Deposit-forming by zinc dithiophosphates in base oils during oxidation

A RECENT report by Bird and Galvin[1] has described experiments in which specimens of En 31 steel were immersed in solutions of zinc dialkyldithiophosphates in white oil and either heated over a range of temperatures for 16 h or rubbed for 10 min against a disk of the same material. Electron spectroscopic investigations of the surface films formed at 140 °C showed a product having a zinc–phosphorus–sulphur ratio of 1 : 1 : 0.6, and this ratio was said to be constant over a range of conditions, and was thus assumed to be a decomposition product of the original additive. Zinc phosphate, sulphide and sulphite formations were not observed.

Work in our laboratories on the oxidation stabilities of mineral oil blends of zinc dithiophosphates has revealed similar decomposition residues. The formation of these was, however, found to depend on both the hydrocarbon group in the dithiophosphate and the nature of the base oil. Thus, when a solution of a zinc disecondary alkyl dithiophosphate in a high sulphur content base oil was heated at 120 °C for 164 h and subjected to a stream of dry oxygen, a residue was formed which had a zinc (24.6%)–phosphorus (12.6%)–sulphur (4.5%) ratio of 1.0 : 1.08 : 0.37, which was not too dissimilar from that found at the iron surface by Bird and Galvin[1]. Further, X-ray examination of this residue showed that it was a complex inorganic material in which zinc oxide, sulphide or phosphate was absent. When blends of this additive in low sulphur content mineral oil base fluids were similarly tested this residue was not produced.

Substitution of zinc diprimary alkyl or diaryl dithiophosphates in the above range of base oils failed to produce any residues. It was therefore concluded that the decomposition was a function both of the base oil and the hydrocarbon group in the dithiophosphate. Previous work has suggested[2] that the decomposition of zinc dialkyldithiophosphates is dependent on the number of β-hydrogen atoms attached to the alkyl constituent, and this is fully consistent with the results obtained in our present work.

Haemoglobin type and superovulation in ewes

PANT and Pandey[1] reported that haemoglobin (Hb) type in Binaneri ewes influences the ovulatory response to exogenous gonadotropin (pregnant mare's serum gonadotropin, PMSG). The practical and physiological implications of this finding prompt us to present the results of a study of the relationship between Hb type and ovulatory response to PMSG in parous, non-lactating Welsh Mountain ewes.

Eighty-six ewes were given 1,000, 1,100 or 1,250 IU PMSG (Folligon, Intervet) on day 12 (day 0 is the day of oestrus) of the oestrous cycle and ovulation rate assessed by counting the corpora lutea present at laparotomy on days 2–8 of the subsequent cycle. Hb type was determined by starch gel electrophoresis in a Tris-EDTA borate buffer system, *p*H 8.2 (ref. 2). An analysis of variance of ovulation rate, after transformation of the raw data to $(x + 1)^{\frac{1}{2}}$, showed no significant effect of either Hb type or dose of PMSG. Table 1 shows the mean ovulation rates for Hb type, the data being pooled for dose of PMSG.

A further 16 ewes were given 500 IU PMSG and ovulation rate examined as before. Mean ± s.e. (number of ewes) ovulation rate for AA, BB and AB Hb types were 1.3±0.21 ($n = 6$), 1.6±0.24 ($n = 5$) and 2.2±0.37 ($n = 5$), respectively.

These results argue strongly against a correlation between Hb type and ovulatory response to superovulation in Welsh Mountain ewes. Breed or environmental differences may, however, explain the discrepancy between our results and those of Pant and Pandey[1]. It is clear that Hb type in Welsh Mountain ewes is not a major determinant of the very substantial individual variation in ovulation rate observed after administration of PMSG.

Volcanic triggering of glaciation

IN his latest contribution to the discussion of the links between volcanism and glaciation[1], Bray perpetuates a concept that he proposed in much stronger terms in his two earlier contributions on the same subject[2,3]; namely that there is evidence of "an apparent correlation between major phases of global ice advance and ash eruptions in New Zealand, Japan and southern South America over the past 42,000 yr". This represents a slight modification of his earlier view that there were worldwide 'waves' of volcanic activity that could be correlated with the same ice advances[3].

I am not in a position to comment on the evidence from Japan or New Zealand, but in my opinion the postulation of correlatable episodes of volcanic activity and ice advance in southern South America is extremely unwise, simply because there is so little factual evidence. All such postulations are based on the widely quoted but rarely read work of Auer[4–7]. It is clear from his descriptions that the ash horizons that Auer used in his work, were, in most cases, air-fall ashes from single volcanic eruptions, which may have been quite small. There is no evidence for any massive eruptions, nor for any waves of eruptions. The weakness of the evidence for such waves is compounded by the very small number of published radiocarbon dates; there are probably less than a dozen such dates for volcanic eruptions in the whole of South America.

It is quite correct, as Bray states, that "the possibility that large Pleistocene ice sheets were initially triggered by massive volcanic eruptions is not contradicted by the geological record". But until further data are available from Patagonia, and especially studies of the ash deposits by volcanologists, the evidence from southern South America should not be used either to support or contradict the argument.

BRAY REPLIES—The main point of Francis[1] is that the evidence of late Pleistocene and Holocene volcanism in southern South America[2] is based on a small number of published radiocarbon dates. The reason I originally included the southern South America volcanic data was that both the radiocarbon-dated ashes and the indirectly dated ashes all occurred at the same time as periods of volcanic activity in New Zealand and Japan. This occurrence seemed to be more than coincidental and I suggested that the apparent synchroneity of volcanic ash data from the three areas reinforced the hypothesis that there have been global waves of volcanic acitivity separated by periods of relative quiescence. Since then, South American volcanic ash dates of 9,000, 11,000, 21,000, 22,000–26,000 and 30,000 yr BP have been published[3] which are also coincident with the New Zealand and Japanese volcanic phases. In addition, I have made a preliminary compilation of North American and European volcanic ash dates which show the following distribution (in 1,000 ^{14}C yr b.p.): 0.2–0.4; 0.6–0.8; 1.2–1.3; 1.6–1.8; 2.0–2.6; 2.8; 3.3–3.5; 3.9; 4.4; 5.0; 6.6; 8.3–8.9; 11.3; 11.7–12.0; 13.1; 18.6; 19.7; 28.5; 31.0; 35.0; 39.5–40.5. A comparison of these dates with the New Zealand and Japanese data in Table 1 (ref. 2) shows that all but five dates are synchronous.

Francis' other point, that some of the southern South American eruptions were minor is correct, but not contradictory to the theme of global waves of volcanic eruptions in the late Pleistocene which have influenced climate and perhaps triggered glacial expansion. In any case, if the large mid-continental Northern Hemisphere ice sheets were triggered by massive eruptions[4], then it is likely that these eruptions occurred in the Northern Hemisphere or perhaps the tropical portion of the Southern Hemisphere. It is in these regions that many of the largest Pleistocene eruptions have occurred as shown by the land record and especially by the ash layers in the ocean[5].

Acoustic Bragg diffraction from human tissues

NICHOLAS AND HILL[1] claim to have presented "qualitative evidence that the method can provide objective characterisation of tissue structure", and that the "diffraction phenomenon . . . can be quantitatively related to the specific structure of the type of tissue".

They present their evidence for the objective characterisation in Fig. 4, where three sets of tissue specimens (of unspecified condition) have a statistical significant difference over a portion of the curve, the curve having been obtained by an arbitrary seven-point smoothing. Whereas the first claim of the authors may be true, the second, regarding the specific structure of the type of tissue, is surely not substantiated by the evidence presented. Differentiation between tissue types may have been demonstrated but there is no evidence presented for its relationship to specific structure. Indeed, it is known[2,3] that the Fourier transform of angular correlation is a spatial spectrum, so that the peaks in the spectrum of Nicholas and Hill's Fig. 3 indicate distances of significance in the tissue specimens, presumably related to structure, as the parallel with X-ray diffraction suggests. This potential source of helpful fundamental information has been removed by cavalier smoothing.

In a field characterised by complexity[4], bedevilled by incomplete reporting[5], and yearning for independent confirmation, the significance of the results reported[1] demands more careful and precise consideration.

NICHOLAS AND HILL REPLY—We accept the criticism[1] of our statement[2] that "this diffraction phenomenon . . . can be quantitatively related to the specific structure of the type of tissue". This statement is out of place in the article concerned and should have been omitted: its truth, however, has been confirmed in other publications[3,4]. The other points raised by Chivers are, in our view, unjustified and in some cases inaccurate.

In all of our investigations the tissues were freshly excised, pathologically normal specimens: although this was not stated explicitly it was thought that the implication of comparing pathologically abnormal tissues with the reported results, justified such an omission.

Chivers' criticism[1] of the curves depicted in our original Fig. 4 (ref. 2)—that the range of the seven-point average was not specified—is, we believe, taken in context, not valid. It was stated in our report[2] that the power spectra were calculated using a fast Fourier transform and, as such, they are both finite and discrete. We also stated that the data in each resulting spectrum was averaged over consecutive seven-points. Thus it is that the range of our averaging was over the whole spectrum, as should be obvious if Fig. 4 is compared with Fig. 3.

Finally, Chivers' comments on the validity of our smoothing procedure should be considered in the light of our objective. We clearly stated that "several possible analytical approaches could be taken towards establishing the significance of differences or similarities between such traces and we report here the results of one of these". Useful information has indeed been removed by smoothing, but the advantage gained is the relative ease with which different traces can thus be compared. It is apparent from our Fig. 3 that the peak separation is of the order of 0.01 cycles per degree, which corresponds to a separation in the angular traces of Fig. 2 of approximately 100°; hardly a significant contribution when considering the 50° of trace illustrated. Chivers' comments on this point, although strictly valid, are therefore of limited relevance to the results presented. We did not imply that the peaks in the power spectrum were artefacts, but merely indicated that the picket-fence effect must have led to some degradation of the resulting power spectra.

Our article was intended purely as an introduction to a new and exciting aspect of tissue characterisation and did not claim to be a complete report. It remains our belief, however, that the results we presented are both significant and precisely defined.

Announcing a New Elsevier Journal

JOURNAL OF MECHANICAL WORKING TECHNOLOGY

Editor:
F. W. TRAVIS, Department of Mechanical Engineering, Sunderland Polytechnic, Chester Road, Sunderland SR1 3SD, U.K.

Advisory Board:
J. M. Alexander (London), B. Avitzur (Bethlehem, Pa.), B. N. Cole (Leeds), J. L. Duncan (Hamilton, Ont.), H. Kudo (Yokohama).

Editorial Board:
T. Altan (Columbus, Ohio), P. Avenas (Paris), I. S. Brammar (Clayton, Vict.), H. Conrad (Lexington, Ky.), B. Crossland (Belfast), L. F. Gillemot (Budapest), F. Jovane (Bari), S. P. Keeler (Ecorse, Mich.), K. Kormi (Abadan), P. E. Lagasse (Louvain), H. Lippmann (Munich), A. T. Male (Pittsburgh, Pa.), Z. Marciniak (Warsaw), K. Matsuno (Tokyo), A. H. Meleka (Bristol), T. Nakagawa (Tokyo), K. Osakada (Kobe), P. L. B. Oxley (Kensington, N.S.W.), R. Pearce (Cranfield), H. L. D. Pugh (East Kilbride), G. W. Rowe (Birmingham), M. W. Sagal (Princeton, N.J.), P. O. Strandell (Stockholm), K. Yoshida (Saitama).

Regional Editors:
For Japan - T. Jimma (Tokyo); for North America - J. A. Schey (Waterloo, Ont.).

Industrial relevance will be a prerequisite of papers accepted for publication and all papers will be required to contain a summary describing the industrial significance of the work and the industrial implications arising from the results of the work. There would appear to be great advantage in the mechanical working field, as in many others, in providing an area of common ground for the academics and the industrialists, to better allow the results of the work of the former to be put to the service of the latter, and so that current industrial problems can be clearly identified. The scope will encompass:

(i) Sheet metalforming in all its variations, including blanking and piercing, pressing and deep drawing, stretch forming, fluid and rubber forming and all other related processes, including high-rate forming and explosive welding.
(ii) Bulk forming processes, including hot and cold forging, rolling and extrusion, and developments in these areas such as injection upsetting, ring rolling, rotary forging, hydrostatic extrusion.
(iii) Powder and non-metal forming, including all aspects of the compaction, sintering, forging and extrusion of powder compacts and the forming of polymers.
(iv) In addition to papers arising from within the clearly defined areas described above, the journal will welcome papers concerned with the relevant areas of materials technology and metallurgy, e.g. thermomechanical treatments, annealing schedules, superplastic materials and with other related topics such as lubrication, process economics and "total system" concepts. Likewise, although the journal is primarily concerned with mechanical working (as opposed to cutting or fabrication), papers offering a comparison of production by the latter operations with production by mechanical working, will be eligible for publication.

The subscription price for Volume 1 (1977) is US $57.75/Dfl. 144.00 including postage.

JOURNAL OF MECHANICAL WORKING TECHNOLOGY will initially be published in quarterly issues; the first issue is expected to appear early in 1977. Free sample copies of this new journal will be available from the Publisher.

Journals are automatically sent by air to the USA and Canada at no extra cost and to Japan, Australia and New Zealand with a small additional postal charge.
Manuscripts should be submitted to the Editor. Instructions to Authors are available from the Publisher on request. Fifty reprints will be supplied free of charge. There will be no page charge.

WILEY
INTERSCIENCE

Dynamic Light Scattering: With Applications to Chemistry, Biology and Physics

By **B. J. Berne**, *Columbia University*, and **R. Pecora**, *Stanford University*

An introduction to the principles governing the application of light scattering to problems in chemistry, biology and physics. Stresses the use of light scattering to study the time dependence of thermal fluctuation in fluid systems.

384 pages	March 1976	£16.50 $27.70

Gluconeogenesis: Its Regulation in Mammalian Species

Edited by **R. W. Hanson**, *Temple University, Medical School*, and **M. A. Mehlman**, *National Institute of Health*

Concentrates on the current state of glucose studies in relation to such human problems as the metabolic regulation of a basic biochemical process which has extensive clinical implications.

620 pages	June 1976	£18.60 $35.40

Microbial Transformations of Non-Steroid Cyclic Compounds

By **K. Kieslich**

The book has two aims firstly it gives preparative organic chemists, microbiologists, biochemists, and biotechnologists an introduction to microbial transformations, and secondly it provides a previously non-existent reference work.

1284 pages	June 1976	£42.50 $85.00

Published by Georg Thieme Verlag Stuttgart, and distributed by John Wiley & Sons Ltd.

Elements of Physical Geology

By **J. H. Zumberge**, *University of Nebraska*, and **C. A. Nelson**, *University of Southern California*

A fundamental text that emphasises the tectonic development of oceans, continents, geological processes, resources from the earth, and environmental problems associated with the geologic sciences.

430 pages	March 1976	£7.20 $14.40

Sewage Treatment in Hot Climates

By **D. Mara**, *University of Dundee*

This book presents modern design procedures for those processes such as waste stabilisation ponds which are suitable for the treatment of sewage in hot climates, while at the same time providing a clear description of their physical and biological basis.

184 pages	June 1976	£7.00 $17.00

The Physics and Chemistry of Minerals and Rocks

Edited by **Dr. R. G. J. Strens**, *School of Physics, The University, Newcastle upon Tyne*

The papers in this volume have three main themes: transport properties, including electrical and thermal properties and convection; the dependence of the macroscopic properties of rocks and minerals on their microstructure; and the reactions, properties and structure of minerals, particularly those containing transition metal ions, at high pressure.

714 pages	May 1976	£19.50 $39.75

Radiopharmacy

Edited by **M. Tubis** and **W. Wolf**, both of *University of Southern California, Los Angeles*

An authoritative interdisciplinary text and reference covering the production, preparation, dispensing, and application of radioactive pharmaceuticals.

928 pages	June 1976	£27.65 $49.40

Artificial and Natural Radionuclides in Marine Life

By **V. G. Tsytsugina, N. S. Risik** and **G. E. Lazorenko**, *Academy of Sciences of the Ukranian SSR*

This book presents the results of research into the karyology and radiation cytogenetics of marine fish, the accumulation and distribution of uranium in marine organisms, and the mechanism by which radionuclides are taken up by algae.

122 pages	February 1976	£9.00 $16.65

Published by IPST Keter, and distributed by John Wiley and Sons Ltd.

Handbook of Environmental Education: With International Case Studies

Edited by **R. N. Saveland**, *University of Georgia*

A Handbook of Environmental Education is sponsored by the International Union for the Conservation of Nature (IUCN). It provides information on methods of environmental education and will promote exchange of details of new methods and materials. The book describes the present world position in environmental education and points the way for future developments.

278 pages	June 1976	£7.50 $14.75

Two important books which are now published in paper editions:—

Mycogenetics: An Introduction to the General Genetics of Fungi

By **J. H. Burnett**, *Sibthorpian Professor of Rural Economy and Fellow of St. John's College, Oxford*

This text puts the subject of fungal genetics in a broad context; it provides a genuine introduction starting from the basis of genetics, using familiar cytological and fungal types.

390 pages	May 1975	(cloth) £12.50	$25.60
390 pages	June 1976	(paper) £3.90	$8.60

Environment and Plant Ecology

By **J. R. Etherington**, *University College, Cardiff, Wales*, and **W. Armstrong**, *University of Hull*

This book discusses the relationship between environment and plant physiological function as the underlying explanation for plant ecological behaviour. It attempts to analyse the integrated function of the ecosystem in terms of the multiple interactions between environment and organisms.

390 pages	February 1975	(cloth) £7.75 $15.90
	In Press	(paper) approx. £3.95 $8.10

reviews

Sorting the muddle in the Middle

W. W. Bishop

After the Australopithecines: Stratigraphy, Ecology, and Culture Change in the Middle Pleistocene (World Anthropology.) Edited by Karl W. Butzer and Glynn Ll. Isaac. Pp. xv+911. (Mouton: The Hague and Paris, 1975.) (Distributed in US and Canada by Aldine: Chicago.) Dutch Guilders 127.50.

THIS is a most timely review of work on the span of the Quaternary, dubbed broadly Middle Pleistocene, younger than the australopithecine—bearing strata that have been calibrated by potassium–argon dating. The period is terminated by the advent of the Later Pleistocene which is followed by the lower limit of radiocarbon dating at ±50,000 yr b.p. The continental deposits in 'the middle' represent a period when reliable dates from sources independent of the fossil faunas or artefact assemblages for which an age is sought are extremely scarce. Lithological comparisons are rendered difficult by isolation of the sedimentary basins and the parochial nature of the deposits. Attempts have been made to use climatic change as the vehicle for correlation, but these are largely unsatisfactory until the Last Interglacial (Ipswichian—Eemian) denotes the onset of the Later Pleistocene.

Middle Pleistocene continental stratigraphy in the Old World is therefore a muddle which this volume does a great deal to clarify by isolating the problems and suggesting solutions. I must carp a little at the length, not to say verbosity, of several of the contributions. Thus 21 papers amount to 887 pages, including excellent black and white illustrations. This yields an average of 42 pages per contributor and is the reason that for most students of the Quaternary, from the undergraduate to professorial grade, this volume priced at £26 sterling per copy, sadly seems destined almost solely for library shelves.

With this caveat it must be noted that the papers have been carefully selected by the editors and the scope of the book is broad but balanced. The geological contributions include the record of deep sea cores (Shackleton), the Mediterranean littoral (Butzer), volcanics of the Massif Central (Bout), European Loess stratigraphy (Kukla) and sediments of East Anglia (Gladfelter). On this substratum, interglacial correlation is discussed by Turner, and various aspects of mammalian palaeontology by Kahlke, Janossy, Jaeger and Maglio, respectively.

The lithic industries of Africa, the Middle East and Europe are then placed into the stratigraphic framework by Mary Leakey, Isaac, Deacon, Bar-Yosef, Clark, Freeman and de Lumley. Finally, Pilbeam reviews the fossil evidence for Middle Pleistocene toolmaking hominids.

The volume is an essential reference book for all workers involved in the problems of the Middle Pleistocene. Space does not permit an analysis of the papers beyond noting that they provide the most up-to-date statement in this field. The papers were revised and submitted to the editors after a conference organised in July 1973 by the Wenner–Gren Foundation for Anthropological Research at Burg Wartenstein, Austria.

The meat of the conference and the conclusions arising from this meeting between workers in different disciplines are provided in two short concluding chapters by Butzer on the Geology and Ecology (18pp) and Isaac on the Archaeology and Anthropology (14pp), together with two Appendices containing correlation charts and the recommendations of the meeting.

The most potent wine is kept until the end of the book (pp901–903). It was recommended unanimously by the conference that the lower boundary of the Middle Pleistocene be defined as the junction between the Matuyama Reversed Epoch and the Brunhes Normal Epoch of the palaeomagnetic reversal chronology (that is at about 0.7 Myr). Magnetostratigraphy is still at an early stage of development but the reasons for choosing "this unique global criterion" include the difficulty experienced in trying to apply other methods; its application to both marine and continental sediments; the fact that it can be established in many existing litho-stratigraphic units; and in some areas there is a good fit with the existing local placement of the boundary. The fact that a major change from the current location of the boundary would be necessary in some other areas points the need to use some global parameter.

The proposed upper boundary is the beginning of the marine transgression associated with the onset of the Last Interglacial. Although the inadequacy of this boundary is recognised it seems to be the best available at present. It is to be hoped that those concerned with codes of stratigraphic nomenclature will recognise the value of the proposed palaeomagnetic reversal boundary for the lower limit and that stratigraphic connoisseurs will find this new wine acceptable to the international palate. ☐

W. W. Bishop is Professor and Head of the Department of Geology at Queen Mary College, University of London, UK. His research interests for the past 20 years have centred on the geological background to fossil man in East Africa.

Controversial morphometrics

Uniqueness and Diversity in Human Evolution: Morphometric Studies of Australopithecines. By Charles E. Oxnard. Pp. viii+133. (University of Chicago: Chicago and London, 1975.) £9.00.

IN spite of caveats about the tentative nature of the results in this volume Oxnard has thrown down the gauntlet firmly at the feet of hominid paleontologists Implicitly throughout much of the book, and explicitly in the final chapter, he claims that the Australopithecines (including *Homo habilis* and *'Homo africanus'*) should be formally excluded from any ancestral relationship to man. The basis for this view is that morphometric studies he cites show them not only to be unique but also, in several computer analyses their nearest analogues are orang-utans, specialised Asian apes. The test is whether Oxnard's book contains sufficiently cogent evidence for such a bold view.

The book is in three sections. The first two chapters consist of a theoretical discussion about how best structure and behaviour can be equated, a review of discriminant analysis and methods for displaying the results, and a review of locomotor classification.

The sine–cosine graphs, apart from inducing vertigo, do provide a convenient way of detecting specimens which although projected on the main canonical axes, in morphometric 'reality' lie some distance away. These chapters are heavy going and the writing style, with long and involved sentences, makes the reader's task more difficult.

The middle section is the longest and reviews multivariate morphometric studies on fossil hominid remains of the upper and lower limb girdles, several tali, humeral fragments, metacarpals and a toe bone. This is no place to take issue on technical details of the analyses and Oxnard fairly draws attention to the differences between the way he and other workers interpret the results of canonical analysis.

The last section is an attempt to synthesise the results followed by a discussion of their relevance, and it is here that the greatest controversy lies. It has recently become evident that locomotor assessments of early hominid fossils were bedevilled because modern human bipedalism was considered as the only bipedal arrangement possible: no close affinities to modern bones, no bipedalism Now it is widely recognised that other models may have existed either as precursors of the modern human system or as parallel models which were destined for extinction. Therefore the 'uniqueness' of some of the fossils comes as no surprise

Some of the analyses are claimed to show similarities between fossil hominid fragments and orang-utan bones, implying a close functional rather than a genetic relationship Whereas the statistical implications of these results are exhaustively examined their conversion back into any biological reality is naive. Most of the fossils are fragmentary, and some form only part of functional units of which other parts are preserved. There is no examination of which variables underly the association with the orang-utan, nor is there any attempt at a functional anatomical or biomechanical explanation of why bones that do not look alike behave similarly in the analyses.

Morphometrics is only one of the methods available to hominid paleontologists in their attempts to analyse the functional implications of hominid fossils and unravel the phylogeny of early man. Such studies were at one time properly criticised for eschewing numerical data, but such data taken in isolation do not guarantee relevant results. The evidence presented in this book, based as it is on only a fraction of the available fossil evidence, is too narrow and conceptually limited to play more than a subsidiary role in the very necessary re-evaluation of our ideas about early hominid structure, function and phylogeny.

Oxnard has nonetheless performed a useful service; the controversy produced by this book may well stimulate the necessary, more balanced, research.

Bernard Wood

Bernard Wood is a senior lecturer in the Department of Anatomy at the Middlesex Hospital Medical School, London, UK.

Crystallography

Space Structures: Their Harmony and Counterpoint. By Arthur L. Loeb Pp. xviii+169 (Addison-Wesley: Reading, Massachusetts and London, February 1976.) Cloth $19.50; paper $9.50.

THE structure of ordinary Euclidean space is not as simple as it seems. Just as the complexity of chemistry arises from the Pauli exclusion principle, forbidding two electrons to have the same set of quantum numbers, so much of the complex structure of space arises from what we might call the Democritean exclusion principle—no two atoms may have the same set of (x, y, z, t) space–time quantum numbers (otherwise knots would fall apart).

Arthur Loeb has produced a fascinating book, at about A-level standard, of interest to crystallographers and applied artists working in space. Indeed it is dedicated to all 'philomorphs'—a useful coinage for a spectrum recognisable as including the 'dome-folk' as well as the graph theorists, the cubists and the biomorphologists.

Much of the material is an exposition of the consequences of the Euler-Schläfli relationship (faces+vertices=edges+2), which is at the heart of the phase rule of chemistry and expresses surprisingly powerful constraints—seen at their best in Rhines' and Craig's analysis of grain growth in aluminium (*Metall. Trans.*, **5**, 413–425, 1974). Truncation, stellation and the division of space into Dirichelet domains are also discussed. It is all fairly familiar material, but well-presented without the obscurities with which graph theoreticians so often cloak their theorems, and is thus of wide popular interest.

A. L. Mackay

Dr Mackay is a reader in the Department of Crystallography at Birkbeck College, University of London, UK

Mapping the insect brain

Atlas of an Insect Brain. By Nicholas J. Strausfeld. Pp. xii+214. (71 plates.) (Springer: Berlin and New York, 1976.) $118.10.

THE combination of Nick Strausfeld's scientific knowledge and literary and artistic abilities with a large format and high production standards has resulted in an admirable monograph about the neuroanatomy of the fly's brain, the text of which merits much discussion and suggests many experiments. There is also an abundance of photomicrographs and drawings, of high quality, illustrating those exquisite ramifications of nerve cells which are so beloved by anatomists, but which can cause the physiologist to despair sometimes of ever fully comprehending the workings of the nervous system.

Divided into seven chapters and two appendices, the book begins with a historical survey and proceeds to a description of the major cell types found in the fly's brain together with a classification of neurones based on the shapes of the processes of the nerve cells. The third chapter describes the primary compartments of the brain and the fourth, the coordinate system which gives the *Atlas* a stereotaxic frame of reference. The *Atlas* itself, composed of serial sections of the brain stained by reduced silver methods, forms chapter 6 and this is preceeded by a chapter which considers some quantitative aspects of brain structure. The final chapter shows the forms and dispositions of various neurones as revealed by variations of the Golgi impregnation technique. One appendix gives a multi-author and multi-lingual dictionary of the terminology of the fly's brain, whereas the other provides valuable information about the various histological techniques which can be applied to the insect nervous system

The vast amount of anatomical information presented forms an excellent substratum on which to build future experiments and into which previous physiological and behavioural studies can be integrated. The neuroanatomy and possible function are related in a heuristically worthwhile manner. The book is marred only by the high incidence of uncorrected typographical errors.

John A. Patterson

John Patterson is at Hunter College of the City University of New York, New York.

Poetic self-portrait

Moulds of Understanding: a Pattern of Natural Philosophy. By Joseph Needham. Pp 320. (Allen and Unwin: London, April 1976.) £7.75.

JOSEPH NEEDHAM is so widely known personally that it must be almost impossible to find a detached reviewer for any of his works. I certainly cannot claim to be detached. This collection of essays confirms one's respect even though it may not convert one to his political convictions. It waves a wide arm over the extensive view he has of ethical imperatives, human love and the sense of what is holy. For this is what these essays are about, even though their titles and their content are scientific in origin and substance.

To call the essays *A Pattern of Natural Philosophy* is to stretch the phrase far beyond its traditional use. They have been selected by Gary Werskey, obviously with a bias towards one aspect of Needham's thought—the political—so that they coalesce into a self-portrait, an animated image of a man who has never forgotten his personal beginnings, but never lowers his sights from the destiny of human kind. Cambridge has been his immediate world, described in an essay of 1932 in poetic language which acknowledges his debt to those contemporaries who chose poetry itself as their way of life.

To those who know only his Chinese work or the earlier embryology, it will come as a surprise to find orthodox Christian religion playing a large part in the formation of his outlook both then and now. One might expect, of course, to find early evidence of his well-known socialist convictions, which he has exhibited ever since with both style and humility which others might do well to emulate, whatever their political convictions may be. But it is fascinating to find judgements of great weight being derived from an appreciation of the numinous elements in the traditional church liturgy (the exponents of so-called popularised versions of the long familiar liturgy in both Anglican and Roman churches might learn something to their advantage from what Needham has to say on this subject).

The other essays are grouped under the headings 'Understanding' (all three concerned in some way or other with science and religion), 'Process' (three studies of evolution considered in relation to the organisational interpretation of the Second Law of Thermodynamics), 'Process and Understanding' (three presentations of a view of man, and particularly scientific man, in a future society formed as much by religious enlightenment as by universal socialism) The final essay is a brief attempt to relate the current Chinese experience to what Needham believes are the World's needs.

One could wish to have more of his rebuttal of the fashionable anti-science of today. For, although a socialism we cannot all accept and a religion for which each of us must be free to seek an alternative, give shape to Needham's philosophy, the solid substance of it is universal science, a progressive science whose development in East and West has played a part in the evolution of the human species just as much as any more obviously biological factor.

Apart from anything else it is a most entertaining book to read, because it is full of good humour and courtesy. He treats his reader by the light of one of his favourite Confucian precepts: "Behave to every man as one receiving a great guest". **Frank Greenaway**

Frank Greenaway is Keeper of the Department of Chemistry at the Science Museum, London, UK.

Delight in animal form

Starfish, Jellyfish, and the Order of Life: Issues in Nineteenth-Century Sciences. (Yale Studies in the History of Science and Medicine, Vol. 10.) By Mary P. Winsor, Pp. x+228. (Yale University: New Haven and London, January 1976.) £10 50.

MARY PICKARD WINSOR'S *Starfish, Jellyfish and the Order of Life* is the tenth in a series of works developed from PhD theses. Her original study was of "Issues in the Classification of Radiates"—a history of the decline and fragmentation of a miscellany of lower Invertebrates so collected together by Cuvier as one of the four major divisions of the Animal Kingdom. Professor Winsor sees the need "to follow scientists into the farthest corners of their research, lest the historian should mirror uncritically their own self-portrait" and to "go beyond . . . textbooks, prefaces and essays intended for the general public". This book is successfully illustrated by half-tone offset lithos of the (mostly) lithographic plates. There is a lively interest in, and competent assessment of MacLeay's Quinorianism, the early study of Alternation of Generations by the student priest Michael Sars of Norway and the Dane Johan Japetus Smith Steenstrup. The young, somewhat erratic, but already the probing doubter T. H. Huxley's relationship with W. S. MacLeay is splendidly documented, and there are a whole sequence of discoveries made in the Agassiz Library at Harvard which houses Louis' and his son Alexander's collection of annotated offprints That radial starfish had bilateral larvae, as Johannes Müller observed on Heligoland, was a great trial to Louis. Moreover many illustrations of what varieties of meaning lay behind the description "Natural Classification" are presented with sufficient documentation. A rich and full book for historians of science, of marine biology and those zoologists who may still delight in animal form. Darwin was much more closely involved in this story than Dr Winsor realises. Her attempts in her glossary to explain the Animals to the historians range at times from the naive to the grotesque. The bibliographies are remarkably good The writing has wit and elegance.

Sydney Smith

Sydney Smith is a lecturer in the Department of Zoology at the University of Cambridge, UK.

Books brief

Spectrophotometric Determination of Elements. By Zygmunt Marczenko. Pp. xi+643. (Ellis Horwood: Chichester, February 1976.) £19.50; $42.90.

THIS volume is one of a series on analytical chemistry being produced by Ellis Horwood Ltd It is based on original Polish (1968) and Russian (1971) editions, but it has been extensively revised and up-dated for the English version, and now includes nearly 7,000 references, up to the end of 1973.

Part I (100pp) deals with the general principles of spectrophotometric analysis, a survey of available spectrophotometric reagents, and a discussion of preconcentration and separation procedures for the elements. Part II (520pp) is a thorough and systematic practical guide to the separation and determination of the individual elements.

The theoretical background to analytical spectrophotometry is briefly but adequately described in Section I, but this is essentially a practical handbook. Descriptions of the determinations of individual elements are presented in a standardised format, and these descriptions are written in a clear and easy-to-follow style. Several possible analytical procedures are outlined in all cases, and the listing of useful colorimetric reagents is extremely thorough.

A useful feature of Marczenko's book for readers in Western Europe and the US is that it covers the Russian and East European literature comprehensively, and includes references to some journals not readily accessible.

The book is well produced, seems to be reasonably free from typographical errors, and although not cheap it should be a useful acquisition for analytical laboratories, or individual research workers needing to use spectrophotometry to analyse for a wide range of elements.

G. Davidson

Migration and Homing in Animals. (Zoophysiology and Ecology, Vol. 6.) By Klaus Schmidt-Koenig Pp xii+99 (Springer Berlin and New York, 1975) DM46; $18.90.

THIS book provides a short, useful summary of the literature, but its excessive price (the text is only 77 small pages) will prohibit its intended audience of laymen and students from buying it. In any case the style of the book makes it more suitable for a reader who is already familiar with some of the original work than for a complete novice The writing is on the whole clear, if uninspired; however, the text is often too terse and dogmatic for the uninitiated. For example, on p48, orientation experiments with turtles and lizards are dismissed as "methodologically . . . not convincing" with no further explanation. Similarly on p65, it is stated as fact that clock-shifting experiments with pigeons refute the sun-arc hypothesis, without explaining why. I would have thought that an introductory book should not only present results but also explain, where possible, the reasoning behind their interpretation.

The organisation of the book is taxonomic: the author works through various groups of arthropods and vertebrates, in each case summarising the field evidence on migration and homing before outlining the experimental work aimed at elucidating mechanisms of orientation or navigation The literature survey seems to be accurate and fairly up to date (especially the section on birds—the author's own interest), and the text is well illustrated. Inexplicably, the book ends with an appendix on statistical methods for the analysis of orientation data, which is rather esoteric for an introductory book

John R. Krebs

The Papers of Joseph Henry. Vol. 2: November 1832–December 1835—The Princeton Years. Edited by Nathan Reingold. Pp. xxxix+524. (Smithsonian Institution: Washington, DC, December 1975.) $30.

THIS second volume maintains the high standard and interest of the first (for review, see *Nature*, **242**, 481–482, 1973). It consists of letters from and to—and occasionally about—Joseph Henry during his early years as a professor at Princeton, interspersed with notebook entries describing his work on electromagnetic induction and other topics. At first there is little about his research; but once really settled in Princeton, and having established contacts with men of science in Philadelphia, Henry got down to work once more We see some of the frustrations of working in what was then a provincial situation, far from the great centres of science in Europe; for although Henry anticipated Faraday in some discoveries his work did not quickly become known outside the USA, and it is only as this volume ends that Henry can be seen making contact with physicists in Europe. These volumes, with their very full and helpful footnotes and indices, not only give us an excellent picture of Henry's social and intellectual life, but are particularly valuable also for casting much light on the gradual formation of a scientific community in the US. Historians will turn to these papers to learn not only about Henry, but about men of science and learning, scientific institutions, and technology in his day as well.

David M. Knight

The Food in Your Future: Steps to Abundance By Keith C. Barrons. Pp. 180. (Van Nostrand Reinhold: New York and London, November 1975.) £4.

I TOOK an immediate dislike to Dr Barrons' book, and with each chapter my dislike intensified. It is surely unreasonable of him to collect together as enemies of good nutrition everyone from conservationists to the Pope. He is also out of date. One might expect 'The Great Protein War' to be about the reappraisal by nutritionists of the status of protein in the dietary pantheon. To Dr Barrons it is the basis for future agricultural strategy, although he does not seem to be aware it was an obsolescent one a decade ago.

The final chapter, entitled 'You—A Part of the Solution?', crystallised his view. Future world food needs are to be met by technology, and somebody called Johnny Q. Citizen eating less, wasting less and lobbying congress. Decency, democracy and technology, these three—a strange recipe in an era when the Green Revolution has wilted and political cynicism become a way of life But overall, although Dr Barrons' book is a tedious, stylistic nightmare, his optimism about both the technological fix and the goodness of man is attractive. His claim that agricultural technology has delivered the goods is true. His belief that it would continue to do so is impressive

I don't like the book, but I admire it for the optimism that pervades it. I shall therefore read it again, and I recommend my colleagues to do the same

John Rivers

obituary

Leonard Ary Woodward died on June 5 at the age of 73. After starting at Oxford reading mathematics, he switched to chemistry for his final degree, and then went to Leipzig for his Ph.D. (1931), where he developed his lifelong interest in spectroscopy.

He came back to the UK, and, after working for a time at the DSIR, returned to Oxford in 1939, where he was to remain for the rest of his career. It was here that, during the war, he worked on the separation of uranium isotopes by diffusion, research which was to have such influential results. After the war, though, he resumed his work on Raman spectroscopy, a field to which he made major theoretical and experimental contributions. He was made the Aldrichian Praelector in Chemistry in 1966 and served for many years as Dean and then Vice-Principal of Jesus College.

Victor Ivor Little, reader in experimental physics at Royal Holloway College, University of London, died on May 30 at the age of 56.

On graduating, in 1941 from King's College, London, he was swept up in the war effort, working on radar and the countermeasures to the V1 and V2. This experience confirmed his feelings of the practical importance of physics, an enthusiastic belief he later expressed in some measure by his work, as Chairman of the Examination Board, in restructuring the London 'A' level exams. He was also a brilliant lecturer.

His major scientific work was done in the field of non-linear optics; he early realised the exciting research possibilities of the laser. He was the first to show that standing laser radiation in fluids could create a three-dimensional grating—like a Bragg crystal grating, but on a much larger scale—and, more recently, he contributed to the development of very intense liquid laser sources.

William Bernard Crow, FLS, FZS, FRSM, died on June 28 at the age of 80. In a varied career as biologist and anthropologist, he studied at the Universities of London and Wales, worked for the Ministry of Munitions in the First World War, returned to Cardiff as a lecturer, became head of the department of Biology at Huddersfield Technical College, senior lecturer at the South West Essex Technical College, a lecturer in adult education (Northern Command) during the Second World War, went to the Leicester College of Technology and finally became Head of the Department of Biology at the Davies, Laing and Dick Tutorial College.

His major scientific interest was in morphology. He published much research in this field as well as a textbook, *Contributions to the Principles of Morphology* (1929). His broad outside interests, however, are reflected in the titles of some of his other publications: *Voice and the Vocal Apparatus; The Science of Dreams, A Synopsis of Biology, A History of Magic, Witchcraft and Occultism* and *Occult Properties of Herbs.*

announcements

Appointments

Professor J. E. Enderby to the Chair of Physics at the University of Bristol.
Dr. H. K. Moffatt to the Chair of Applied Mathematics at the University of Bristol.
Professor D. L. Gardner to the Chair of Histopathology at the University of Manchester.
Dr T. B. Grimley and **Dr A. Ledwith** as Professors of Chemistry at the University of Liverpool.

Awards

The EPS Hewlett–Packard Europhysics Prize has been awarded to **Professor Wolfgang Helfrich** of the Freie Universitat, Berlin for work on the physics of Liquid Crystals.

The President of the USA has awarded the National Medal of Science to: **John W. Backus** of San Francisco; **Manson Benedict** of Weston, Massachusetts; **Hans A. Bethe** of Ithaca, New York; **Shiing-Shen Chern** of El Cerrito, California; **George B. Dantzig** of Stanford, California; **Hallowell Davis** of St Louis, Missouri; **Paul Gyorgy** (posthumous award); **Sterling Brown Hendricks** of Silver Spring, Maryland; **Joseph O. Hirschfelder** of Madison, Wisconsin; **William H. Pickering** of Pasadena, California; **Lewis H. Sarett** of Skillman, New Jersey; **Frederick E. Terman,** of Stanford, California, **Orville Alvin Vogel** of Pullman, Washington; **E. Bright Wilson, Jr** of Concord, Massachusetts and **Chien-Shiung Wu** of New York.
The Simon Memorial Prize of the Institute of Physics has been awarded to **Drs D. M. Lee, D. Osheroff** and **R. C. Richardson** for their work on the superfluid phase of ^{3}He.

Meetings

August 21–27, **Birth Defects,** Montreal (Deadline for abstracts: March 1, 1977) (International Birth Defects Congress Ltd, 1275 Mamoroneck Avenue, White Plains, New York 10605).

September 7–10, **Meeting of the European Geophysical Society,** Amsterdam (3rd EGS Meeting (Registration), c/o Vrije Universiteit, de Boelelaan 1105, Amsterdam).

September 13–15, **Solar Energy in Agriculture,** Reading (The Secretary, UK-ISES, The Royal Institution, 21 Albemarle Street, London W1X 4BS).

September 26–28, **Planning for Water and Waste in Hot Countries,** Loughborough (John Pickford, University of Technology, Loughborough, Leics. LE11 3TU, UK).
September 29–October 1, **Comparative Planetology,** College Park (Dr Cyril Ponnamperuma, Laboratory of Chemical Evolution, Department of Chemistry, University of Maryland, College Park, Maryland 20742).
September 30–October 1, **Pacific NW Regional Meeting of the AGU,** Victoria, British Columbia (Deadline for abstracts: August 27) (John T. Weaver, Dept of Physics, University of Victoria, Victoria, B.C., Canada V8W 2Y2).

October 18–20, **Protein Synthesis,**

Bethesda, Maryland (Dr William Merrick, Symposium Director, Building 10, Room 7D-18, NIH, Bethesda, Maryland 20014).

October 28, **Sources for Emission Spectroscopy,** Middlesbrough (The Analytical Division, Chemical Society, Burlington House, London W1V 0BN).

November 17–18, **Ozone/Chlorine Dioxide Oxidation Products of Organic Materials,** Cincinnati (Dr Rip G. Rice, International Ozone Institute, Syracuse University, New York 13210).

November 24, **Synthesis of Cyclic Compounds,** London (The Assistant Secretary, Society of Chemical Industry, 14 Belgrave Square, London SW1 8PS).

November 24, **Applications of Fluorimetry to Chromotography,** Guildford (Mr D. Irish, UV Group, c/o Pye Unicam Ltd, York Street, Cambridge).

December 10, **Observation of Surfaces and Surface Reactions by TEM,** London (Deadline for abstracts to Dr W. M. Stobbs, Cavendish Laboratory, Madingley Road, Cambridge CB3 0ME: November 1) (The Meetings Officer, The Institute of Physics, 47 Belgrave Square, London SW1 8QX).

December 13–15, **Optical Properties and Effects of Atmospheric Aerosols,** Williamsburg, Virgina (Deadline for papers: September 10) (Franklin S. Harris, Jr, MS475, NASA Langley Research Center, Hampton, Virginia 23665).

January 10–14, 1977, **Molecular Cloning of Recombinant DNA** and **Genetic Manipulation as it affects the Cancer Problem,** Miami (Miami Winter Symposia, PO Box 520906, Miami, Florida 33152).

March 29–31, 1977, **Luminescence Processes in Phosphors for Cathode-Ray Tubes and Lamps,** Weybridge, Surrey (Dr P. Greenough, General Electric Co Ltd, Hirst Research Centre, East Lane, Wembley, Middlesex HA9 7PP, UK).

April 25–29, 1977, **Mitosis: Facts and Questions** (Deadline for applications: September 30) (Organising Committee, Kennwort: Mitosis, Institut für Zellforschung, Deutsches Krebsforschungszentrum, PO Box 101949, D-6900 Heidelberg, FRG).

June 1–3, 1977, **Pathobiology of Environmental Pollutants,** University of Connecticut (Deadline for abstracts: January 1, 1977) (George Migaki, D.V.M., Registry of Comparative Pathology, Armed Forces Institute of Pathology, Washington, D.C. 20306).

July 6–8, 1977, **Hot Electrons in Semiconductors,** Denton, Texas (Deadline for abstracts· March 1, 1977) (Dr D. G. Seiler, Physics Dept, North Texas State University, Denton, Texas 76203.)

August 9–19, 1977, **IASPEI/IAVCEI Assembly,** Durham (Dr R. E. Long, IASPEI/IAVCEI Assembly Office, University of Durham, Dept of Geological Sciences, Science Laboratories, South Road, Durham DH1 3LE, UK).

Person to Person

The Superconducting Magnet Research Group at the SRC Rutherford Laboratory now provides superconductor testing facilities for users in industry, universities and other research establishments. Tests on the behaviour of the critical superconducting current will be performed with two superconducting magnets: One of 85-mm bore produces 9 T, while the second gives 10.5 T in a 50-mm bore solenoid. A 15-T magnet will be available later.

The Commission of the European Communities, advised by the Committee on Medical Research and Public Health (CRM/CREST), is sponsoring European Travelling Fellowships for physicians, medical researchers or public health officers who are actively engaged in public health or population studies. Applications to the Commission of the European Communities, Directorate-General Research, Science and Education, XII/C-1, 200, rue de la Loi 1049, Brussels.

There will be no charge for this service Send items (not more than 60 words) to Martin Goldman at the London office. The section will include exchanges of accommodation, personal announcements and scientific queries. We reserve the right to decline material submitted. No commercial transactions.

September 4–9, 1977, **4th International Congress of Photosynthesis,** Reading (Dr J. Coombs, c/o Tate and Lyle Ltd, Group Research and Development, PO Box 68, Reading RG6 2BX, Berks, UK).

September 6–9, 1977, **Plant Cell and Tissue Culture: Principles and Applications,** Columbus, Ohio (Fourth Annual Colloquium, College of Biological Sciences, 484 W. 12th Avenue, The Ohio State University, Columbus, Ohio 43210).

September 19–22, 1977, **Electron Diffraction,** London (The Meetings Officer, The Institute of Physics, 47 Belgrave Square, London SW1 8QX).

September 19–24, 1977, **Availability and Rational Uses of Energy Resources,** Istanbul (The Secretary General of the World Energy Conference, 5 Bury Street, St James's, London SW1Y 6AB, UK).

October 31–November 3, 1977, **Advancing Energy Technology,** Eastbourne, Sussex (Deadline for abstracts: January 3, 1977) (Prof A. Williams, The University of Leeds, Leeds LS2 9JT, UK).

Making it in the Civil Service

IT is now eight years since the Fulton Report on the British Civil Service advocated fairly comprehensive reforms in many aspects of the service, ranging from recruitment policies and staff training to job categorisation. Eight years is not a long period for an organisation with such inbuilt momentum as the Civil Service, but the Select Committee on Expenditure of the House of Commons deems it time to have a look at the way reform has been progressing Last week was the turn of the Institution of Professional Civil Servants (IPCS), the body which represents professional, technical and scientific civil servants, to give its first evidence.

This past year hasn't been a particularly good one for the Civil Service. It has been the victim of a fairly regular stream of what the IPCS called "unfair attacks" and what others might call penetrating questioning of its role; the mutterings—and much more that hasn't surfaced—can be fairly clearly associated with the privileged position in which the civil servant finds him or herself at the moment. There has always, of course, been grumbling about job security and its dulling effect, the complaints have recently been about the way in which salaries and pension rights in the public sector seem to have become so much more favourable than those in the private sector, in which there is little job security.

It is, then, inevitable that what civil servants say about themselves and their situation is looked at in a rather hawk-eyed way; the IPCS at least didn't fall into the trap of telling the committee its members were underpaid. But they are, it was claimed, underprivileged —the words "second class" kept cropping up. In short, the IPCS believes there has not been a proper commitment by the Civil Service Department to implementing Fulton recommendations on removing vertical barriers between different classes or categories, notably the Administrative, Professional and Scientific categories At the very top this has been done, at least formally, though whether it means much is questionable. What the IPCS would like to see is the removal of category labels much further down the system, in the hopes that this would allow policy-making and management prospects to open up at all levels for those who are at present confined by being 'professionals' or scientific'.

For all the IPCS's professed admiration for the administrators, this move is a thinly disguised assault on the administrative citadel wherein, in the spirit of the genteel class warfare that is alleged to go on in the Civil Service, are housed the first-class characters who really have all the power and make all the decisions. Scientists, of course, run their own laboratories, so the call by the IPCS must be seen as an attempt to broaden the stage on which their members can operate.

There are problems The first is that the IPCS, in making the point elsewhere in their submission that the distinction between generalists (that is, administrators) and specialists is artificial, acknowledges that administration contains a range of specialisms such as finance, accounts, contracts, personnel and computers and indeed that "public administration itself is a specialism". If we are all specialists now, the administrators will prove as defensive about opening up their ranks as would scientists about having administrators join them in some scientific venture.

The second problem is the sort of person who might be helped by such schemes. Outstanding professionals find their way to the top and go where they want to go without the need for much outside help. There is, however, a much greater number of what might be called the solid and reliable, and a real and as yet unsolved difficulty inherent in Civil Service use of professionals is how to prevent the solid and reliable from becoming disheartened, maybe as early as their mid-thirties, at the lack of prospects. But are there large numbers of jobs going begging in the administration categories or are there posts that ought to be created to allow these people to spread their wings? There are, after all, many solid and reliable administrators who are also likely to be in pursuit of such posts. The challenge then, is to the IPCS to do some extensive research and provide the Select Committee with some formidable evidence, down to chapter and verse, that there really are, as Fulton asserted, a significant number of jobs in the service, requiring both technical and managerial ability, which could be filled by technical people and which at present are not.

We have in the past advocated more radical approaches to the problem, particularly the golden handshake and enhanced mobility into and out of the service, but we believe that a detailed case is worth making for a different sort of solution. ☐

Tracking nuclear decisions (1)

JET: will it ever get started?

Chris Sherwell traces the tortuous course of a decision the EEC cannot take

WHEN, on the last day of last month, Mr Gaston Thorn relinquished the presidency of the EEC's Council of Ministers, he was frustrated and dissatisfied. The inertia paralysing the Community, he indicated, could be relieved by a move in the Council away from unanimous voting. It was the echo of a view expressed in many quarters many times before, though not perhaps by so senior or so obviously political a personage as the Luxembourg Prime Minister.

The widely-praised Heads of Government meeting two weeks later provided a much-needed boost for the Community. But its upper echelons are plainly troubled. Herr Guido Brunner, European Commissioner for Research, gave vent to his feelings when he visited London earlier last month. He too spoke of majority voting. But he had a specific matter on his mind—the Joint European Torus, JET. JET represents the next stage in the Community's effort to harness the power of nuclear fusion (see box, page 341). It also offers a remarkably fine illustration of what torments men like Gaston Thorn and Guido Brunner, not to mention scores of Community officials and countless people in the nine member states.

The immediate problem is that the Nine cannot agree to go ahead with the project without deciding on where it should be sited. The latest effort, at last week's meeting of the Council of Foreign Ministers, produced a piece of diplomatic mystification: the European Commission had asked for a decision of principle, before the summer recess, on the building of JET. This, it was thought, would facilitate a decision on the site when the Council of Research Ministers meets in October, and thus help prevent a split in the JET design team.

But the delays which have brought matters to their sorry pass were not ended. The Foreign Ministers watered down the Commission proposal, deciding merely to "adopt a favourable opinion on the rapid undertaking of the enterprise", which they thought should be put before the next Council of Research Ministers meeting for a decision. In short, the ball was put right back where it had been before, in the Research Ministers' court, and without any further movement over the site. This means that when a decision on where to site JET comes in October—if it comes then—a full year will have been lost on a programme in which time is regarded as being of major importance.

What makes things worse, however, is that there must be some doubt attached to the prospect of an October decision, for the precedents are truly inauspicious.

Euratom infusion

The Community's Fusion Programme, under the overall directorship of Signor Donato Palumbo of Italy, has its origins in the 1950s with the formation of Euratom and the EEC itself. Two five-year programmes were implemented between 1958 and 1967; work continued on a year-to-year basis between 1968 and 1970, when a third five-year programme was agreed. Once it was appreciated that, with the progress being made in fusion research, plans to build a large Tokamak—JET—could only be realised through an EEC-wide effort, a European design team of more than 50 members was brought together. The overall EEC fusion effort was coordinated by Euratom through a complex bureaucratic web of steering committees; JET is its centrepiece.

The laboratories at Culham, near Oxford, were offered as a location for the JET team. They form the United Kingdom Atomic Energy Authority's fusion research centre and, in the words of a Culham man, were offered "without prejudice to the final decision on the site for JET", which it was expected would be made by the end of 1975, when the original two-year contracts for the team's members expired.

All the advice the European Commission received in its wide consultations on the project acknowledged the risk attached to it, but the response was positive and members of the European Parliament gave their backing. So, with progress on the conceptual design of JET—a design which received additional backing at international meetings—the new overall plan for fusion research for the next five-year period (1976–1980) was put forward.

The total fusion effort for the period was put at 246 million units of account (mua). The estimated cost of the JET project was 135 mua—£80 million; the Community as a collective accepted responsibility for 80% of this (108 mua); member states would contribute the balance in proportion to GNP. Of the £80 million, some 21½% would go on the JET device itself, 23½% on manpower, 17% on power supplies; the rest was for buildings (11½%), auxiliary systems (6¼%), the operating budget (6½%), instrumentation (5¼%) and contingencies.

As long as all these details were busily working their way up through committees towards the key arena of the Council of Research Ministers, and the customary problems involved in setting up a Council meeting persisted, a quick decision was not possible. With the putative deadline of 1976 looming closer, efforts were redoubled to secure a commitment on JET from the Council. But the Council of Finance Ministers, meeting first, would not decide on a financial allocation for a project on which a decision had yet to be taken. The Commission, facing the prospect of a sanctioned project not going ahead in the absence of a budget, obtained money to tide things over from the European Parliament under a special provision. It was a foretaste of the degree to which the Commission's ingenuity would be taxed. The Research Ministers finally met in December. And at that point the trouble really started.

See the sites

The meeting provided the first real indication that the Commission had completely underestimated the political problems involved. It emerged that Britain, with Culham, France, with Cadarache, West Germany, with Garching and Julich, and Belgium, with Mol, all thought their own sites were suitable for JET. Italy, pushing for the Italian establishment of the Community's Joint Research Centre (JRC) at Ispra, refused to approve the whole 1976–1980 research programme in thermonuclear fusion and plasma physics unless a decision on JET's site was taken at the same time. No decision was taken, the programme was not approved, and the meeting broke up. Ahead of the next meeting, set for February, the Council's Atomic Questions Group exchanged views, and the Committee of Permanent Representatives examined its report, without taking anything further.

The difficulties were quickly compounded. Italy, having sought bilateral talks on the matter, failed to persuade Britain to support Ispra, and the British goverment started disclosing its own pro-Culham position publicly in the House of Lords. West Germany reasserted its willingness to take on 15% of the project's overall costs if Jülich or Garching was chosen as the site. Researchers at Culham reportedly began writing to Brussels urging an early decision.

That was not all. In late January, the Commission released the results of its

Confusion profusion: the arguments about the site

"If JET goes to Ispra, it is better that it does not get done at all." **Senior official, Culham fusion research centre.**

"If JET does not go to Ispra, it is not worth doing." **Senior official, European Commission.**

Culham and Ispra are probably the two main contending sites for the JET project. France's involvement in the Superphénix fast breeder is thought to make its bid for Cadarache more an attempt to score political points than a determined effort to win the project. Garching's candidacy is regarded with more severe respect and remains a powerful contender, but it has not planned to take JET in the way that Culham, with the design team, has done.

Only Italy defends Ispra with vigour; apart from Britain, though, none of the Nine openly backs Culham. The arguments concerning all the sites are finely balanced. The technical assessment of the Commission's site committee looked at the alternatives in terms of power supplies, infrastructure, safety and social facilities. On each criterion each site was fair to excellent: no site was best on all aspects, but all sites were suitable for the construction of JET.

It was chiefly on the power supply and social aspects that the Commission originally chose Ispra. It is fed directly from a conveniently located power supply; it already has an adequate infrastructure and social facilities, including an international school; it has staff already available for the project; and it has the equipment and expertise needed for the heavy engineering involved in handling large-scale plant and materials.

But the arguments in favour of Ispra now, if they didn't do so before, traverse broader territory than this. Perhaps the most potent actually comes from its supporters in the Commission itself, representing the collective Community interest. It is in the best long term Community interests, the argument goes, that the project be pursued as a Community effort. The project, particularly as it is largely Community financed, should therefore preferably be sited at a Community centre. And the premier establishment of the Community's Joint Research Centre (JRC)—indeed the only one capable of handling the project—is at Ispra, in northern Italy.

The argument goes further, into psychology. Ispra, it says, has been dogged by uncertainty in recent years, and the latest programme of research is due to end this year. Although much of the multi-annual programme planned for 1977–80 will be conducted at Ispra, JET would insure its own future as the Community's leading research centre, which might in turn halt the fragmentation of research. Siting the project at Ispra would at the same time compensate Italy's loss by its exclusion from the UK–West Germany–Netherlands Gas Centrifuge Treaty for Uranium Enrichment.

The case against Ispra has come mainly from Britain, a point that has not gone unnoticed amongst senior Community officials. It turns most importantly on the project's chances of success. The chief scientist at the Energy Department, Dr Walter Marshall, not known as a fusion enthusiast, puts it this way: there is "an appreciable chance" that the project will fail, not because it is badly conceived but because it is so ambitious; it should not therefore go to any site which "lacks experience and know-how in solving the plasma physics problems that are bound to arise." Ispra's fusion experience (often described in Britain as "modest") is not great.

Marshall does think that the project should go ahead. But he judges that other sites, including Culham, satisfy his criterion in a way that Ispra does not. Moreover, he is "very much frightened" that if the counter-arguments about symbols of European collaboration win the day, then the project really will be a failure. If he could be persuaded of the scientific capability of a site, he has said, he would recommend it, but this he says has not been done; there had only been a "review of the characteristics" of the sites.

The implication is that a site (like Ispra) ought not to be chosen for an additional reason—to solve an administrative problem. Others allege in addition that Ispra's resources, and its capacity to get them, are not great. It has even been said that scientists would be reluctant to work at Ispra, especially as it has not managed a large project before. Past labour problems add to its reported reputation for mismanagement—a reputation also pinned on the Commission, whose allegedly closed mind over the matter has proved a sore point in Britain. That Ispra could prove to be the most expensive site, which is also suggested, is a point that Guido Brunner, European Research Commissioner, disputes. He says the differences in cost between the various sites is no more than 10%.

The arguments in favour of Culham are partly the arguments against Ispra reversed. Culham, it is said, is already a centre of excellence in fusion, commanding large experience and resources, possessing a good "track record" and making progress that is more than comparable with the USA and USSR. Furthermore, it not only fits the bill on such essential criteria as power supplies, it also has the land ready to take JET and, most importantly, a team already settled there to continue the work it has successfully begun. Such continuity, it is argued, ensures the maximum chances of success. Culham, says Alex Eadie, junior minister at the Energy Department, is the best site on technical, scientific and operational grounds. But another reason offered in support of Culham is more nakedly political: namely, that there is as yet no high technology Community project in Britain. This gives it some sort of advantage over Garching, for example, since West Germany has the Patent Office and the European Molecular Biology Organisation.

Arguments against Culham throw doubts on its back-up facilities, on the lack of a school and so on. Beyond these, though, it is said that expertise in fusion is not really relevant for much of the project's duration, since most of the time would be spent in JET's construction; moreover, any problems that arose would probably be too big for any one laboratory to solve alone. More subtle arguments point to the recent experience with the Dragon high temperature reactor project at Winfrith, Dorset, during which Britain attracted from many European countries criticism of its foot-dragging, if not obstructionist, tactics over the project's fate.

The site stand-off preventing JET's take-off is thus a complicated affair. It has tried the patience of the contending host countries, whose Community spirit is already under scrutiny. It has aggravated the frustrations of the smaller member states who these days have enough reason to feel left out in the cold. And it has threatened the role of the Commission, whose ambiguous position has rendered its influence and authority more tenuous than it might otherwise have been. The Community's worst enemies couldn't ask for more. ☐

independent siting committee. It had not previously pushed any one site; now it came down in favour of Ispra. Moreover, it delivered its view as a communication instead of as a "proposed decision" for the Council, as was customary; this it defended by saying that only the whole project, including the matter of the site, and not the site alone, involved a decision. The boundaries of the Commission's competence to decide on the matter thus became an issue as well.

The February 24 meeting of the Research Council began by avoiding an immediate break-up over the site. British, French and West German pressure wrought a reduction in the total fusion budget from 246 mua to 232 mua, thereby leaving less for the fusion research not directly related to JET. This, however, entailed the abandonment by Italy of the position under which she had linked a decision on the site with approval of other fusion research programmes; but she still insisted, successfully, that the meeting sanction just one year's expenditure—20.8 mua. But that at least meant the programme could go ahead.

When it came to discussions of the site, however, none of the contending countries withdrew their applications to host the project. After hours of debate, the Ministers failed even to agree on a method for deciding where JET should go. They rejected a proposal that the Commission, as the competent authority, should decide, and also the idea of an exhaustive ballot among themselves. Eventually, applying an old adage ("When in doubt, never commit yourself, committee yourself"), they agreed to call for a new report on the alternative sites. This was to come from a special committee established by the meeting, the Consultative Committee for the Fusion Programme, consisting of a representative from each of the Nine, a Commission representative and representatives from third countries involved in the fusion programme. It would report on comparative technical merits in May, in time for the next Council meeting, set for mid-June.

Some states openly regarded this as a waste of time; Italy hoped that the question of the site would not be reopened. For the Commission, Brunner still claimed the matter was within its competence: he couldn't see what new light would be thrown on the problem by more technical assessments; only something very dramatic could change the Commission's mind. For all its immobility though, the Commission did not apparently intend to try and impose its choice.

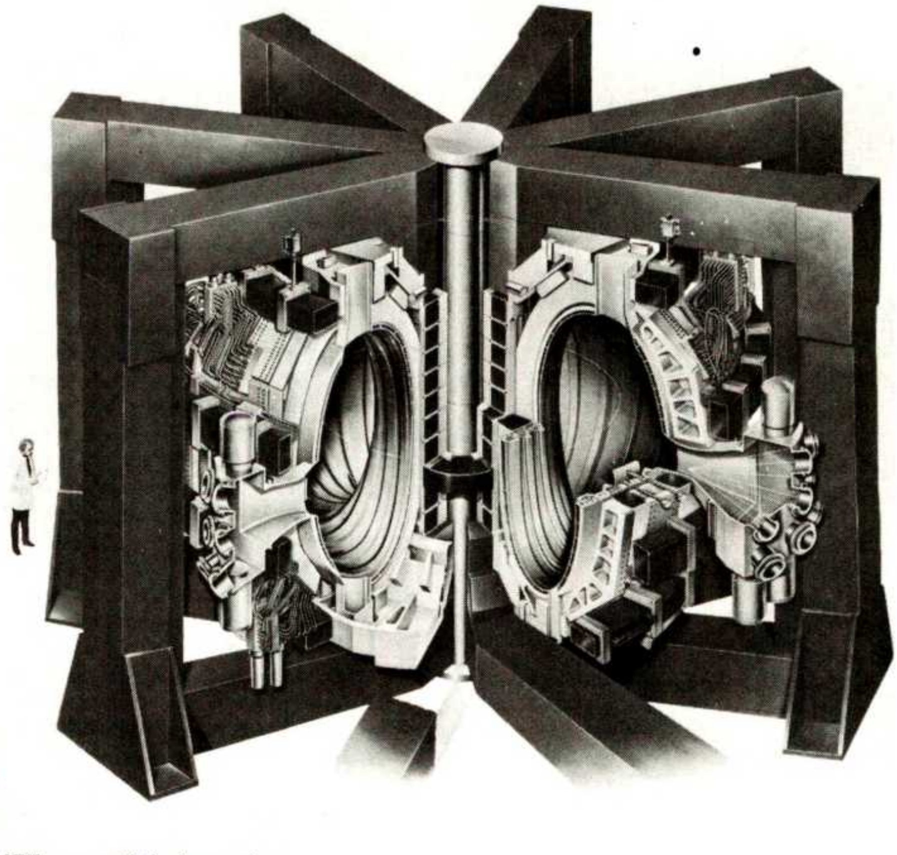
By now the threat of rising costs was starting to make speed vital; so too was the ground being lost against the USA and USSR; and the team's declining morale, with the increasing prospect of its break-up in spite of a renegotiation of contracts for a six-month extension. But the rest of the fusion programme was assured for a year; and the new committee had also been accorded a general role in respect of the whole programme, which would help its development. All the same, it looked as though the JET problem was so intractable that it would need resolution by the Council of Foreign Ministers or by the nine Heads of Govenrment—a suggestion which the Dutch had by now put forward.

Fight goes on

With the fighting now well developed, two sites were withdrawn—Mol in Belgium and Jülich in West Germany. Reports of job offers from the USA for members of the design team grew, and a few actually left the project. Britain made a climb-down more difficult when she put her view favouring Culham to the House of Commons in March. The "common front" of trade unions at Ispra called a press conference later that month to urge a decision in favour of Ispra and of a Europe independent in energy and science.

The Consultative Committee, at its first meeting in early April, received an independent report on JET's design details from the UK-based Risley group. This confirmed the team's plans, and the Committee recommended that a decision to build was needed forthwith. It recommended too the immediate creation of a management committee for JET together with a strengthened fusion directorate at the Commission. But the Committee also heard estimates that certain costs had drifted upwards, making overall costs some 23 mua greater than the original 135 mua. Another meeting was set for mid-May to discuss a final report following consultations with the JET team over the Risley report. Incredibly, the Committee did not discuss the matter of the site.

Neither was it discussed at the Council of Foreign Ministers meeting in early May, even though Luxembourg, backed by Belgium and Holland, was trying to put it on the agenda. In fact the agenda was already too full. The lack of movement encouraged some European parliamentarians to speak out volubly, questioning whether European collaboration was possible, and whether latest estimates of Europe's future energy requirements didn't tilt the balance one way or the other. In mid-May Brunner signed the draft agreement on Sweden's participation in the fusion programme; negotiations with Switzerland, something which with the Swedish precedent was not expected to take long, were almost



EEC picture

JET : an artist's impression

ready to commence and soon received the go-ahead. The pace was quickening again.

The Italian general election, set for June 20, just two days after the crucial Council of Research Ministers meeting, now intervened. With the prospect of an upset result producing an Italian government which might disagree with any decision taken by the Council, it began to seem pointless having the meeting at all. At Italy's request it was decided that the meeting would not take place. The Dutch proposed a meeting for mid-July; this was agreed in principle. As late as the first week of June, Brunner was expressing the hope that a decision on the site would be taken at such a meeting. Days later it was clear that no meeting was likely before the summer recesss. No early decision on the site would therefore be possible unless the idea of a determination by the nine Foreign Ministers was resuscitated.

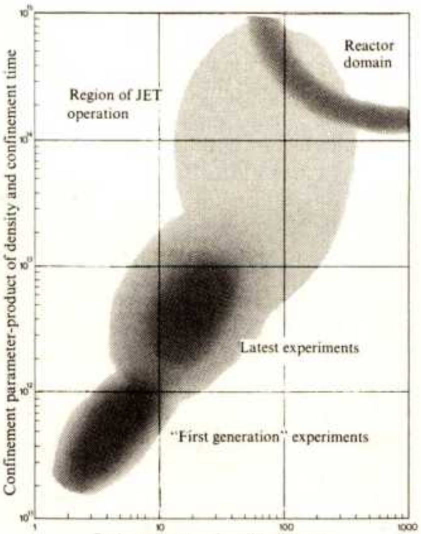
The Commission had itself come round to this view. It had also been busy on the central problem of the site: by the end of May it had finished preparing additional information for the Council of Research Ministers in order to make the choice easier. This included, first of all, the news that consultations concerning the higher cost estimates had produced agreement that the extra amounts involved were in fact negligible, at about 5 mua. The Commission also contended that insufficient emphasis had been attached previously to the matter of the power supply: if JET was to be fed directly, Ispra, fed by a line from a thermal and a hydroelectric station, possessed another advantage over other sites. Finally, the Commission stressed the costs of delay. Increasingly frustrated, it therefore argued that no attempt to justify a further delay could be based on arguments of a scientific, technical, financial or adminstrative nature.

With no prospect of a meeting of the Council of Research Ministers before mid-October, and the need for decisions growing more desperate, it was now time to change tack. At the end of June, therefore, and at the request of the Dutch (who were about to take over the Council presidencies), the nine Foreign Ministers had a brief exchange on the siting of JET. The Commission was now looking for a decision of principle on the building of JET before the recess in order at least to supply more adhesive to the JET team than the second six-month extension to contracts just put together.

The matter was put on the agenda of the Heads of Government meeting on July 12. The boost they were busy giving to the Community did not extend as far as JET, however, and it was not discussed. Assurances were given that last week's Foreign Ministers meeting would deal with the matter in some detail though it was not on the official agenda. Nothing approaching progress which would satisfy the Commission resulted. The recess is now imminent. October is two more months away.

JET lag importance

The persistent procrastination, far from indicating that the EEC perceives the JET decision as having comparatively minor consequence, is precisely a reflection of the project's importance. JET is a major Community research project, perhaps the first of its type,



Fusion research: where it's at

FUSION research, which seeks to harness the energy released when nuclei of light elements are brought together to form heavier ones, aims ultimately to design a practical fusion reactor that produces electricity economically. The aim is thus to approach more closely the conditions at which the energy released from the deuterium–tritium reaction (the fusion reaction selected as the most promising of several possibilities) is greater than that expended both in heating the plasma in which the reaction occurs, and in losses.

The immediate goals are therefore to find ways of heating the plasma to the necessary temperature, and to confine that plasma for the necessary time. Apart from the passage of electric current, methods of heating currently being investigated include the use of intense laser beams and the use of beams of high-energy neutralised particles originally produced from an ion source. The method of confinement in a doughnut (torus) shape uses a helical magnetic field. This is made up of two components, a toroidal field produced by large external coils, and a poloidal field which, in the case of tokamaks like jet, is produced by a toroidal current in the plasma.

Tokamaks, however, represent only one of three classes of toroidal device now being examined for their confinement capabilities. These are in fact distinguished by the way the poloidal field is produced:

(a) **Tokamaks,** and **Reversed-field Pinches** (high beta systems). In tokamaks the toroidal field is greater than the poloidal field; in reversed-field pinches the two are about the same and the toroidal field is reversed in the outer regions of the plasma. In both, the plasma current which heats the plasma also creates the poloidal field.

(b) **Stellarators** (low beta systems). In this class of device, currents in helical conductors wrapped round the torus and outside the plasma produce the field which, with the toroidal field, confines the plasma.

(c) **Toroidal multipole.** Here the poloidal field is produced by a steady current flowing in a levitated superconducting ring located in the centre of the vacuum chamber with the plasma.

Magnetic confinement produces a plasma of modest density, so the confinement time necessary to boost the "confinement parameter" (density x confinement time) is longer compared to a plasma of very high density.

Obtaining a high-density plasma is the aim of inertial confinement, in which the necessary time of confinement is actually shorter than the period in which the particles will escape from the reacting zone. This confinement is achieved by irradiation with high-power laser beams. Extremely intense, short laser pulses bombard a solid deuterium–tritium fuel pellet, causing it to turn into a plasma so hot and so compressed that fusion reactions yield a surplus of energy before the pellet decays as a result of expansion. The method does not simply offer the possibility of avoiding the difficulties of using magnetic fields for confinement; it also offers the theoretical possibility of using a series of laser pulses to cause a succession of these explosions.

The selling of fusion power has turned largely on its ostensible advantages in respect of the fuel it uses and its safety. But the supply of lithium (used to produce tritium) is at least not certain, and neutron production in the reactor has the potential to make the reactor materials highly radioactive. There are other problems relating to possible lithium fires and tritium leakage. And since fusion is so patently a prospect for the distant future, guesses about its economics remain exactly that—all of which makes any choice between fusion and fast-breeder fission, if such a choice exists, correspondingly more difficult to make.

JET is effectively a "third generation" tokamak device. Its equivalent in the USSR is known as T–20, in the USA as TFTR, and in Japan as JT–60. "Second generation" tokamaks include DITE at Culham, T–10 in the USSR and PLT in the USA.

For the post-Jet period, the following sort of sequence is imagined:

1980–1985	Tritium burning experiment
1985–1990	Experimental reactor
1990–2000	Prototype
2000–2010	Demonstration

Other common facilities envisaged over this period include a material testing facility and a superconducting magnet assembly.

perhaps the first of many. Money is to be spent, and there are contracts to be had. That means large and powerful interests are involved, not just on both sides of various sectors of manufacturing industry, but within state administrations and institutions and within the EEC's own administrative structures.

With so much at stake, the decision on the site had to become the prime focus of interest. To win JET was (and is) to win fusion in Europe. There are some, notably the Italians, who have claimed that JET, being just one part of an even larger overall programme, would not by its location determine where the European centre of excellence would lie. The argument is that the other projects to come would be sited elsewhere. But no one seems to believe it. Whoever wins JET, most are saying, acquires the huge investment that goes with it, the location for future reactors and the investment that goes with them too; whatever the spreading of the contracts, and no matter what clauses are inserted as safeguards into the agreement, the host country is said to have the advantage. That country's cap acquires the fusion feather—and the reputation, the prestige and the national pride. It seems rather a lot to hang on a unanimous decision of a group of Research Ministers.

The Commission, in the form of Signor Palumbo, finds all this a trifle exaggerated. He claims that the press has "transformed a technical and limited problem into one of prestige", and points out that there is another aspect of the problem beyond the interest of a country in having JET. This is the interest in having JET at the best possible site. Suppose, he says, a super-intelligent, objective man could identify both the best and the worst sites among those competing for JET. The difference between the value of the best site and the value of the worst site, he argues, is hugely outweighed by the damage done by a one-year delay to the JET project and to the common fusion programme. Indeed, all sites could host JET. The choice of the site, while blocking everything, is thus irrelevant, he claims, and he goes on the repeat the growing view—that if the Commission's choice is not approved, the Council of Ministers must give up its jealously guarded unanimity rule to come to a definite choice.

He certainly seems to be right about the urgency. Existing programmes for medium scale devices at Jülich, Cadarache, Garching and Culham all depend technically and financially on a decision on the site for JET. Delay is discouraging the JET staff even further, making it difficult to maintain the team and impossible to expand it. It has been possible to farm out some small study contracts relating to the project, but money available for this is almost totally spent, and a Council decision is required for more. Plans for buildings cannot be finalised, of course, buildings cannot be built, and orders cannot be placed for equipment that might be unsuitable or superfluous if another site is chosen. As the Commission has itself put it, any decision concerning further work without the site being known would be unrealistic, perhaps dangerous and almost certainly expensive.

Just how expensive is perhaps not appreciated. The delay, apart from jeopardising the project itself and the whole fusion programme, may now be jeopardising the spirit of cooperation that exists in Europe. It may also be damaging the credibility of the Community's decision-making procedures among other international organisations and in other non-EEC countries. Most importantly, it may soon start affecting Europe's own public, whose tacit support for the expenditure of so much money is less likely if the persistent delays (and the corresponding progress of the Americans and Russians) make the project seem pointless.

Optimists point out that a decision in October would mean that a delay of only a year had been incurred. No decision in October might mean leaving the decision as late as the next Heads of Government meeting in The Hague in December. But the viability of the whole project may have been brought into question by that time: as Herr Schuster, Director General at DG XII in Brussels, puts it, if there is no decision by then, the project is dead in an EEC framework. Yet it is Schuster who freely acknowledges that the German elections later this year might intervene, Italian-style.

An alternative has already been mooted: that JET becomes a British–French–German operation. But a British minister has already said Britain is committed to European collaboration. And the Commission heaps derision on the idea. Alternative combinations, it is said, are "futurology": the three countries can't agree among themselves, and JET is anyway "owned 100%," by the Commission. But political facts could conceivably change things. The Community is being brought into disrepute. Fusion itself is being brought into disrepute. Unless something is done, a Community fusion project might therefore be a forlorn hope. □

Tracking nuclear decisions (2)

FBR: will it ever be stopped?

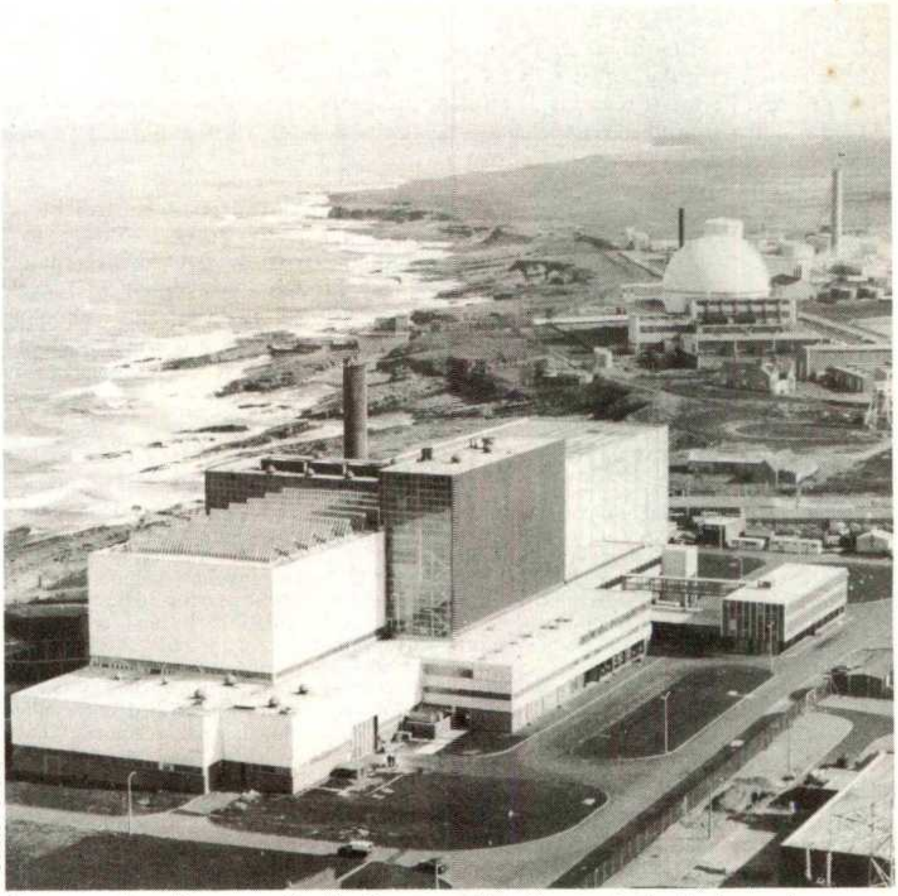
Allan Piper looks at the arguments concerning the fast breeder reactor

THE UK Energy Secretary, Anthony Wedgwood Benn, decides this autumn whether Britain will build a commercial scale fast breeder reactor. It is a measure of the task he faces that, from one viewpoint, the FBR is an elegant and timely solution to immediately foreseeable energy problems, while from another it looks like potentially the most disastrous technological development imaginable. The dichotomy is simply explained: the reactor's most attractive advantage—an ability to create its own fuel—is precisely its major disadvantage. For the fuel so created is plutonium, the stuff of nuclear weaponry.

Mr Benn is fully aware of the enormity of his decision's implications, whatever he chooses. Not much is known of how he will reach it, beyond the fact that a certain amount of public debate is involved. Some people believe the decision is being taken too quickly and ought to be delayed, saying the FBR is not yet needed; others contend that an early decision is vital for the industry and the country. The arguments are complicated, but what Mr Benn has to decide is, first, whether fast reactor technology is an essential element of the future energy scene; second, whether it can be developed to an acceptable level of safety; and, finally, whether it is socially desirable. He must make his decision against a backdrop of clear signs that the FBR will be developed elsewhere if not in Britain, and delay could spoil the chances of an early foothold in a potentially lucrative worldwide market.

The case for the FBR rests squarely on its fuel breeding capacity (see box, page 344). Unlike existing commercial thermal reactors, which use less than 1% of the energy available in uranium, the FBR extracts more than 60%. At the same time it contributes towards future energy supplies by "breeding" plutonium. These simple advantages mark it out as the potential saviour of an energy hungry world.

Consideration of Britain's nuclear fuel prospect highlights the possible benefits of the FBR. Since the middle 1950s the UK thermal reactor pro-



Prototype Fast Reactor with the Dounreay Fast Reactor in the background

Photo: UKAEA

gramme has produced 20,000 tons of depleted uranium. Ordinarily of little value, this stackpile, together with the 13 tons or so of plutonium that have also accumulated, could be used in fast breeders to provide as much energy as the nation's total known reserves of coal. For a country with a sizeable (5 GW) and expanding nuclear programme, this represents an indigenous energy source that could become ever more crucial as the domestic requirements of the uranium exporting nations themselves increase. British imports from Canada could be squeezed, as could possible future supplies from Australia. A large political question mark hangs over Namibian uranium, Britain's only other source of reactor fuel.

Worldwide nuclear expansion will also introduce economic pressures. Present assessments of world uranium reserves are as elastic as the market prices assumed in calculations, but at the existing price of around $15 a pound an estimated 3.4 million tons of high grade ore are available, though only half of that is so far proven. Whether this can last beyond 1990, even with today's worldwide nuclear capacity, is already a matter of debate.

There is less doubt, however, that by the turn of the century the continued use of thermal reactors alone could force the exploitation of lower grade ores. The consequent increase in prices, which might rise as high as $100–$200 a pound if forecasts from the US Energy Research and Development Administration prove correct, is likely to be matched only by the increased amount of environmental despoliation accompanying the extraction of ores with energy contents similar to that of coal. (Currently used ores provide around 25,000 times as much energy as coal in thermal reactors, or up to about 1.5 million times as much in fast breeders.)

What bearing this has on the case for a British FBR programme is rather a matter of viewpoint. On the one hand, energy demand forecasts from within the nuclear industry and the Department of Energy (DEN) identify the FBR as an indispensable cornerstone of the British energy scene until fusion power arrives. On the other, it is easy to query the accuracy of forecasts. The degree of uncertainty involved was underlined during the recent national energy conference when British Gas leaders refuted predictions of a UK energy gap before the end of the century.

Independent research units similarly believe that electrical energy demands may already be near to peaking, while pressure groups claim that demand can be regulated by conservation measures, ensuring that sufficient nuclear capacity is achieved economically using more efficient thermal reactors systems such as CANDU (see box). There are also calls for more research and development (R&D) effort on high temperature reactors, which open up the possibilities of the thorium cycle. But the UK Atomic Energy Authority (UKAEA) is less enthusiastic, wary of the huge initial uranium investments needed to launch such a programme.

UKAEA forecasts predict that by the turn of the century almost 75% of the national energy demand must be met by nuclear power. Of the 198 GW needed to do this job, almost 33 GW, nearly seven times the current total installed nuclear capacity, will come from fast breeders. Whether this target is treated entirely seriously by the DEN remains doubtful, particularly as the Central Electricity Generating Board (CEGB) could by then handle a maximum of only 20 GW from FBRs. Moreover, Walter Marshall, Chief Scientist at the DEN, has several times publicly voiced the conviction that the number of commercial fast breeders operating by the year 2000 is unlikely to exceed two or three.

Nonetheless, this only reinforces the UKAEA's case for early clearance for their planned 1,300 MW demonstrated FBR, CFR–1. It has built up a good head of steam for the off. Its R&D effort on FBR technology extends back over 25 years, with operational experience dating from the start-up of the 14 MW experimental FBR at Dounreay in Scotland (DFR) in 1959. The programme advanced a further major step two years ago with the introduction at low power of a 250 MW prototype (PFR), also at Dounreay.

Estimates of the total cost involved in coming thus far vary between £200 and £400 millions, but the UKAEA's present level of financial commitment speaks for itself. Though cuts of up to £4 millions are expected as part of current UK expenditure savings, R&D spending on FBR technology over the past three years has stood at around an annual £40 millions, almost a third of the total nuclear R&D cake, and by far the largest single slice. Moreover, about half of the overall nuclear R&D workforce is involved with the FBR.

The UKAEA therefore understandably feels that the next logical step is the design and construction of CFR–1, expected to take about 10 years. Confidence generated by almost two decades of reasonable progress with DFR, which has pumped more than 500 kWh into the national grid, extends beyond the reactor itself, into every area of the related fuel cycle.

At least one group does not share the UKAEA's confidence. Friends of the Earth (FOE) have vocally attacked the international record of fast reactor development with single minded conviction. During a recent House of

Commons Select Committee meeting FOE listed a series of developmental setbacks that provokes sober reflection. The Enrico-Fermi FBR in Detroit, Michigan, for example, was constantly beset by potentially dangerous disruptions during its sporadic, nine-year operational life, while more recently the Soviet BN–350 FBR on the Caspian coast has suffered several serious leaks in the steam generating plant. Welding has, indeed, proved a persistent problem, and has delayed the full-power operation of the Dounreay PFR. The molten sodium used in the cooling circuits is highly corrosive. Void formation—the occurrence of gas bubbles in the coolant—is another major problem common to all FBRs and has still to be overcome.

Remaining hitches in reactor technology can, it is argued, be straightened out during the 20-year run-up to a commercial FBR network. But doubts linger over the associated fuel cycle. They arise not only at the technological level, where experience already gained by British Nuclear Fuels Ltd has been encouraging, if somewhat controversial, but also at environmental and political levels.

In a submission last year to the Royal Commission on Environmental Pollution (RCEP), which is due to publish a report on radiological hazards before Mr Benn's autumn decision, the UKAEA covered the environmental issues. Its arguments that the hazards of long-lived, highly active wastes can be satisfactorily controlled are likely to tip the scales in favour of the FBR. Mr Benn has indicated that the RCEP report will influence his decision, and it is now clear that the Commission itself, for some time reportedly divided over nuclear issues, will back CFR–1. In a recent reference to commercial FBR development Sir Brian Flowers, Chairman of the RCEP, said that while the implications and alternatives had not been explored with the level of resources and dedication devoted to the nuclear programme itself, he would not oppose the building of CFR–1 alone.

But the social and political implications of FBR reprocessing most worry those who believe that one step forward to CFR–1 will carry too much momentum for subsequent withdrawal. Though FBRs produce plutonium at a slower net rate than thermal reactors their proliferation would introduce the need for widespread plutonium transport. On UKAEA reckoning there could be 250 tons at various stages of the fuel cycle in Britain by the year 2000.

FBR opponents fear that the security measures required would be not far short of Draconian. A Bill to introduce the arming of nuclear security police has already been passed by the UK Parliament, and a US Government official this month called for an armed international security force. Additional doubts have been expressed about the sort of political arrangements needed to ensure worldwide adherence to safeguards such as those already implemented on a more limited scale by the International Atomic Energy Agency.

In France, the political and technological fears have led to civil disturbances involving qualified and well-informed opponents of the 1,200 MW Superphénix project now beginning on on the Rhône. But in Britain there is little public awareness of the issues. Sir Brian Flowers recently charged that the UK Government apparently preferred to keep things in the dark. Similar concern has also led the Liberal Peer, Lord Avebury, to call for a Green Paper once the RCEP report is available, and to hint that a national referendum would not be inappropriate. Mr Benn has said only that a questionnaire will be produced for limited, and so far unspecified, circulation.

Though it is clear that the case for

How the FBR is different

NUCLEAR power installations harness the heat energy released during controlled nuclear fission, and convert it into usable electricity. Fast breeder reactors (FBRs) differ from existing commercial reactors (known as "thermal" reactors) because, along with energy, they produce more fissile material than they consume—a self-sustaining bonus which could considerably stretch world uranium resources.

Like fast breeders, thermal reactors produce some plutonium but only in minute amounts. This is because more than 97% of the uranium used in thermal reactors fuel is non-fissile uranium-238, which is partially converted into plutonium while fission of the small fraction of uranium-235 proceeds. But plutonium is itself fissile, and most of it rapidly breaks down again, adding to the overall energy output of the system. (The Canadian CANDU reactor is designed to take full benefit of this phenomenon, optimising fuel efficiency.) Thus only about 1% of spent fuel from thermal reactors remains as plutonium.

On the other hand, the FBR can breed plutonium, using fast neutrons rather than the slow neutrons used in thermal reactors. Although fast neutrons are less efficient in inducing fission, the chain reaction they set up produces the greater number of additional neutrons needed to convert uranium-238. Consequently, the moderators used to decelerate fast neutrons in thermal reactors are absent from fast breeders.

The problem of decreased fission efficiency is overcome by pushing the neutron density in FBR fuel elements above the level achieved in thermal reactors. This means that the core assembly must be extremely compact, while the concentration of fissile material must be boosted way above the maximum enrichment factor of 3% needed in thermal fuel.

The 14 MW experimental FBR at Dounreay (DFR), for instance, uses 75% enriched metallic uranium in a core of little more than 100 litres. At Dounreay, as in all FBRs, the uranium-238 needed for breeding is located in a "blanket" around the core, where the neutron density is no longer sufficient to break down the fissile plutonium formed.

In assessing the doubling time of an FBR—the period required for the reactor to reproduce the amount of fissile material originally in the reactor core—the entire fuel cycle is considered. At any one instant, for example, fissile material may be within the reactor itself, undergoing cooling, reprocessing or refabrication, or in transport.

It is thus possible to control the doubling time by retiming any of the operations involved in the cycle. Current UKAEA plans envisage a doubling time of about 28 years for Britain's first commercial FBRs early next century, a figure that neatly matches the expected expansion rate of the reactors themselves.

With the high neutron density in an FBR core, heat is generated more efficiently than in thermal reactors. Thus, while most thermal reactors operate at temperatures well below 300 °C, the 250 MW prototype FBR at Dounreay (PFR) has a design outlet temperature of almost 600 °C. Fast breeder fuel elements must be designed to withstand the extra heat.

It soon became apparent that the metallic uranium core used in the DFR would melt at operating temperatures above 350 °C. As a result, the PFR is fuelled by sintered pellets of uranium oxide and plutonium oxide. Uranium-235 is not an essential component, however, and fast breeders of the future could be fuelled with fissile plutonium-239 alone, though uranium-238 breeding material would, of course, have to be present. It is in by-passing the need for the scarce uranium-235 isotope that the FBR can stretch available uranium resources.

The fast breeders so far developed in Britain, France, Germany, Japan, the USA and the USSR are all designed to use liquid metal coolant circuits to carry the heat away from the core. They are therefore known as liquid metal fast breeder reactors. By using sodium, which is normally molten between 98 °C and 880 °C, the unnecessary hazards associated with pressurised operation procedures can be avoided.

To minimise the risk of radioactive contamination, sodium circulated around the core in the primary reactor chamber passes its collected heat onto a secondary, external sodium circuit shielded from radiation. This circuit in turn carries heat to the steam generators.

FBR development has not run altogether smoothly. After 17 years operational experience with the DFR and the PFR, the UK nuclear industry is still struggling with problems in the steam generating plant of the PFR. The CEGB, however, which is prepared to have 20 GW of FBR capacity plugged into the national grid by the year 2000, has also declared a watchful interest in the development of helium-cooled fast breeders, which could provide an even better alternative to the liquid metal FBRs.

the FBR is far from open and shut, Mr Benn's view of international developments may persuade him to nod CFR-1 through. France, Germany, and the USA are all aiming for commercial FBR capacity by the 1990s, with Japan and Russia not far behind. UKAEA collaboration agreements already exist in one form or another with all of these countries, while the CEGB, currently chasing a minor share of the Superphénix project, also holds an interest in the German SNR-30 FBR prototype.

UKAEA feeling is that delays with CFR-1 will not help strengthen collaboration, perhaps damaging Britain's relative position in a commercial development race that will be run anyway. One man who disagrees is John Surrey, who last month resigned as nuclear adviser to the Select Committee on Science and Technology. He has argued publicly that Britain can learn much from the sidelines, and that restraint at this stage will allow the channelling of larger funds into other areas of energy R&D, including conservation. The UKAEA must hope that Mr Benn is unimpressed by that reasoning: it has already placed a contract with the Nuclear Power Company for design and engineering work "related" to CFR-1. On the question of a possible site, there has been official silence. □

Tracking nuclear decisions (3)

Exports: time for a stand?

Colin Norman in Washington examines the NRC's problems concerning the export of uranium to India

EARLY next month, the Nuclear Regulatory Commission (NRC) will decide whether to allow 12,261 kg of slightly enriched uranium to be exported to India. Its decision, the toughest it has yet faced, will have major foreign policy implications, for it will represent a crucial milestone in the United States' efforts to prevent the proliferation of nuclear weapons. In fact, it is the kind of foreign policy decision that is usually made by the President.

NRC is thrust into the middle of the issue because it alone has the authority to grant or deny an application for a licence to export nuclear material from the United States. Its decisions can only be overturned by an Act of Congress. In this instance, it has under consideration an application to export fuel for the giant Tarapur Atomic Reactor Station near Bombay, an American-built reactor which has been operating since the early 1960s with fuel supplied by the United States.

Understandably, NRC is treating the matter with considerable caution. Last week, it held a public hearing to receive testimony on the licence application—the first public hearing ever called to discuss a nuclear export licence—and it was given a wealth of conflicting advice. On the one hand, the State Department and the Commission's own staff recommended that the application be approved, while on the other, a powerful coalition of arms control experts, Congressmen, environmentalists and nuclear critics argued that the licence should be denied.

Underlying the debate, of course, is the fact that on May 18, 1974, Indian scientists exploded a nuclear device constructed from plutonium produced in a Canadian-supplied reactor. It was the first time that any nation had used imported technology to join the nuclear club, and as a result Canada earlier this year decided to bar any further nuclear assistance to India. Opponents of the request to ship enriched uranium for the Tarapur reactor are urging that the United States should follow Canada's example.

Representative Clarence D. Long of Maryland for example, told NRC that "our response to India is the first test of whether the United States has a real policy of stemming the spread of nuclear weapons". Similar sentiments were also expressed by Dr Herbert Scoville, former deputy Director of the Central Intelligence Agency, and Adrian Fisher, former chief negotiator for the Nuclear Non-proliferation Treaty (NPT). Fisher argued, for example, that "the continued supply by the US of nuclear fuel for the Indian atomic program can only be looked on by other nations as tacit approval by the United States of the Indian nuclear explosive program".

The United States has been supplying enriched uranium for the Tarapur reactor for more than a decade under a unique agreement. In short, the agreement specifies that the reactor can only be operated with fuel supplied by the United States, and that such fuel cannot be used in any other facility in India. The United States also has an option to buy back spent fuel discharged from the reactor—nearly 200,000 tons have so far been accumulated—and no reprocessing of that fuel can take place in India without US permission. Moreover, operation of the Tarapur reactor is subject to monitoring by the International Atomic Energy Agency (IAEA).

But India has an extensive nuclear programme in addition to the Tarapur reactor which is not covered by the agreement and which is not subject to international safeguards. The explosive device detonated in 1974, for example, was made from plutonium produced in a Canadian-supplied research reactor and separated in a small reprocessing plant built by the Indians themselves. And a new factor has recently been introduced because India has recently completed construction of a large reprocessing facility adjacent to the Tarapur reactor. According to State Department spokesmen at last week's NRC hearing, the facility is now undergoing tests and it will soon have the capacity to reprocess much of the spent fuel from India's entire nuclear programme. The construction of the plant has given India at least the capacity of building large numbers of explosive devices.

Opponents of the proposal to ship more fuel for Tarapur, led by the Natural Resources Defense Council, the Union of Concerned Scientists and the Sierra Club, argued at last week's hearings that, at the very least, NRC should deny the application until India has agreed to several stringent conditions. First, the Indian government should pledge not to construct further explosive devices. Second, the United States should exercise its option to buy back spent fuel already produced by the Tarapur reactor. Third, India should agree to place all its nuclear facilities under international safeguards. And fourth, India should agree not to reprocess any spent fuel, at least for the time being.

Clearly, the Indian government would not readily accept such conditions. But the opponents of the licence application point out that India would be hard pressed to find an alternative fuel supplier. The only other exporter of enriched uranium is the Soviet Union, and potential European exporters are at least ten years away from having significant export capacity. Thus, they argue that "if India wishes to avoid a shut-down of the Tarapur reactors, it may well have to deal with the United States, and the Commission has leverage to obtain non-proliferation ends".

But those views are not shared by the State Department. In a long statement delivered to the NRC last week, for example, Assistant Secretary of State Myron Kratzer argued that "the credibility of the United States as a reliable supplier of nuclear materials, equipment, and services is an essential element in achievement of our non-proliferation objectives". Kratzer argued that the US–Indian agreement covering the Tarapur reactor is sufficient to prevent diversion of its plutonium to weapons production. And he warned that if the United States refuses to ship more fuel for the reactor, the Indian government could claim that the original agreement had been broken and that the spent fuel is therefore no longer under safeguards.

Kratzer announced, however, that the State Department is looking into the possibility of taking up the option to buy back the spent fuel which has already accumulated from the Tarapur reactor.

One key issue which surfaced during last week's hearings concerns the extent to which the United States provided aid for the production of India's first explosive device. The Cirus reactor, which provided plutonium for the device, was moderated by heavy water bought from the United States on condition that it be used only for peaceful purposes.

When Senator Abraham Ribicoff last month drew attention to the possibility that American material had helped India produce its first atomic blast, the State Department demurred. It argued that, by the time the Cirus reactor began producing plutonium for the device, the US-supplied heavy water had been replaced with heavy water manufactured in India. Kratzer confirmed last week, however, that some US-supplied heavy water was probably still in the reactors at the time India used it to manufacture plutonium for the explosive. Consequently, critics of the proposed fuel sale argued that India cannot be trusted to abide by its pledges not to develop nuclear weapons.

The nub of this whole dispute is really that the opponents of the application are arguing that the time has come for the United States to make a public demonstration that it is serious in its efforts to deter the spread of nuclear weapons, while the State Department is arguing that abrogation of the agreement to fuel Tarapur would jeopardise those US non-proliferation policies. The four NRC commissioners will be hard put to decide which side is correct.

At this stage, it's difficult to predict with certainty what the Commissioners will decide, but at least there is a clue. Earlier this year, there were two applications outstanding for exports of fuel for Tarapur—the 12,261 kg which was the subject of last week's hearings, and a separate shipment of 9,165 kg. Because at least one shipment was required urgently to avoid shutdown of the reactors, NRC approved the export of the smaller quantity on July 2. It did so by a vote of 3 to 1, but explicitly stated that the action would not prejudice its consideration of the second licence application. Its final decision will probably be made in the first week of August. □

IN BRIEF

Stever's appointment

After weeks of uncertainty and delay, President Ford last week nominated Dr H. Guyford Stever to be his science adviser and the first Director of the new White House Office of Science and Technology Policy (OSTP). Stever's nomination must be confirmed by the Senate, but swift approval is expected. The appointment was delayed because four right-wing Republican Senators last month criticised Stever's record as Director of the National Science Foundation and urged Ford not to nominate him for the White House post. The delay has ensured that OSTP will have little influence for several months. The Ford Administration's longevity is in considerable doubt, and with the election in full swing, few people will pay attention to the office. Nevertheless, President Ford can at least claim that he has restored science advice to the White House.

The axeman cometh

The £1,000 million public expenditure cuts announced by the UK Government last week, which are due to take effect in 1977–78, have not left science-related activities unscathed. With the axe falling on capital investment programmes of the nationalised industries, the energy sector (with the exception of the British National Oil Corporation) is particularly hard hit. Coal, gas and electricity will be seeking a total saving of about £70 million through deferred projects. Apart from the Selby coal scheme, this may involve a 12-month postponement on the Steam Generating Heavy Water Reactor and a cutback on research and development of the fast breeder reactor. A cut of £100 million is being sought from the Ministry of Defence: most of the cuts will be achieved by removing or rephasing existing programmes, and research work may not escape. At the Department of Education and Science the science budget will be cut in 1977–78 by £5 million. Details have yet to be made known, and it is thought that advice from the Advisory Board for the Research Councils will be sought before final decisions are made.

Geothermal energy research programme

A three-year programme of geothermal research in the UK is to be supported by the Department of Energy following the publication of a report, *Geothermal Energy: the case for research in the United Kingdom* (HMSO, £1.85). The report, by Dr J. D. Garnish of the Energy Technology Support Unit (ETSU), Harwell, reckons that likely returns warrant a modest research programme of collection and refinement of data.

Interest centres on two techniques—the extraction of hot water from aquifers in sedimentary basins or near springs, and the hydrofracturing of rocks, usually granite, with a higher than average temperature. Temperatures likely to be encountered with either technique are in the 100 to 200 °C range.

Much of the £840,000 involved in the research programme (which ETSU will supervise) will go to the Institute of Geological Sciences for data gathering, particularly in Cornwall, Durham, Bath, Bristol, the Hampshire Basin and the Midland Valley of Scotland. Imperial College and Oxford University are also likely to receive support.

Plea for prisoners

Two scientists, Sergei Kovalyov (Soviet Union) and Sandor Arancibia (Chile) were the subject of appeals by a group of distinguished biologists on the occasion of international congresses of endocrinology and biochemistry in Hamburg recently. Kovalyov, an electrophysiologist, was sentenced in December 1975 to seven years in prison and three years exile for anti-Soviet activities. Arancibia, a neuroendocrinologist, was given a life sentence—he had been a prefect in the Valdivian region before the 1973 change of regime. Signatories included A. Lwoff, F. Jacob, J.-P. Changeux, F. Gros, F. Morel, Y. Laporte, E. Baulieu, J. Nunez, C. Kordon, C. B. Anfinsen, C. deDuve, G. Wald, D. Baltimore, R. Dulbecco, S. Luria, A. Szent-Györgyi, J. D. Watson, H. Krebs, H. Temin, J. Axelrod, V. Ramirez, L. Martini and J.-P. Waller. They call on Mr Brezhnev and General Pinochet to free their colleagues strictly for humanitarian purposes since "their lives are in danger and those of their families are broken".

The history of the term 'ionosphere'

from C. S. Gillmor

FOR more than four decades the term "ionosphere" has been used to designate the ionised regions from about 60 kilometres to some thousands of kilometres above the Earth's surface. These regions were not always so named. In the first years after G. Marconi's demonstration in 1901 of trans-Atlantic radio communication, some pioneers of wireless, such as A. E. Kennelly, O. Heaviside and J. Erskine-Murray, designated the upper atmospheric region which supposedly played a part in long distance radio transmission as the "upper reflecting surface" or the "conducting layer". Many others, of course, believed no such ionised region existed. Discussion was stimulated by G. Marconi's lectures where he described the difference between day and night transmission (Marconi, *Proc. R. Soc. A.*, **70**, 344–347; 1902). Marconi termed the "day effect" (what would later be called the "night effect"), the phenomenon that radio transmission during the daytime seemed possible over a distance only two-fifths as great as that at night. Marconi's original explanation was that this was due to local effects of sunlight on the transmitting antennae. Others attributed the effect to increased ionisation of the upper atmosphere by the Sun.

The work of W. H. Eccles, L. de Forest, and L. F. Fuller just before World War I (Tuve, *J. atmos. terr. Phys.*, **36**, 2079–2083; 1974) stimulated a great debate on the nature and effective height of the upper region. Though Eccles suggested the name "Heaviside layer" in 1912 (Eccles, *Proc. R. Soc. A.*, **87**, 79–99, 1912), no single term emerged. L. W. Austin, O. Lodge, L. Cohen, G. W. O. Howe and others spoke of the "upper atmosphere", "upper conducting layer", "far upper regions", and "ionised upper atmosphere". Following World War I, Eccles' term was revived and "Heaviside layer" ("Kennelly-Heaviside layer" according to some), became the most frequently used term with "upper conducting layer" the next preferred.

By the early 1920s it was not so clear that "Heaviside layer" should be synonymous with the upper ionised regions of the atmosphere because various geophysical phenomena were known to occur at different heights in the upper atmosphere. A. Schuster called them the "upper conducting *layers*" (Schuster, *Electrician*, **89**, 325; Sept. 22, 1922). W. H. Eccles pointed out that the "night effect" was probably caused by the lower edge of the upper region of the atmosphere where free electrons "exist more or less permanently" (Eccles, *Electrician*, **94**, 208; Feb. 20, 1925). This lower edge is the Heaviside layer, he said, and it might be located higher or lower than the ionised region needed to explain the diurnal magnetic variations. Below this was the "middle atmosphere" where ions of molecular size are formed daily by sunlight. These ideas were not new, he said, but had been assumed long ago by students of wireless.

As a scientific specialty matures it concerns itself with standards of measurement, technique and nomenclature. This is evidenced by the actions of the British Radio Research Board (RRB), set up after World War I. In the autumn of 1921 the RRB Sub-Committee A, on Propagation of Wireless Waves, discussed (*RRB Sub-Committee A, Paper 27*; 1921) the recommendations of an international committee which had proposed standardising terms: "radio" in place of "wireless telegraphy"; "atmospherics" in place of "parasitics", "statics" or "X" (strays); "electronic tube" in place of "valve", "lamp" or "audion": and "antenna" in place of "aerial". In the spring of 1924 the Sub-Committee discussed (*RRB Sub-Committee A, Paper 68;* March 8, 1924) terms for the classification of radio emissions (Continuous Waves (CW) and modulated forms of CW, and Damped Waves). It was probably at some similar meeting in the autumn of 1926 that the question was raised of agreeing on a term to designate the entire atmospheric region or regions where ionised particles accounted for the major phenomena. In fact, R. A. Watson-Watt referred to recent discussions on nomenclature in a letter to the Secretary of the RRB. In this letter (Gardiner, *Nature*, **224**, 1096; 1969), dated November 8, 1926, Watson-Watt suggested the term "ionosphere" in place of what had been loosely termed the "upper conducting layer", and mentioned the analogy to stratosphere and troposphere.

Now it seems that E. V. Appleton was thinking similarly, for in a letter (*Edinburgh University Library, MS. Gen. 1985/21*) to J. A. Ratcliffe dated November 2, 1926 Appleton wrote:

> "For the ionised part of the upper atmosphere I think the terms ionosphere or electrosphere might be useful. Which do you prefer? Cf. Stratosphere & Troposphere".

Watson-Watt and Appleton had numerous opportunities in those days for conversation at the Radio Research Station at Slough, at meetings of the RRB, and at King's College, London. In spite of the RRB discussions, "ionosphere" seems at first to have fared little better than the terms designed to replace "wireless" or "valve". The first to use the term "ionosphere" in print was Watson-Watt in 1929 in the Symond Memorial Lecture to the Royal Meteorological Society (Watson-Watt, *Q. Jl R. met. Soc.*, **55**, 273–301; 1929). He noted:

> "It might be permissible to call it the Balfour-Stewart-Fitzgerald-Heaviside - Kennelly - Zenneck - Schuster -Eccles-Larmor- Appleton space, but something less direct is desirable. I have suggested the name ionosphere to make a systematic group troposphere, stratosphere, ionosphere but meanwhile the term 'upper conducting layers' seems to hold the field".

The term was next used, in its German form "ionosphäre", by H. Plendl who, independently, suggested it early in 1931 and used it in articles published later that year (Plendl, *Jb. dt. Vers Anst. Luftf.*, 665–671; 1931).

"Ionosphere" came into use widely beginning only in the period 1932-1934 when Watson-Watt, Appleton, Ratcliffe, W. Dieminger, I. Ranzi, D. F. Martyn, S. K. Mitra and others began to use the word in the *titles* of published papers and lectures. An example of its legitimisation was the prominent use of "Ionosphere" in the Kelvin Lecture delivered at the Institution of Electrical Engineers in April 1933 by Sir Frank Smith, Secretary of the Department of Scientific and Industrial Research (Smith, *Electrician*, **110**, 581–582; May 5, 1933). It was thus that the term began to appear in library indices and abstracting categories. It then began to be used in related forms; the pulsing vertical incidence radar became known as the ionosonde, and ionospheric workers were sometimes known as ionospherists. Use of the term was at its relative maximum during the early 1950s when about 35% of all published papers on ionospheric physics (Manning, *Bibliography of the Ionosphere*, Stanford University Press, Stanford, California, 1962) had the word ionosphere or a form of it in their titles. This trend has reversed as other specialties have developed out of ionospheric physics and terms such as "magnetosphere" and "STP" (solar–terrestrial–physics) have come into common use to designate many subjects which formerly were included primarily within the specialty of ionospheric physics. ☐

Transformation and tumorigenicity

from Robert Shields

SOME recent observations on the properties of cells transformed by mammalian tumour viruses and their ability to cause tumours when injected into the commonly used nude mouse, raise several questions on the validity of treating these experimental systems as a model for real cancers.

Ever since the first mammalian cell cultures were transformed by tumour viruses a great deal of effort has been expended in attempts to understand the process of oncogenic change *in vitro*. Studies using a few cell types and even fewer viruses have collected an enormous number of *in vitro* cellular properties that are often associated with tumorigenicity. These include changes in cellular morphology, increased cell autonomy, loss of density-dependent inhibition of growth, decreased dependence on high levels of serum in the culture fluid, increased agglutinability by plant lectins, changes in membrane composition, increased ability to grow in gel suspension (loss of anchorage dependence) and so on and so on. What is a pity is that much of the work on these properties has been performed on established lines of virally transformed cells so it has been impossible to unravel which changes are caused by the virus and which have arisen through selection in culture.

One way around this problem has been to select at random clones of 3T3 or primary rat embryo cells recently infected with SV40 and examine each clone for various parameters of transformation (Risser and Pollack, *Virology*, **59**, 477, 1974; Risser, Rifkin, and Pollack, *Cold Spring Harbor Symp. quant. Biol.*, **39**, 317; 1974). In this way it was hoped to find which parameters of transformed cells are related to the viral gene, which changes are related to each other, and which changes confer tumorigenicity.

The results from these experiments showed that the virus was able to elicit a whole spectrum of changes. The only alteration in some clones of 3T3 cells was that they could grow in low concentrations of serum, and that they could grow to higher cell densities. These cells were negative for the virus-specified T antigen, no virus could be rescued from them and the cells could be fully transformed by reinfection with SV40. All this suggests that these changes may be caused by a hit and run action of the virus rather than by the continued presence of the viral gene.

The only *in vitro* cellular property that correlated with the ability of the cells to cause tumours in nude mice (which lack cell-mediated immunity), was their ability to grow in methocel suspension (anchorage independence) (Shin *et al.*, *Proc. natn. Acad. Sci. U.S.A.*, **72**, 4435; 1975) and this property was in turn correlated with the ability of the cells to produce a protease that converts plasminogen in the serum to plasmin (Pollack *et al.*, *Proc. natn. Acad. Sci. U.S.A.*, **71**, 4792; 1974). These experiments were performed with only two cell types and one transforming agent but many other reports have suggested a correlation between anchorage-independent growth and tumorigenicity (Freedman and Shin, *Cell*, **3**, 355; 1974; Laug *et al.*, *J. natn. Cancer Inst.*, **54**, 173; 1975).

The correlation between growth in suspension and tumorigenicity is far from absolute, however. Examination of epithelial cell lines derived from a number of human carcinomas show that some cells grow in suspension and fail to form tumours in nude mice, some anchorage-dependent lines are tumorigenic and furthermore there is no correlation between the ability to activate plasmin and either growth in suspension or tumorigenicity (Marshall, Franks and Carbonell, personal communication; Pearlstein *et al.*, *Cancer Res.*, **36**, 1575; 1976; Jones *et al.*, *Int. J. Cancer*, **16**, 616; 1975).

These observations raise several questions not least of which is the suitability of the commonly used 'fibroblast' cells and their viral transformants as suitable models for real cancer, but also the use of the nude mouse as a means of detecting tumorigenicity.

There have been mutterings about established cell lines such as 3T3 for some time, especially because of their heteroploid karyotype. It is now clear, however, that the BALB/c3T3 cell line is frankly tumorigenic when attached to glass beads and innoculated into suitable hosts (Boone, *Science*, **188**, 68; 1975). Moreover, the tumours formed are 'vasoformative sarcomas' (Boone *et al.*, *Cancer Res.*, **36**, 1626; 1976) so it seems that these cells are not fibroblasts but arise from endothelial tissue. In fact, a great many cell lines established from a wide variety of tissues appear to be derived from the endothelial cells and pericytes of small blood vessels (Franks and Wilson, *Eur. J. Cancer*, **6**, 517; 1970), so many of the different established cell lines may represent a very restricted sample of the variety of cell types in the body.

Studies of the incidence with age of a great many naturally occurring cancers in man lend support to the hypothesis that cancer cells arise after a small number of heritable changes have occurred in a normal cell. Presumably the altered cell becomes a successful cancer if these changes result in it being better able to proliferate than the cell type it comes from. There is no reason to suppose that the changes which confer a selective advantage on one cell type in one environment will confer selective advantage on another, nor even that selective advantage within a given tissue need arise through a unique series of steps; other pathways could be equally effective. As a consequence tumour cells from widely different tissues might be expected to have widely different properties when studied *in vitro*. After all what is good for the endothelial cell may not be so good for the bladder.

Such generalisations that have been drawn about the nature of neoplastic change from the use of cultured cells may simply reflect the small number of cell types examined and the even smaller number of oncogenic agents.

Mars from Viking 1

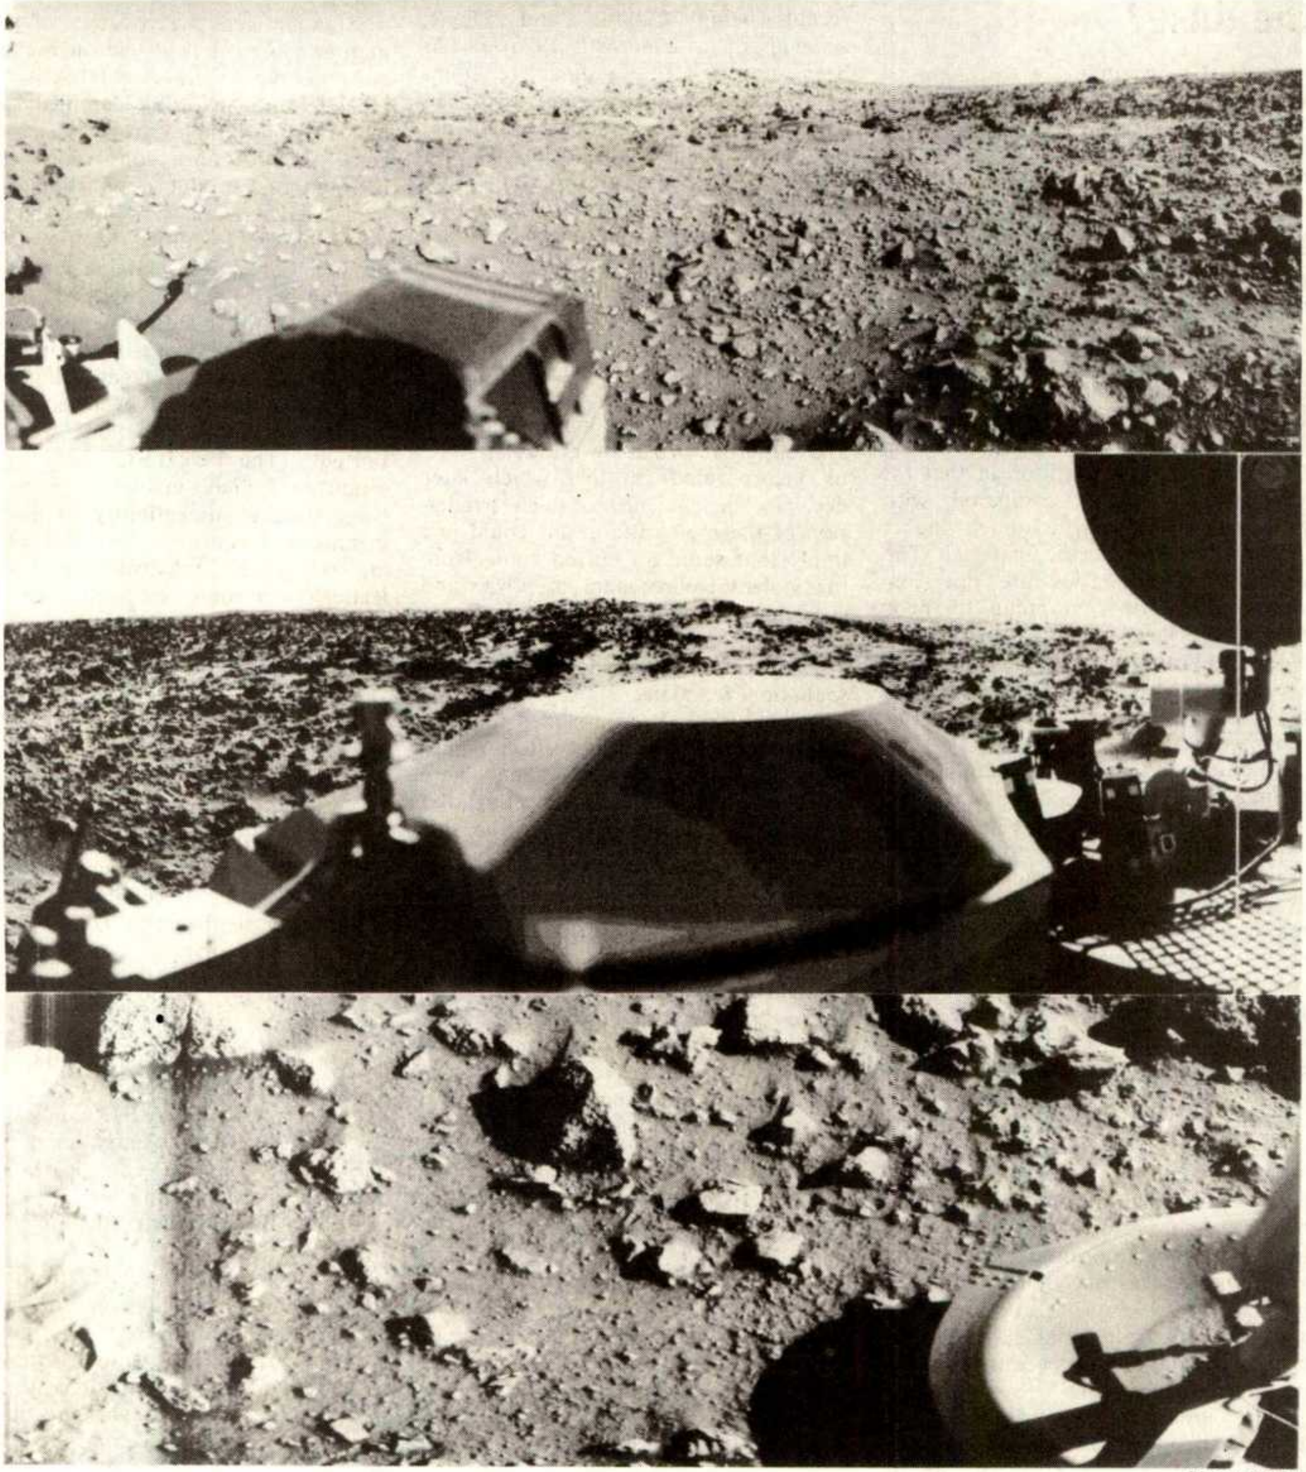

Photo: NASA

THE top two pictures provide the first panorama of the Martian landscape as seen from Viking 1, taken in the late Martian afternoon. A plateau can be seen on the horizon to the left of the top picture, approximately 3 kilometres (1.8 miles) away. The out-of-focus spacecraft component left of centre is the housing for the sample arm (which is now in full working order after becoming jammed when first tested). The centre photograph is the continuation to the right of the 300° panorama. At left is the low-gain antenna which receives commands from Earth. In the right foreground are colour charts for lander camera calibration, a mirror for the Viking magnetic properties experiment and part of a grid on the top of the lander body. At upper right is the high-gain dish antenna for direct communication between the landed spacecraft and Earth. Toward the right edge is an array of smooth fine-grained material which shows some hint of ripple structure and may be the beginning of a large dune field off to the right of the picture.

The bottom picture, the first ever of the surface of Mars, was taken minutes after the spacecraft landed.

Do exploding stars leave tracks in the dust?

from M. G. Edmunds

HAVE grains of dust, formed in the explosion of stars, managed to survive incorporation into Solar System meteorites? A most interesting observation, although unfortunately open to rather ambiguous theoretical interpretation, has recently been reported by J. Audouze and co-workers (*Astrophys. J. Lett.* **206,** L185; 1976).

They examined micron-sized grains extracted from a separated part of the Orgueil meteorite. The material from which these grains came shows an unusual chemical composition in that the abundance of ^{22}Ne, compared with other neon isotopes, is much higher than in most meteoritic material. The unusual isotope ratios are not consistent with either trapping of neon from the solar wind, or with creation of neon by nuclear reactions involving the impact of high-energy cosmic ray particles. The origin of the excess ^{22}Ne remains disputed.

Audouze *et al.* use a technique of chemically etching the radiation damage tracks left by the passage of energetic heavy ions through the grains. The etched tracks can be examined with a high voltage electron microscope. They found tracks in those grains which appeared amorphous and rounded, and the density of tracks implies that these grains have been strongly irradiated at some time. Andouze *et al.* take the view that the irradiating particles were probably heavy ions with masses comparable to iron nuclei. An experimental exposure to a beam of iron nuclei caused crystalline grains (which did not initially have tracks) to show tracks similar to those found in the amorphous grains. By assuming the currently observed ratio of heavy ions to protons in cosmic rays and particles from solar flares, a net proton irradiation can be estimated for the amorphous grains.

One interpretation of the ^{22}Ne anomaly is offered by production from spallation nuclear reaction of the irradiating protons on ^{25}Mg, but this requires that the energy spectrum of the protons has a rather peculiar "pulse" shape to avoid overproduction of the other neon isotopes. A high flux of particles might have occurred during the early history of the Solar System, but the observed irradiation would imply a very much higher flux of particles from the Sun at early times compared with that observed today.

A second interpretation is perhaps more interesting. It may be possible for grains to condense in the expanding envelope of gas generated by the supernova or nova explosion of a star. In a series of papers (the most recent being Clayton and Hoyle, *Astrophys. J.*, **203,** 490; 1976) it has been suggested that radioactive atoms from the explosive nucleosynthesis occurring in novae or supernovae could become trapped in the grains as they condense. If these grains could subsequently survive the physical conditions during the formation of the Solar System and be incorporated into meteorites, then the products of radiodecay of the nuclei trapped in the grains could show up as isotopic anomalies. The excess ^{22}Ne for example might come from the decay of ^{22}Na produced in explosive nucleosynthesis, and either absorbed by grains as ^{22}Ne, or incorporated as ^{22}Na which later decays. The evidence of high irradiation of the meteoritic grains could just imply that some do indeed come from the violent environment of novae and supernovae where high particle fluxes are expected. The particle flux could also provide some additional ^{22}Ne by spallation reactions.

It has usually been assumed that the meteoritic isotope ratios reflect conditions in the early Solar System. There exists a real difficulty in accepting that grains from novae or supernovae survive into meteorites. Such grains would bring other isotopic anomalies with them which would upset the elegant inferences about the timescales involved in the formation of the Solar System drawn from isotope ratios (so-called "nucleocosmochronology"). But there are plenty of isotopic anomalies, and a surprising lack of them for certain elements, to keep discussion alive before a revision of timescales is accepted. Audouze *et al.*'s paper at least indicates that violent irradiation of grains existing when the meteorites formed did occur somewhere, and has to be explained. □

HLA and disease

from G. Nicholas Rogentine Jr

> The First International Symposium on HLA and disease was held in Paris on June 23–25. It was organised by J. Dausset and A. Svejgaard. The proceedings will be published as a book.

BASIC and clinical scientists gathered in Paris to try to understand the meaning of the association of HLA antigens with disease. While the meeting did not fully achieve this goal, it did establish clearly that many highly significant HLA antigen frequency perturbations exist in a remarkable variety of human diseases.

HLA antigens are products of genes at four closely linked loci on the sixth chromosome. HLA-A, HLA-B and HLA-C antigens are identified serologically on lymphocytes. These antigens are found on most cell membranes. Products of the fourth locus, HLA-D, are defined by the mixed leukocyte culture reaction; these products or closely related ones also seem to be B-lymphocyte alloantigens.

Most of the exciting new data was presented in the workshops, organised according to disease classification. Well established associations were confirmed and many new correlations were reported. The clearest, all highly significant and involving increases (suggesting a susceptibility to disease) in antigen frequency, were the following: HLA-B27, ankylosing spondylitis, Reiter's syndrome and acute anterior uveitis; HLA-Dw4, rheumatoid arthritis; HLA-Dw2 and HLA-B7, multiple sclerosis; HLA-Dw3 and/or HLA-B8, gluten-sensitive enteropathy, dermatitis herpetiformis, myasthenia gravis (in young females without thyomas), juvenile diabetes, Graves' disease, chronic active hepatitis and Sjögren's syndrome; HLA-B5, Behcet's disease; HLA-A3, idiopathic haemochromatosis; HLA-A2, childhood acute lymphocytic leukaemia; HLA-A2 and SIN2, nasophanyngeal carcinoma in Chinese; HLA-A1, Hodgkin's disease; HLA-Bw40, oesophageal carcinoma in Northern Iranians. In Orientals, who as a race do not have HLA-B8, myasthenia gravis and Graves' disease were associated with HLA-B12 and HLA-Bw35, respectively. Nearly all patients with gluten-sensitive enteropathy and dermatitis herpetiformis are also positive for a B-lymphocyte alloantigen not linked to HLA.

A strong theme unrelated to disease susceptibility emerged from the workshop on malignant diseases: the possession of certain HLA antigens may be associated with long term survival. This has been seen in acute lymphocytic and acute myelocytic leukaemia, Hodgkin's disease, and bronchogenic carcinoma. These observations need confirmation by large scale prospective studies.

What do these associations mean pathophysiologically? As suggested by H. McDevitt (Palo Alto), many correlations could be explained by invoking a pathogenically active immune response gene in linkage disequilibrium with the disease-associated HLA gene, the latter being merely a marker. Linkage disequilibrium is known to occur all along the HLA region and, by analogy with mice, immune response genes probably reside in this area, too. But proof of a human immune response gene does not exist yet. R. Zinkernagel (La Jolla) and G. Shearer (Bethesda) suggested that HLA antigens are directly involved in the disease process by analogy with their findings with mice—the "altered self" hypothesis, in which histocompatibility antigens are modified by viruses or other substances rendering them susceptible to attack by autologous T lymphocytes. A. Svejgaard (Copenhagen) speculated that HLA antigens might competitively inhibit binding of various non-immune ligands, hormones, for example, and in this way provoke disease. F. Lilly's (New York) work with murine Friend virus leukaemogenesis suggests that some D-region H-2 antigens are receptors for leukaemia virus and thus participate directly in disease susceptibility. The mouse D region seems to be analogous with the human HLA-A locus. This locus is implicated in leukaemia, Hodgkin's disease and nasopharyngeal carcinoma.

Although no definite pathophysiological links between HLA and disease have been found, in at least two disorders—gluten-sensitive enteropathy and chronic active hepatitis—they may be discovered soon. Both these diseases have known causal agents and disordered immunity. Both are HLA-Dw3 or HLA-B8-associated.

J. Dausset (Paris) emphasised several areas where these associations might be clinically useful. One interesting area is preventative medicine and early diagnosis Any HLA–disease association necessarily implies a greater risk of developing the disease in a person who has that particular antigen. The relative risk for developing ankylosing spondylitis in HLA-B27 positive Caucasian males is about 90 times that of HLA-B27 negative males. Although most HLA-B27 positives do not develop this disease, nevertheless, they are more likely to do so than the B27 negatives. Knowing these risk factors can help focus awareness on the kinds of diseases most likely to affect each individual during his lifetime. It is not too far-fetched to expect that establishing HLA types will become an integral part of preventative medicine and health maintenance in the future. ☐

A hundred years ago

LIEUT. CHRISTIE, R. E., writing to us from Madras with regard to the use of selenium in telegraphy, says that if we could do away with the man (or woman) signaller, and substitute a commutator actuated by a current of electricity generated by the action of light upon a piece of selenium, we should (supposing the sensitiveness of the selenium to be adequate) have a combination capable of enormously increased rapidity. The message to be transmitted would be first set up (by mechanical means) in the Morse character, in long and short *slits* in an opaque screen; and this perforated screen being passed rapidly between the selenium and a source of light, the currents of electricity would be generated which are required for actuating the commutator. The possibility of such a combination depends on the sensitiveness of selenium to the influence of light. Assuming the combination to be possible, the rapidity of signalling would seem to be limited only by either the mechanical conditions of the commutator (or relay), or the power of the printing instrument at the receiving station.

THE Vienna earthquake, to which we referred last week, occurred on July 17 at 1.22 P.M. The principal seat of the commotion was Scheibbs, a small country place forty miles west of Vienna; almost every house in Scheibbs has been damaged. The area of the commotion was very large, equal to about two-thirds of England. It reached Austria proper, Moravia, part of Bohemia, and Hungary. The last earthquake in Vienna was on January 3, 1873. Fifteen instances of earthquake have been recorded in Vienna from the beginning of the thirteenth to the end of the eighteenth century. None of them produced any real damage, except those of September, 1590, and December 4, 1689.

r, K and evolution

from Peter D. Moore

THERE is a taxonomic imperative in man which makes him delight in pigeon holes and simple labels. One of its most recent products in the ecological field has been the concept of *r* and *K* selection, whereby organisms can be classified along a continuum according to the proportion of their energy expended on reproduction. A high proportion results in a high initial rate of population increase (*r* in the logistic equation describing population growth). In unstable, unpredictable habitats, selective pressures operate in favour of this type of organism, whereas such taxa are at no advantage in stable environments.

Within many groups of organisms it is possible to recognise species which tend towards one end or other of the *r–K* continuum. For example, Southward *et al.* (*Am. Nat.*, **108**, 791; 1974) have considered its application to birds and Lepidoptera, and come to the conclusion that *r*-selected organisms are more likely sources of evolution and speciation than are *K*-selected organisms. Some rapidly evolving plant taxa even seem to have an *r–K* spectrum exhibited within a species or microspecies cluster, for example, in dandelions (Solbrig and Simpson, *J. Ecol.*, **62**, 473; 1974) and in sunflowers (Gaines *et al.*, *Am. Nat.*, **108**, 889; 1974).

Two further examples of this evolutionary process have now come to light, the kidney vetch (*Anthyllis vulneraria*) in Europe and the bigberry manzanita (*Arctostaphylos glauca*) in North America. Sterk (*Acta. bot. neerl.*, **24**, 315; 1975) has examined the population dynamics of coastal and inland populations of *Anthyllis* in the Netherlands. In the open, unstable, coastal sites the population density fluctuated from year to year. Mortality seemed to be related to stresses in the abiotic environment, such as drought, whereas mortality in the inland, stable sites was the outcome of competitive interplay. In the inland sites, fewer flowers were produced per plant than at the coast and flowering began when the plants were older. The data seem to conform with the idea of a relative *r* and *K* selection being operative respectively at the coast and inland sites.

Vasek and Clovis (*Am. J. Bot.*, **63**, 189; 1976) describe two ecotypes of *Arctostaphylos glauca*, one an upright shrub of the chaparral, and the other a low, spreading plant of desert pinyon woodland. Apart from these morphological differences, the two ecotypes differ in their flowering behaviour. The chaparral ecotype produces almost double the number of flowers, is more seasonally constrained in its flowering, and the total amount of fruit produced is about five times that of the desert ecotype. The morphological adaptations of these plants can be related to climatic conditions; fruiting potential may be a consequence of disturbance of the chaparral by frequent fires. In the more stable desert community, vegetative reproduction (by layering) becomes possible and seed production is therefore of lesser importance. Once again it can be argued that these ecotypes represent a genetic divergence in response to *r* and *K* selection in these habitats, but in this case the contribution of vegetative spread to the reproductive capacity of the "*K*-selected" ecotype complicates the issue. Seed production is easily measured so it is tempting to use this as an index of a plant's capacity to expand its population rapidly (high '*r*'). But in many plant species this represents only a portion of the total energy resource devoted to reproduction.

If the selective pressures of stable environments always favour a reduction in seed output, how does one explain the figures of Salisbury (*Proc. R. Soc., Lond.*, **B188**, 183; 1975, and **192**, 323; 1976) concerning seed production in plants? Within a single habitat, such as calcareous grassland, there is a considerable range of seed production per plant, for example, *Thesium humifusum*, produces 100 per plant, *Polygala calcarea*, 270; *Carlina vulgaris*, 680, *Anacamptis pyramidalis*, 35,000; *Senecio jacobaea*, 50,000; *Orchis maculata*, 56,000 and *Orobanche elatior*, 98,000 As Salisbury points out, these figures relate most closely to the relative risks experienced with different mechanisms of seed dispersal, wind being more risky (and therefore more wasteful) than animal dispersal.

Salisbury (1976) quotes *Juncus effusus* and *J. tenuis* as an example of contrasting seed production resulting from the use of different dispersal mechanisms *J effusus* produces between 1 5 and 3 million seeds per plant (wind dispersed) whereas *J. tenuis* produces 3,000–4,000 (adhesion to animals and vehicles). Thus two species of the same genus, both occupying unstable habitats, in the successional sense, differ in their seed production by three orders of magnitude.

Evidently there are several evolutionary answers to any environmental problem. In a given set of conditions, the output of seed from a taxon is influenced by such factors as the relative importance of vegetative reproduction and the seed dispersal mechanism used, as well as any response to the stabiltiy (*r*–*K*) gradient The simplest answers may be the most attractive, but they are not necessarily the most complete ones. □

Aggression in sticklebacks

from John Krebs

THE question of how different types of aggression in animals are related to one another has been a source of continual controversy. Aggressive behaviour in natural conditions is usually seen in competitive social encounters between members of the same species, for example in territorial defence and dominance disputes On the other hand many experimental laboratory studies have been concerned with attacks directed at inanimate objects or at members of another species (for example a rat attacking a mouse). There have been few attempts to examine whether or not aggression in these different contexts depends on a common internal mechanism.

In a recent study F. A. Huntingford (*Anim. Behav.*, **24**, 245–260; 1976) has examined this question. Using that traditional ethological beast, the three-spined stickleback, she carried out a series of experiments to test whether individual males which were highly aggressive in one context would also score high in other situations. It has long been known that a male stickleback will vigorously attack a 'rival' male which is presented to him near his nest in a glass tube. Huntingford used this technique to compare the aggressive response, measured by biting and lunging, to a rival male, a male of the closely related but quite distinct ten-spined stickleback, and a female smooth newt (a common inhabitant of the streams favoured by sticklebacks). Briefly, she found that the aggression scores for individual males to all three stimuli were well correlated. In two further experiments, Huntingford measured the reaction of the same group of males to a predator (a pike) and to being placed in an unfamiliar tank She analysed these results by Principle Components Analysis and was able to identify a group of behaviours which could be classified as indicating 'boldness'; these included approaching the pike and showing normal swimming movements. Individuals which had scored high on the aggression tests also tended to be bold in the face of a predator and in an unfamiliar tank, and this was not simply a result of higher overall activity.

These results suggest that territorial aggression and aggression against predators may depend in part on common internal factors. Huntingford points out that this makes evolutionary sense, because stickleback populations exposed to heavy predation should not only tend to become timid in the presence of a predator, but also make themselves inconspicuous by not engaging in vigorous territorial displays. •

Chemistry does not define environment

from Peter J. Smith

IN the past, many workers have placed great reliance on chemical characteristics as indicators of the geological, and especially crustal, environments in which Archean basalts were emplaced. Some, for example, have seen the lack of crustal contamination observed in low-potassium tholeiites in greenstone belts as an important argument against the presence of sialic crust beneath the successions. Others have regarded the calc-alkaline affinities of certain greenstone basalts as evidence of an original island arc environment. According to Gill and Bridgwater (*Earth planet. Sci. Lett.*, **29**, 276, 1976), however, the use of chemical comparisons between modern basalts and Archean basic rocks to identify ancient environments must now be regarded as a questionable procedure.

Gill and Bridgwater base their case on a study of the Ameralik dykes of West Greenland. This heterogeneous group of metamorphosed minor basic intrusions, emplaced in 3,700–3,600 Myr old gneisses forming part of the western edge of the North Atlantic craton, has been affected variably by subsequent magmatic and tectonic events which enable a lower limit of 3,040 Myr to be placed on the dykes' ages. The total area of older sialic crust cut by the dykes exceeds 12,000 km^2, although there is no *a priori* reason for supposing all the dykes to have been emplaced in a single episode nor any for supposing all the dykes to have been derived from the same parent magma.

And the chemistry of the dykes suggests that any such suppositions would indeed be wrong Although all the dykes studied were basaltic, their compositions ranged from that of primitive basalts reminiscent of modern oceanic basalts to more differentiated types akin to iron-rich tholeiites of modern continental flood basalt provinces. Some of this variation is undoubtedly due to subsequent metasomatism; but Gill and Bridgwater conclude from Rare Earth Element patterns, Ni, Sr, Ti and Zr contents and other chemical indicators that much of it reflects a range of primary compositions.

If this is so, the dilemma is clear. The ridge-like Ameralik basalts, for example, were evidently not intruded into early ocean floor, although had they not equally evidently been intruded into granite gneiss their chemistry could have been taken incorrectly to indicate an oceanic origin. Moreover, these same ridge-like basalts are comparable in composition to greenstone successions in South Africa and Australia and some greenstone belts in the Canadian Shield. It is most reasonable, claim Gill and Bridgwater, to assume that the primary compositional variations represent differences in the depth of melting in the mantle and/or the speed at which the magmas rose to the surface. In other words, the variations reflect changes in the melting régime and/or degree of differentiation rather than differences in crustal environment (oceanic, continental, island arc). Ergo, inferences about crustal environment drawn from chemistry alone must be suspect. □

review article

Analysis of erythropoiesis at the molecular level

P. R. Harrison*

Recent work has clarified how different erythroid functions may be regulated during normal erythropoiesis, and have helped to define the role of the hormone erythropoietin. Studies with cell lines (Friend cells) capable of undergoing erythroid differentiation in culture have made possible a comparison of normal and leukaemic erythropoiesis, by the combined approaches of cell biology, molecular biology and somatic cell genetics.

Normal erythroid systems

ERYTHROPOIESIS has been recognised for many years as a useful model system for investigating how functions characteristic of a specialised differentiated cell are regulated in a coordinate manner within a single cell lineage. It is well established that erythroid cells as well as other blood cell types (almost certainly also including the lymphocyte population) are derived from a common haematopoietic stem cell (CFU-S, Fig. 1), and that commitment of CFU-S cells to a particular haematopoietic lineage is influenced by the microenvironment of particular haematopoietic organs. An elegant demonstration of the importance of such microenvironmental factors in commitment is in the classical experiments by Trentin and coworkers[1] which show that the type of haematopoietic cells formed (granulocytic or erythroid) changes dramatically in colonies growing across the junction of a plug of marrow grafted into spleen tissue The existence of the Steel (*Sl*) mutant in mice also demonstrates how a specific genetic locus can govern microenvironmental function in haematopoietic stem cell proliferation and differentiation, particularly affecting the erythroid lineage[2,3].

After commitment to the erythroid lineage, erythroid stem cells seem to proliferate for a few generations before becoming sensitive to the hormone erythropoietin[4]. An age structure therefore exists within the committed erythroid stem cell population; this is further demonstrated by recent techniques in which erythroid precursor cells are cloned *in vitro*[5–7] In the presence of erythropoietin, two types of colony are produced· the first appears within 2 d of culture and consists of small differentiated erythroid colonies (about 60 cells) which are presumed to arise from late committed erythroid stem cells (CFU-E, Fig. 1) of limited proliferative potential[5,6]. The second type of colony appears later (after about 10 d of culture) but comprises very large numbers (about 10^4) of differentiated erythroid cells[7,8]. These colonies are thought to arise by extensive proliferation of stem cells isolated soon after commitment to the erythroid line (BFU-E, Fig. 1).

Various groups of workers have attempted to analyse the regulatory mechanisms governing how committed erythroid stem cells differentiate to mature red blood cells, using various normal erythropoietic systems, for example, foetal liver during the hepatic phase of erythropoiesis. Recent work now seems to have established beyond reasonable doubt that foetal erythropoiesis is initiated by haematopoietic stem cells migrating from the yolk sac[9], rather than by stem cells originating *in situ* by inductive effects within the foetal liver itself[10] CFU-S stem cells reach maximum numbers in foetal liver from day 14 of gestation[11], whereas stem cells committed to the erythroid line reach a peak at the days 15–16 of gestation (that is at the time of maximum production of red blood cells), after which they decline rapidly[2].

For many years, several groups have sought to analyse the process of erythroid differentiation in molecular terms, using *in vitro* cultures of erythroid cells. It is now generally accepted that erythropoietin acts primarily by increasing the proliferation of committed erythroid stem cells and proerythroblasts which then differentiate into mature erythroid cells containing haemoglobin[12–14]. More recent work by groups at the Beatson Institute and Columbia University (Marks, Rifkind and coworkers) has been concerned with identifying the stage at which the globin genes become active during erythroid development and whether erythropoietin has any effect on the timing of these events. At the Beatson Institute we have tried to elucidate this question by determining the earliest erythroid precursor cell in which globin messenger RNA accumulates, using a novel autoradiographic procedure[15] for detecting cytoplasmic globin messenger RNA in fixed preparations of cells by *in situ* hybridisation with globin cDNA (that is, a highly radioactive transcript of globin messenger RNA prepared using reverse transcriptase). These studies show that globin messenger RNAs accumulate at the basophilic erythroblast stage (Fig. 1), but are not present in significant amounts in proerythroblasts from early foetal livers[16]. This conclusion is also consistent with conventional hybridisation studies[16] with immature erythroid cells obtained from total foetal liver cells by removing mature cells by immune lysis using an antiserum raised against erythrocytes[17,18]. Subsequent studies by the Beatson group have shown that elevated levels of erythropoietin enhance the accumulation of globin messenger RNAs in proerythroblasts, both in developing foetal livers *in vivo* or in culture *in vitro*, and in spleens of anaemic adult mice[19]. As suggested by Clissold[20], this result may explain her finding that immature erythroblasts isolated from severely anaemic rabbits, but not normal rabbits, are able to differentiate in culture without erythropoietin. This effect of elevated erythropoietin levels can have the result that globin messenger RNA and subsequently haemoglobin accumulate earlier than normal relative to other morpho-

---

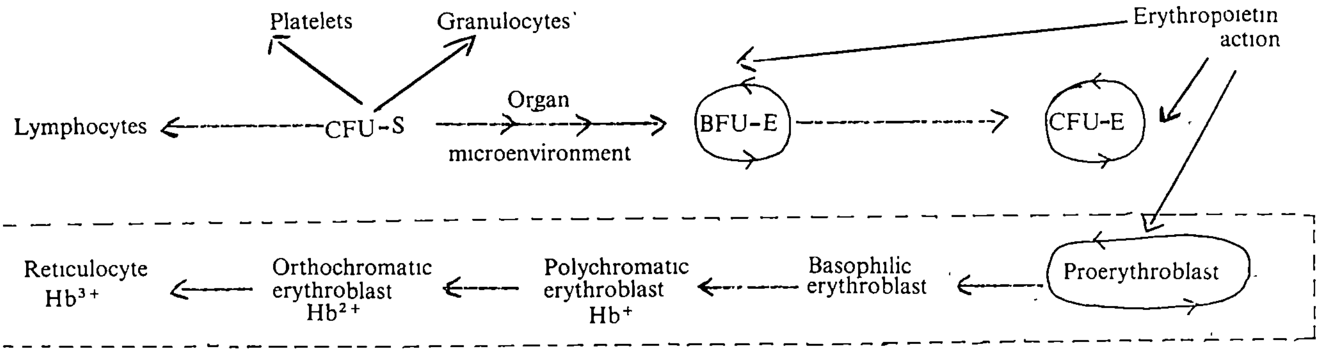

Fig. 1 Outline of formation of erythroid cells. Hb^{+}–Hb^{3+} cells containing increasing amounts of haemoglobin. The cell types in the dotted box represent the recognisable erythroid series.

logical criteria, so that an atypical series of macroerythroblasts may be formed[13,14] similar to that found in certain megaloblastic anaemias[21].

Independently, the Columbia group has arrived at basically similar conclusions. Immature erythroid precursor cells (80–90% proerythroblasts[22]) from foetal liver cells isolated by the immune-lysis procedure, contain negligible globin messenger RNAs as assayed either by translation in the Krebs ascites system[23] or by hybridisation with globin cDNA[24]. After culture of such cells for 10 or 22 h, however, the cellular level of globin messenger RNAs increases 5 or 100 times[24] during which time most of the cells differentiate to the basophilic erythroblast stage[22] and begin to synthesise globin chains[23], although haemoglobin is not detectable cytochemically until 44 h of culture[24]. These studies, therefore, also support the hypothesis that globin messenger RNA accumulation is enhanced between the proerythroblast and basophilic erythroblast stages of development; and further show that there is no pool of untranslatable globin messenger RNA in immature erythroid cells. However, the Columbia group find that treatment of cultures with erythropoietin does not increase the average cellular content of globin messenger RNA; although the number of globin messenger RNA-containing cells is greatly increased[24]. The explanation for this discrepancy may be in the doses of erythropoietin, or the degree of anaemia, involved in the two series of experiments.

The Friend cell system

Studies with normal erythropoietic systems are limited by the difficulties of obtaining large numbers of erythroid cells at specific stages of development, the short term nature of the *in vitro* culture systems, and the impossibility of performing genetic studies. The discovery by Dr Charlotte Friend of tissue culture cell lines which are capable of undergoing erythroid differentiation has therefore opened up new possibilities.

Friend cells were obtained by culturing fragments of spleens from mice infected with the Friend virus complex[25]. The nature and host control of Friend virus infection have already been reviewed in considerable detail[26,27] and will not be further considered here in spite of their importance and relevance. In interpreting any studies with Friend cells, it is, however, important to be clear about their relationship to normal erythroid precursor cells. Although this is still to some extent a subject of controversy[28], it seems most probable that the target cell for Friend virus is a late committed erythroid stem cell (CFU-E, Fig. 1). Two recent and compelling lines of evidence favour this hypothesis. First, the elimination of multipotential, but not erythroid committed stem cells, does not eliminate Friend virus-induced proliferation of erythroid cells in the spleens of polycythaemic mice; whereas no response to Friend virus is observed in mice in which the committed erythroid cell compartment has been depressed[29] Second, inoculation of lethally irradiated mice with normal spleen cells gives rise to erythroid, granulocytic and megakaryocytic colonies in the spleen; however, infection of such mice with Friend virus four days after grafting yields in addition hyperbasophilic (Friend cell) colonies solely within the differentiated erythroid colonies[10], although all types of haematopoietic colonies in the spleen are known to contain multi-potential stem cells[1]. Thus, although the number of non-erythroid cell types may also be affected[31], Friend virus seems to have specific effects on committed erythroid cells, rendering them capable of proliferation and differentiation independently of the hormone erythropoietin[32–34]. Friend cell lines established in culture seem to be transformed erythroid precursor cells selected by the culture conditions (or otherwise) which are arrested at the proerythroblast stage of development[25], and are not responsive to erythropoietin[35–37]. In this respect, Friend cells are therefore quite different from normal erythroid precursor cells. In fact, there is one report that Friend cells grown *in vivo* or in plasma clots *in vitro* do show manifestations of granulocytic differentiation[38], but this remains to be substantiated.

On treatment with dimethylsulphoxide (DMSO)[39] or a range of other chemical agents[40–43], Friend cells undergo a series of changes many of which are characteristics of normal erythroid cell differentiation; for example: chromatin condensation and other morphological changes resulting in a non-dividing cell[39]; accumulation of globin messenger RNAs[44–46] and strain-specific globins[47,48], increase in δ-aminolaevulinic acid synthetase activity[49] and haem synthesis[39]; erythrocyte-specific membrane changes[50,51] and an increase in the major erythrocyte-specific membrane protein (H. Eisen, personal communication); and an increase in carbonic anhydrase activity[52]. Changes in histone F2A2 subfractions also occur[53]. Thus, although Friend cells are abnormal in their dependence of the hormone erythropoietin, in certain conditions they do exhibit many characteristics of normal erythropoiesis.

Recently, Orkin *et al.*[54] have shown that during treatment of Friend cells with DMSO the ratio of α to β globin mRNAs decreases from about 3.5 to about 1.0, the value characteristic of the normal erythrocyte. Our own hybridisation studies performed with purified normal erythroid precursor cells[16], and also those of the Columbia University group[24], suggest, but do not prove definitively, that this differential timing of expression of the α and β globin genes is not a characteristic of normal erythroid cell development.

The mechanism whereby the various inducers of erythroid differentiation operate is not clear. Sieber[55] has made the interesting observation that DMSO enhances the sensitivity of normal CFU-Es, but not BFU-Es, to non-saturating doses of erythropoietin. This result may be related to the finding that Friend cells seem to be marginally sensitive to erythropoietin after DMSO treatment[35]. Certainly, membrane function seems to be involved since local anaesthetics prevent the action of all inducers of erythroid differentiation so far tested without affecting proliferation of Friend cells[56] *per se*.

Several circumstantial lines of evidence suggest that induction of differentiation in Friend cells requires some cell-cycle dependent process. McClintock and Papaconstantinou[57] have observed a correlation between the cell doubling time and the time of onset of haemoglobin synthesis. But Levy and his coworkers[18] made the surprising observation that treatment of Friend cells for 24–30 h is required before the intracellular space is equilibrated with respect to DMSO in the culture medium. Nevertheless, their results with synchronised Friend cells also suggest that the cells do require at least one period of DNA synthesis in the presence of DMSO for haemoglobin to be induced. In contrast, using a Friend cell line of independent origin (T3C12), Leder and Leder[19] have reported that the inhibition of DNA synthesis with hydroxyurea does not prevent the induction of haemoglobin by butyric acid.

We (P. R. H, D Conkie, A Wood, G. Yeoh and J. Paul, unpublished) have attempted to examine this problem at the single cell level, by cloning various Friend cell lines in methocel. In these conditions, most of the cells in clones grown in the presence of various inducers (DMSO, *N*-methylopyrrolidone, *N*-methylacetamide or butyric acid) produce haemoglobin within 3–4 d. Clones arrested at the single-cell stage by the action of hydroxyurea or cytosine arabinoside, or by omission of isoleucine from the culture medium, however, fail to produce haemoglobin; whereas many of the doublet colonies (or binucleate single cells) in the same cultures do produce haemoglobin. Moreover, single cells arrested for 3 d in inducer in the absence of isoleucine do proliferate and produce haemoglobin 4 d after addition of isoleucine. Thus, it seems quite clear that induction of haemoglobin synthesis in our Friend cell lines (which were obtained from Dr C. Friend as were those of McClintock and Papaconstantinou and Levy *et al.*) are dependent on some process within the cell cycle, but that this does not necessarily involve asymmetric division since in many of the doublet colonies both daughter cells contain haemoglobin. Our studies with the T3C12 cell line seem to suggest, in agreement with the findings of Leder and Leder[59], that a considerable proportion of butyric acid-treated cells arrested with hydroxyurea can produce haemoglobin. Interestingly, in our experiments many of these haemoglobin-containing single cells are in fact binucleate. Thus the discrepancies between the various groups of workers may be more apparent than real, if some process before, or associated with, nuclear division is required for differentiation. Alternatively, butyric acid may act differently from the other inducers; it is also possible that the T3C12 cell line may have been transformed by Friend virus at a later stage of development. Resolution of this question is clearly of importance in elucidating whether, and at what stage, a critical cell division is involved in erythroid cell differentiation.

Friend cell lines are also a useful system in which to attempt more sophisticated molecular and genetic studies of erythroid differentiation. In our own laboratory, a three-stage strategy has been adopted. The first is to obtain stable non-inducible variants, second, these variants are then screened to find out at what molecular level erythroid differentiation is affected; and third, variants are subjected to genetic analysis by cell fusion. By exploiting the fact that the inducible cells differentiate to a non-dividing stage in the presence of DMSO, we can isolate non-inducible variants by continuous growth or cloning in DMSO[60] Most of our DMSO-resistant lines are also non-inducible by other inducers, although one DMSO-resistant line does respond to *N*-methylpyrrolidone. One DMSO-resistant variant (FtI^{D-}) fails to accumulate globin-specifying sequences in the nucleus, either because of a defect in transcription of the globin genes or instability of the transcripts[61]. Moreover, this defect acts in a *trans*-dominant manner in preventing haemoglobin or globin RNA accumulation in cell hybrids constructed between the FtI^{D-} variant and the normal inducible parent. A second variant, FwI^{D-}, also fails to accumulate haemoglobin[60] or globin messenger RNAs[61] in response to DMSO or butyric acid, unless it is also treated with haemin[61]. This effect of haemin is specific for the FwI^{D-} variant, and cannot be replaced by a precursor to haem (δ-aminolaevulinic acid). Moreover, this defect in inducibility also operates in a *trans*-dominant manner, although loss of a few, as yet unidentified, chromosomes can lead to re-expression of haemoglobin synthesis[61,62]. Extinction of induction of globin messenger RNA has also been reported by Orkin *et al.*[63] in hybrids constructed between high and low inducible cell lines and by Deisseroth *et al.*[64] in cell hybrids between Friend cells and fibroblasts. Interestingly, however, hybrids between Friend cells and human bone marrow or Chinese hamster erythroid cells could be induced to synthesise globins of both parental types, although in these intraspecific hybrids, extensive segregation of human or Chinese hamster chromosomes had occurred[65]. Thus the general picture which emerges from these studies is that when a Friend cell is fused to a non-inducible, or non-erythroid, cell, extinction of induction of haemoglobin production occurs. This result is similar to that obtained with other differentiating systems (reviewed in refs 66 and 67). Often it has been assumed that extinction of differentiation is due to a negative control system analogous to the bacterial repression systems acting at transcription. In none of these cell fusion experiments cited, however, has it yet been proven that extinction acts at the transcriptional level. For example, although in our own studies we have demonstrated that extinction of haemoglobin synthesis in certain cell hybrids acts at the nuclear level, it has not yet proved possible to demonstrate that globin gene transcripts are not synthesised.

That regulation of differentiation can operate at different molecular levels is illustrated by our molecular analysis of a hybrid cell formed between the Friend cell and the lymphoma cell. This hybrid cell shows extinction of induction of haemoglobin and morphological differentiation, although globin messenger RNA is inducible[61]. Both functions are, however, expressed on treatment with haemin in addition to DMSO[61]. The precise role of haem in this process requires clarification, for example, by studies of factors in Friend cells analogous to the haemin-controlled repressor in reticulocytes[68]. Furthermore, it is not yet known whether this phenomenon is a property merely of this lymphoma cell line, of lymphoma cells in general or of normal lymphoid cells. But this interesting observation illustrates at the molecular level the diversity of control mechanisms which affect regulation or erythroid differentiation and shows how complex interactions may exist between independent erythroid functions.

Perspectives

The experiments described in this article give some indication of the possibilities of normal erythroid cells and particularly the Friend cell system as a model of a differentiating cell, in which to attempt to dissect the regulatory mechanisms by a combination of cellular, molecular and genetic approaches. It may, therefore, be useful to take a sober look at some of the limitations of the system. The Friend cell is a transformed cell and its relevance as a model for normal differentiation must, therefore, be evaluated critically· as mentioned above, Friend cells seem to be abnormal in that their proliferation is no longer regulated by erythropoietin as in the normal erythroid precursor cell; but differentiation, once it is induced, seems to be relatively normal. Second, the Friend cell is derived from cells transformed after commitment to the erythroid line and the events induced by DMSO may, therefore, be relevant only to the later processes of erythroid differentiation. The important question of the molecular nature of the events concerned with commitment of haematopoietic stem cells to the erythroid line probably cannot be answered with the Friend cell system. Hope that this may prove possible in the future stems from the work of Dexter and colleagues[69], who have been able to maintain multi-potential stem cells in culture using an appropriate feeder layer. Another promising approach for the future lies in differentiation of teratocarcinoma cells (reviewed in ref. 70) which various groups of workers have recently shown to behave like normal germ cells when transplanted into the environment of the normal embryo at the blastocyst stage of development[71,72]. It may prove possible to mimic commitment of stem cells to the erythroid line with normal haematopoietic stem cells or teratocarcinoma cells cultured in the appropriate environment. Application to these systems of the kind of molecular/genetic analysis developed for the Friend cell system could then increase enormously our understanding of the relationship between commitment to the erythroid line and subsequent differentiation.

Accretion flows in the magnetospheres of Vela X-1, AO535+26 and Her X-1

R. F. Elsner

We suggest a model for the complex pulse shapes of the long period, pulsating X-ray sources, Vela X-1 and AO535+26. We discuss the flow of accreting matter on to these slow rotators and contrast it with that expected in systems such as Her X-1 which contain a rapidly rotating neutron star.

THE recent discovery of the pulsating X-ray source AO535+26 (ref. 1) and unexpected detection of X-ray pulsations in the relatively well studied binary source Vela X-1 (ref. 2) have aroused considerable interest, in part because their pulse periods (104 s in AO535+26 and 283 s in Vela X-1) and very complex 1–10 keV pulse shapes (refs 2, 3) are strikingly different from those of the previously identified pulsating X-ray sources Her X-1 and Cen X-3, which are believed to be rotating neutron stars (see refs 4 and 5).

Several pieces of evidence indicate that in spite of these differences, Vela X-1 and AO535+26 may also be rotating neutron stars. Optical and X-ray observations yield a probable lower bound of $1.4M_\odot$ on the mass of Vela X-1 (ref. 6, and references therein), very close to the upper mass limit for slowly rotating white dwarfs. If Vela X-1 is at a distance $D \sim 1.3$ kpc (refs 6, 7), it has a typical X-ray luminosity $L_x \sim 0.2\text{–}2\times10^{36}$ erg s^{-1} (ref. 2). The distance to AO535+26 is as yet unknown, but its 1975 May high state intensity was comparable with that of the Crab Nebula[3], implying $L_x \gtrsim 3\times10^{36}$ erg s^{-1} if $D \gtrsim 1$ kpc. Such high luminosities are incompatible with current models of X-ray emission by degenerate dwarfs (see ref. 8). The long rotation periods of these sources may be the result of spin down by a combination of magnetic torques and interaction with surrounding plasma[9], or the result of spin down in the pre-supernova star, leading to formation of a few neutron stars with spin periods as long as $10\text{–}10^3$ s (ref. 10).

Our purpose is, first, to suggest that the complex pulse shapes of Vela X-1 and AO535+26 in the energy range 1–10 keV can be understood if both are slowly rotating neutron stars in which broad, smooth emission pulse shapes, like those seen at 15–30 keV, are modified as the result of cyclotron absorption by clumps of matter entrained in magnetic field irregularities near the stellar surface.

Second, we suggest that accretion flows in the magnetospheres of rapidly rotating neutron stars, such as Her X-1 and Cen X-3, are different from those in slow rotators, and that the observed properties of these sources reflect this difference. In slow rotators accreting plasma probably enters the magnetosphere as a consequence of the Rayleigh–Taylor instability of the magnetospheric boundary (ref. 11), and may plunge close to the surface of the star before being channelled towards polar emission regions by the stellar magnetic field. In fast rotators, on the other hand, the near cancellation of gravitational and centrifugal forces at the magnetospheric boundary may lead to accumulation of matter there, and to more effective channelling of plasma towards the polar caps while it is still far from the star.

We discuss the observational implications of this model of accretion flows, and draw attention to ways in which the differences between fast and slow rotators can be explored observationally.

Accretion by slow rotators

Consider first accretion by slowly rotating neutron stars. Let us assume for the moment that accreting matter approaches a star of mass M approximately radially; at a radius r_s from the star it is shock heated to a temperature $T_s \sim T_{ff}(r_s)$, where

$$T_{ff}(r) = GMm_p/k_Br = 1.6\times10^{10}(M/M_\odot)(r/10^8\text{ cm})^{-1}\text{ K} \quad (1)$$

in terms of the proton mass, m_p. The radius r_s at which shock heating occurs is determined by the radius, r_A, of the Alfvén surface, where the Alfvén velocity v_A in the stellar magnetic field equals the plasma inflow velocity, v, and the magnetic field of the star first dominates the flow[12]. Regardless of the complexity of the magnetic field near the surface of the star, at large distances the stellar field will be dominated by its dipole component; for spherically-symmetric, radial free-fall towards a star with dipole moment μ_{30}, in units of 10^{30} gauss cm^3, r_A has the characteristic value

$$r_A{}^0 = 2.9\times10^8\,\mu_{30}{}^{4/7}\,(M/M_\odot)^{1/7}\,L_{37}{}^{-2/7}\,R_6{}^{-2/7}\text{ cm} \quad (2)$$

Here L_{37} is the accretion luminosity in units of 10^{37} erg s^{-1} and R_6 is the stellar radius in units of 10^6 cm. The effect of the star's rotation on the accretion flow can, to a first approximation, be neglected if the angular velocity of the star, Ω_s, satisfies $\Omega_s \ll \Omega_k(r_A) = (GM/r_A{}^3)^{1/2}$ or, equivalently, $r_A \ll r_c \equiv (GM/\Omega_s{}^2)^{1/3}$ (ref. 12). This is the condition for 'slow rotation'.

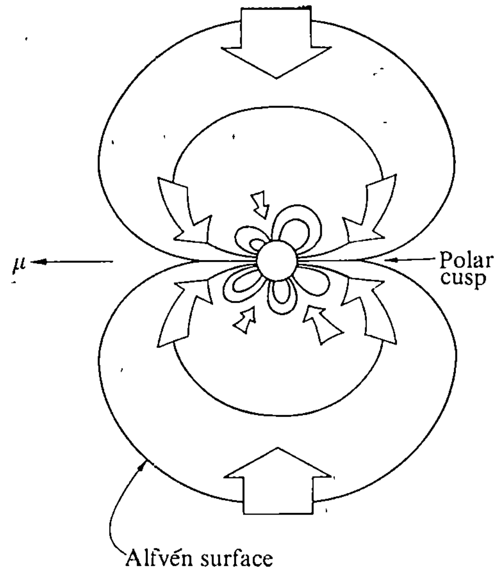

Fig. 1 Suggested plasma flow pattern in slow rotators with complex surface magnetic fields. Plasma enters the magnetosphere as the result of the Rayleigh–Taylor instability of the magnetospheric boundary and plunges close to the stellar surface before being channelled by the stellar magnetic field. Most of the plasma is channelled towards the polar caps, but some flows along field lines that lead to other parts of the stellar surface.

The flow of highly conducting plasma towards the star tends to close the magnetosphere (ref. 12). Since the magnetospheric boundary is convex towards the accreting plasma, the gradient of the field is such as to stabilise the boundary. Nevertheless, the weight of the plasma will drive the boundary locally Rayleigh–Taylor instable if

$$g_{eff} = \cos\theta GM/r_m{}^2 - \kappa B_m{}^2/4\pi\rho_m > 0 \quad (3)$$

Here θ is the angle between the radius vector and the outward normal to the boundary, r_m is the exact radius of the magnetospheric boundary ($\sim r_A$), B_m and ρ_m are the stellar magnetic field and plasma density at the boundary, $\kappa \sim 1/r_m$ is the curvature of the boundary, and we have neglected radiation pressure forces. If the boundary is in magnetohydrostatic equilibrium, one has $B_m{}^2/8\pi = n_mk_BT_m$, where n_m and T_m are the particle density and temperature in the plasma just outside the boundary. Thus, the condition for the onset of the Rayleigh–Taylor instability can be written

$$T_m < T_{crit} = \cos\theta T_{ff}(r_m)/(2\kappa r_m)$$

where B_m, r_m, and κ are roughly independent of T_m.

Detailed model calculations show that in the absence of cooling, the weight of the plasma is insufficient to drive the boundary unstable (Elsner and Lamb, to be published; see also ref. 13). These calculations show further that instability sets in when the plasma at the boundary has cooled to a temperature $T_{crit} \sim 0.3T_{ff}(r_m)$, and that $T_{crit}/T_{ff}(r_m)$ is largest at the magnetic equator. Once instability occurs, plasma may penetrate the magnetosphere over much of the magnetospheric boundary except at the axes of the polar cusps, where the boundary is stable. Unfortunately, there are at present no reliable calculations of the properties of the fully developed Rayleigh–Taylor instability in the nonlinear regime, and the precise boundary condition to be imposed on the flow at r_m is therefore unknown. Therefore we adopt the simplest boundary condition that gives a qualitatively correct flow solution: since the growth of the Rayleigh–Taylor instability is rapid and other modes of plasma entry are relatively ineffective, we shall assume that, in a steady state, the region of shock-heated plasma extends a distance Δ_s outside r_m such that T_m is less than but of order T_{crit}.

If the neutron star accretes plasma from a disk, the flow may still resemble in certain respects the flow just described. Thus if the disk thickens near r_A and the flow becomes roughly

Table 1 Characteristics of fast and slow rotators

Source property	Slow rotators ($r_A \ll r_c$)	Fast rotators ($r_A \simeq r_c$)
Period changes	Either spin up or spin down, but not both, unless disk flow reverses	Spin down as well as spin up, even if disk flow does not reverse
t_s	$\sim t_s^0$ for disk inflow	$\gg t_s^0$ even for disk inflow
Spectrum	Intense soft ($\sim$0.1 keV) component not expected	Intense soft ($\sim$0.1 keV) component possible
Pulse shapes	More complex at lower energies, simpler at higher energies	Simpler at all energies

spherically symmetric there, the flow outside the magnetosphere should resemble the post-shock flow described above. Even if the disk remains thin, the Rayleigh–Taylor instability may well play an important role in allowing the relatively cold disk plasma to penetrate the magnetosphere.

Of particular relevance for the present discussion, recent research on two-dimensional models of accretion disks around magnetic stars (ref. 14 and Ghosh, Lamb, and Pethick, in preparation) suggests that radial flow velocities $v_r \sim v_{ff}$ in the neighbourhood of r_A are a general feature of disk accretion by slow rotators (if shear stresses are large, v_r may become $\sim v_{ff}$ outside the magnetospheric boundary; in any case one expects $v_r \sim v_{ff}$ inside the magnetosphere). If this is the case, one expects $r_A \sim r_A^0$ even for disk inflow[12] and, for disks rotating in the same direction as the star, a spin up timescale, t_s, of order

$$t_s^0 = \frac{I\Omega_s}{(MGMr_A^0)^{\frac{1}{2}}} \tag{4}$$

where I is the star's moment of inertia and M is the mass accretion rate.

For sources with luminosities $L \gtrsim 10^{36}$ erg s^{-1}, the optical depth to Compton scattering of shock-heated plasma outside r_A is

$$\tau_c \simeq 0.03\left(\frac{r_A}{10^8\text{cm}}\right)^{-4/5}\left(\frac{M}{M_\odot}\right)^{1/5}\left(\frac{\ln\Lambda}{15}\right)^{-2/5} R_6^{3/5} \tag{5}$$

where $\ln\Lambda$ is the Coulomb logarithm, $\sim$ 15 at r_A. Thus, in slow rotators the rapid development of the Rayleigh–Taylor instability and the large inflow velocities at r_A imply that there is little plasma there to absorb and reradiate keV X rays produced at the stellar surface. An intense soft component ($\varepsilon \sim 0.1$ keV) is therefore not expected in the spectrum of slow rotators.

Pulse shapes

Although the Rayleigh–Taylor instability causes plasma to penetrate the magnetosphere 'between' stellar field lines, the plasma is unlikely to be effectively channelled along these field lines until it is threaded by them; this can occur either by diffusion of the infalling plasma on to stellar field lines or by reconnection of magnetic field lines embedded in the infalling plasma to stellar field lines. If cooling is rapid and threading occurs relatively slowly, the plasma may fall to within a few stellar radii of the star's surface before being funnelled towards the magnetic poles. If in addition the topology of the stellar surface field is complex, with numerous flux concentrations at points other than the poles of the dipolar component of the field, the flow pattern of plasma near the stellar surface may be similar to that shown schematically in Fig. 1.

How long can small scale magnetic flux concentrations be expected to survive in the crust of a neutron star? If the crustal conductivity is σ, such concentrations will decay away on a time scale

$$t_d \simeq 4\pi\sigma l_m^2/c^2 = 4\times10^6\,(l_m/10^5\,\text{cm})^2\,(\sigma/10^{24}\,\text{s}^{-1})\,\text{yr} \tag{6}$$

assuming they go to a depth $\sim l_m$. To be present now, they may have had to survive for an evolutionary timescale $t_{ev} \sim 10^6$ yr (ref. 15), which would require $\sigma \gtrsim 3\times10^{23}$ s^{-1} if $l_m \sim 10^5$ cm. Now the temperature of the stellar surface must be $\lesssim 10^6$ K, since otherwise it would be seen as an intense source of soft X rays, and the temperature in the crust itself may be similar. Recent calculations of crustal conductivities[16] show that at this temperature, field decay in the crust from electron–phonon interactions would be entirely negligible after 10^6 yr, while that from electron–charge disorder interactions would be negligible except in lighter stars ($M \lesssim 0.5\,M_\odot$) whose crusts are as impure as possible. Decay from scattering off dislocations can also be neglected unless the distance between dislocations is microscopic. Thus, it is entirely reasonable that a large proportion of neutron star X-ray sources may have complex surface magnetic fields.

Since the dipole component of the field is dominant except within a few stellar radii of the surface, most of the matter will still be channelled to the polar caps, as in purely dipolar models, and most of the keV X-ray emission will come from hot spots there, producing broad, smooth pulses at energies $\varepsilon \gg \hbar\omega_c \simeq 10B_{12}$ keV, where B_{12} is the surface field in units of 10^{12} gauss and $\omega_c = eB/m_ec$ is the electron cyclotron frequency. A small fraction of the accreting plasma is, however, likely to be channelled along field lines that lead to other parts of the stellar surface. Then, as the star turns, the broad emission pattern from the polar hot spots will be seen through varying amounts of cyclotron-absorbing plasma, producing complex waveforms at energies $\varepsilon \sim \hbar\omega_c$.

For surface field strengths $B \sim 10^{11}$–10^{12} gauss and temperatures $k_BT \sim 10^7$–10^8 K one has $\hbar\omega_c \sim k_BT$, and the quantum-mechanical expression[17] for the cyclotron cross section must be used. The optical depth through a clump of dimension size l_c at $\varepsilon = \hbar\omega_c$ is

$$\tau_{cyc} = \frac{l_c\omega_{pe}^2}{c\omega_c}\left(\frac{\pi m_ec^2}{2k_BT}\right)^{1/2}\frac{1}{1-\exp(-\hbar\omega_c/k_BT)} \tag{7}$$

where ω_{pe} is the electron plasma frequency. Thus one has $\tau_{cyc} \gtrsim 1$ for column densities $\rho l_c \gtrsim 2.9\times10^{-5}B_{12}T_8^{1/2}$ g cm^{-2}, where $T_8 = T/10^8$ K. For clumps of dimension $l_c \sim 10^5$ cm, this represents a density only $\sim 10^{-3}$ that above the polar caps.

In the absence of absorption processes, cyclotron scattering, in which an electron makes a transition from one Landau orbital to the next higher one and back again, is likely to dominate, and will create an anisotropic angular distribution of the radiation emitted by the polar caps without significantly altering its energy distribution. For example, if there are N clumps of size $l_c \sim 10^5$ cm at a distance $d \sim 10^6$ cm from a polar cap, then when a clump is in the line of sight, the X-ray flux at energy ε from that polar cap will be reduced to a fraction $f \sim N(l_c/d)^2 \sim 0.01\,N$ of its value when the line of sight lies between clumps, assuming $\exp(-\tau_{cyc}(\varepsilon)) \ll f \ll 1$. On the other hand, if the energy falling on the clumps were thermalised and then reradiated, the temperature T_c of the clumps would be a factor $\sim (l_p/d)^{1.2} \sim 0.3$ lower than that of polar caps of dimension l_p, and the energy distribution as well as the angular distribution would be altered. In either case the spectrum would appear heavily 'absorbed' at low points in the pulse waveform.

Vela X-1 and A0535+26

If A0535+26 and Vela X-1 are magnetic neutron stars with spin periods, P, of 104 and 283 s, respectively, then both are probably slow rotators. Using the estimate (2) for r_A^0, the condition $r_A^0 \ll r_c$ becomes $L \gg L_{crit}$, where

$$L_{crit} = 1.0\times10^{38}\,P^{-7/3}\,\mu_{30}^2\,(M/M_\odot)^{-2/3}\,R_6^{-1}\,\text{erg s}^{-1} \tag{8}$$

a condition which is easily satisfied by Vela X-1, and by

AO535+26 if it has an accretion luminosity $L \gtrsim 10^{35}$ erg s^{-1}, assuming $\mu_{30} \sim 1$. (Note, however, that $L_{\rm crit}$ depends sensitively on μ.)

Consider now some of the observational implications of the hypothesis that these sources are slowly rotating neutron stars:

(1) If there is a Keplerian accretion disk around the magnetosphere and the disk rotates in the same direction as the star, the star should spin up on a timescale $\sim t_s^0$, with $\dot{P}$ proportional to L. Changes from spin up to spin down should not occur as the result of accretion torques unless the flow departs from this pattern. In the absence of disk flow, t_s should be $\gg t_s^0$, while a reversed disk could lead to spin down on the timescale t_s^0. (Were these sources degenerate dwarfs, the timescale t_s^0 would be very much longer, since I would be $\sim 10^6$ times larger.)

(2) Because little plasma accumulates near r_A, intense soft X-ray emission is not expected.

(3) If the complex 1—10-keV pulse shapes arise from scattering or absorption by clumps of matter entrained in complex magnetic fields near the stellar surface, as we have suggested, the number and positions of the basic features in time-averaged pulse waveforms should remain fixed, since the field configuration is fixed, although the sizes of various features may change if the flow pattern of the plasma approaching r_A changes. (Were the features instead caused by random clumping of the infalling plasma, independent of the surface field geometry, they should average out on timescales of minutes. Such complicated pulse shapes also seem unlikely to be the result of complex variations in $\dot{M}$ controlled at the magnetospheric boundary[12] since it is there, at $r \gg R$, that the stellar field should be most symmetric; moreover, in slow rotators plasma is likely to enter the magnetosphere over a substantial fraction of its surface, at least in the absence of strong X-ray beaming effects.)

We note that the narrowness of some of the features (in AO535+26, for example, some have widths $\leqslant 0.05$ in pulse phase) favours an interpretation in terms of scattering or absorption rather than beaming, since such narrow features are unlikely to be produced by beaming in quasi-thermal sources such as these, but can easily be produced by absorption if the absorbing clumps are small, close to the stellar surface, and have sizes comparable with those of the polar cap emitting regions

(4) If the features at 1–10 keV are caused by cyclotron scattering in plasma clumps a distance $\sim d$ above the surface and d is $\sim 10^5$ cm, then the surface fields in both stars must be $\sim 10^{12}$–10^{13} gauss. Above 15 keV the polarisation should change smoothly across the pulses (see ref. 19); below 10 keV the polarisation should change smoothly across a given peak in the waveform, but could change abruptly from one peak to the next, since it is the result of absorption of smoothly varying polarised emission at the polar caps by clumps of matter whose absorption polarisations may differ significantly from one to another.

Comparison with fast rotators

We have seen that many of the properties of Vela X-1 and AO535+26 can be understood if they are slowly rotating neutron stars. For comparison, let us consider briefly how the properties of fast rotators, in which $r_A \simeq r_c$, might be expected to differ from those of slow rotators

If a fast rotator is fed by an accretion disk around its rotation equator, rotating in the same sense as the star, the force of gravity at the disk–magnetospheric boundary will be largely cancelled by centrigufal forces; as a result the growth rate of the Rayleigh–Taylor instability will be reduced and the plasma will fall inward between stellar magnetic field lines more slowly. Thus there will be more time for the accreting plasma to become threaded by stellar field lines far from the stellar surface, perhaps helped along by the Kelvin–Helmholtz instability (see also ref. 13), and channelling of the flow by the stellar field is therefore likely to occur at $r \gg R$. Finally, since the dipolar component of the field dominates at $r \gg R$, the flow is likely to be more effectively funnelled towards the two polar caps than in slow rotators.

If this difference in the accretion flow does occur, it will be reflected by the properties of such sources:

(1) If an extreme fast rotator is surrounded by a Keplerian accretion disk rotating in the same direction as the star, the accretion torque caused by material stresses at r_A can be largely cancelled or even reversed by magnetic and viscous stresses. Thus, even if such a source is disk fed, the average spin up timescale should be longer than t_s^0, and occasional episodes of spin down would be expected.

(2) If the infall of plasma is significantly slowed by near cancellation of gravity by centrifugal forces, a substantial quantity of matter may accumulate near r_A, producing a soft X-ray component in the spectrum by reprocessing keV X rays emitted at the stellar surface[5]. If sufficient matter accumulates, the pulsed fraction in the energy range 0.1–1 keV will be reduced, and the pulse phase in general shifted from that at 1–10 keV.

(3) If the slowly infalling plasma is effectively channelled along stellar field lines far from the star's surface, essentially all of the plasma may be funnelled towards the two polar caps, producing broad, smooth pulses throughout the keV energy range.

These expected properties of fast rotators surrounded by accretion disks are well illustrated by Her X-1, which has a spin period of 1.24 s. Assuming $M = 1.3 M_\odot$ (ref. 20), $R_6 = 1.5$ (ref. 21), and $L_{37} = 5.8$, appropriate to a distance of 6 kpc (ref. 7), equation (2) gives $r_A^0 \sim r_c$ for $\mu_{30} \sim 1$, indicating that Her X-1 is indeed a fast rotator. Even though Her X-1 is believed to be surrounded by a Keplerian accretion disk[6] it shows episodes of spin down as well as spin up[4]. Moreover, the observed average spin up time, 3×10^6 yr (ref. 22), is a factor ~ 40 longer than the slow-rotator estimate (4), if $I \simeq 2 \times 10^{45}$ g cm^2 (ref. 21). This factor is too large to be accounted for by uncertainties in I or in r_A (since $t_s^0 \propto r_A^{-1/2}$, r_A would have to be a factor $\sim 10^3$ smaller than our estimate), and is strong evidence that material stresses at r_A are closely cancelled by magnetic and viscous stresses. In addition, there is an intense soft X-ray component in the spectrum of Her X-1 (ref. 23) that has been interpreted in terms of a centrifugally-supported opaque shell of accumulated matter partially surrounding the neutron star magnetosphere (ref. 24; reprocessing by plasma at the magnetospheric boundary has also been mentioned in ref. 25). Such an accumulation of matter cannot be supported by magnetic forces or radiation pressure since it would be Rayleigh–Taylor instable on a dynamical timescale. Finally, the pulse waveforms seen in Her X-1 are comparatively simple throughout the energy range 1–30 keV, as would be expected if all the accreting plasma were funnelled towards the two polar caps. (Alternatively, these simple pulse shapes could arise simply from the absence of complex surface magnetic fields in Her X-1, but we believe this possibility is less likely.)

If a fast rotator is fed by more nearly radial inflow, or by a disk which is not aligned with the stellar rotation, the accretion flow is likely to be more complicated with a possibility of centrifugally-supported matter in the rotation equator and rapid inflow near the rotation axis.

Discussion

We have suggested that Vela X-1 and AO535+26 are slowly rotating neutron stars in which complex 1–10-keV pulse shapes are produced by cyclotron absorption near the stellar surface, and have indicated several ways in which this hypothesis can be checked.

We have also suggested that accretion flows in the magnetospheres of fast rotators are different from those in slow rotators, and that the properties of X-ray sources will reflect this difference. Some of these properties are summarised in Table 1. Further study of other pulsating X-ray sources will show whether this model of accretion flows is correct. Thus SMC X-1, with a recently discovered period of 0.71 s (ref. 26) and a luminosity $\sim 6\times10^{38}$ erg s^{-1} is a prime candidate for fast rotation, while 3U1728–24, with a period of 123 s (refs 27, 28) and a luminosity (if it lies near the galactic centre) $\sim 10^{38}$ erg s^{-1}, should be a slow rotator. It is also possible that 3U1813−14, 3U1223−62, and 3U0352+30, which have recently been reported to be pulsating[27], are slowly rotating neutron stars.

A further implication of this model of accretion flows is that a rapidly rotating neutron star located in a binary system where the mass transfer rate is very high might be completely surrounded by a centrifugally-supported opaque cloud. If such a cloud smears out periodic intensity variations without reprocessing too large a fraction of the keV X-ray emission into soft X rays, it could account for the observed properties of unpulsed sources like Sco X-1 and Cyg X-2 (ref. 5); such a possibility has also been recently suggested by Sunyaev (private communication through R. McCray).

We conclude by pointing out that a given source can change from fast rotation to slow rotation, or vice versa, if it is 'choked' or 'starved' of accreting matter. One source that might show such transitions is Cen X-3, which shows some characteristics of both types of accretion flows and apparently undergoes large changes in accretion rate[29]. Although Cen X-3 usually has a comparatively simple pulse shape and also shows occasional spin down episodes[30], both of which are characteristics of fast rotators, equation (2) gives r_A only $\sim 0.3\ r_c$ for $P = 4.84$ s, $\mu_{30} \sim 1$, and $L_{37} \sim 6$ (appropriate for an X-ray high state at a distance ~ 10 kpc), and the average spin up timescale is $\sim 3\times10^3$ yr, in rough agreement with the slow rotator result, equation (4). Cen X-3 has been observed to have a more pronounced double pulse structure during what is believed to have been a 'choke-out' (Fabbiano and Schreier, personal communication), but the observation appears inconclusive as a test of the accretion flow pattern. The enhanced pulse-to-pulse variations in pulse shape seen during one 'starve-out' are probably unrelated to the increased complexity in the time-averaged waveform expected were Cen X-3 to become a true slow rotator. Clearly, observation of a transition from fast to slow rotation would provide an important check on the model.

We thank Professors D. Q. Lamb, D. Pines, and M. J. Rees and Dr A. C. Fabian for helpful conversations. One of us (F.K.L.) thanks the Institute of Astronomy, Cambridge, for its warm hospitality. This research was supported in part by the NSF and by the Alfred P. Sloan Foundation.

Membrane action of DMSO and other chemical inducers of Friend leukaemic cell differentiation

Gary H. Lyman & Harvey D. Preisler

DMSO and other cryoprotective agents produce a pronounced increase on the phase transition temperature of phospholipid membranes, indicating an increased stability. The effects of DMSO and the other cryoprotective agents, divalent cations, and local anaesthetics on the transition temperature of phospholipid membranes seem to correlate with their effects on the differentiation of Friend leukaemic cells in vitro. *These studies suggest that the induction of differentiation by cryoprotective agents may be the result of the interaction of these agents with cell membranes.*

GROWTH of Friend leukaemic cells (FLC) in suspension culture in the presence of any one of a variety of cryoprotective agents results in the differentiation of these cells along the erythroid pathway[1,2]. Although evidence has been presented that DMSO must ultimately influence the control of differentiation at the level of transcription[3], the primary site of action of these agents remains unknown. The known properties of these agents as penetrant-carriers and cryoprotectants suggested to us that their initial and perhaps major effects might be on the cell membrane. Considerable speculation has recently been directed towards possible alteration of membrane properties during cell differentiation and malignant transformation[4]. We have used differential scanning calorimetry (DSC) to study the effects of these agents on membrane properties. This technique has been used extensively to obtain a direct measure of a temperature and enthalpy of the lipid phase transition from the solid to the liquid-crystalline state[5,6]. The temperature at which the phase transition occurs in a given system is related to the fluidity of the membranes, and lipid fluidity has been shown to be an important parameter in various functions of biological membranes[7–9].

The studies reported here demonstrate that DMSO and other compounds which induce cell differentiation, alter the properties of phospholipid membranes causing the appearance of a new transition at higher temperatures. This effect indicates stabilisation of the membranes and we interpret it as evidence for decreased membrane fluidity. Local anaesthetics, which increase membrane fluidity[10,11] inhibit the artificial membrane effects as well as the induction of benzidine positivity in FLC *in vitro* by these chemical agents. Divalent cations enhance the effects of the inducing agents and reverse the inhibitory effects of the local anaesthetics on the artificial membranes and on FLC growing in suspension culture. These studies suggest that interaction of chemical inducing agents with membrane phospholipids may be involved indirectly in the induction of FLC differentiation by the same agents.

Effects of DMSO on phospholipid membrane transition temperature

Our initial studies were with DMSO, the first inducer recognised and one of the most potent agents available. Figure 1 demonstrates the effect of increasing concentrations of DMSO on the thermotropic properties of DMPG. Increasing concentrations of DMSO produce a shift of the T_c of the normal transition towards higher temperatures (mid-point T_c from 33.0 to 36.8 °C), while apparently reducing its magnitude until it disappears (curve *e*). DMSO also causes the appearance of a previously unrecognised endothermic transition at much higher temperatures (60–70 °C) which also shifts towards higher temperatures with increasing concentrations (Fig. 1). The upper transition first appears at a DMSO concentration of 2% (v/v), it becomes predominant at about 20% (v/v/) and is the only transition present at 30% (v/v). It should be noted that the optimal concentration of DMSO for inducing FLC differentiation is 2% (v/v) which is in the range of observed effects on phospholipid membranes seen here. The appearance of the new transition at high temperature was associated with visible flocculation of the lipid preparation following dispersion of the sample.

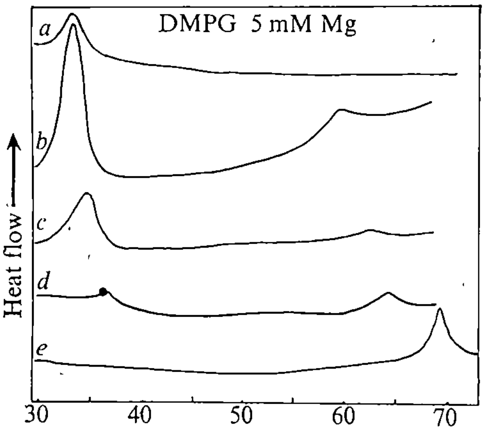

Fig. 1 The phospholipid used in these studies was dimyristoylphosphatidylglycerol (DMPG) synthesised as described previously[12]. It was stored under nitrogen in sealed ampoules at −50 °C at a concentration of approximately 10 µmol ml^{-1}. Multilamellar vesicles were prepared by the method of Bangham *et al.*[13]. The phospholipid was dispersed in phosphate-buffered saline (PBS) prepared in the presence of 5 mM magnesium chloride but free of calcium. Following dispersion at 37 °C, 2–3 µmol of lipid were distributed into individual sample tubes to which was added 5–10 ml of the solution to be studied The vesicles were then incubated in PBS in the presence of 5 mM magnesium chloride for 3 h at 37 °C in the following conditions: *a*, controls, no additions or in the presence of; *b*, DMSO 2% (v/v), 0.26 M; *c*, DMSO 10% (v/v), 1 3 M; *d*, DMSO 20% (v/v), 2.6 M; *e*, DMSO 30% (v/v) 3.9 M After incubation, the lipid suspension was centrifuged at 2,000 r p m for 30 min and the wet pellet transferred to a sample pan and covered Using a PBS standard, the phase transition temperature (T_c) of the phospholipid vesicle suspension was determined using a Differential Scanning Calorimeter (DSC-2, Perkin-Elmer, Norwalk, Connecticut). In all the studies a sensitivity scale of 1 mcalorie s^{-1}, a chart speed of 20 mm min^{-1} and a scanning rate of 50 °C min^{-1} were used The T_c, defined as the midpoint of the transition temperature, was found by heating the lipid samples at the indicated rate. The amount of lipid in each sample was not identical in each sample, so that the total heat of the transition which is represented by the area under the peak varies with different samples Consequently, comparisons between different samples were made only with respect to the T_c, and with the relative area under each peak when two peaks were present

Table 1 Effects of chemical inducers

Inducer	Benzidine-positive cells* (%) Experiment No. 1		Experiment No. 2

*Friend leukaemic cells (FLC), line 745A, were grown in suspension culture in Eagle's basal media with Earle's balanced salts (Gibco), made 15% with foetal calf serum (FCS) (Gibco). The cells were incubated at 37 °C in a humidified atmosphere consisting of 5% CO_2 and 95% room air. Cultures were seeded at 1×10^5 cells ml^{-1} and routinely passed at 3–4-d intervals. The chemical agents under study were added either alone or in combination at the time of seeding of the culture into 2-ml plates in duplicate. After 5 d of growth the cultures were collected, counted, and slides were made using a centrifuge, stained with benzidine Wright–Giemsa and the proportion of benzidine-positive cells was determined by one observer who counted 300 cells in a single blinded fashion. Cell viability was determined by Trypan blue exclusion

†Concentrations: Mg^{2+}, 8×10^{-3} M; Ca^{2+}, 14.3×10^{-3} M; Dibucaine, 5×10^{-6} M; Procaine, 7.3×10^{-4} M. Procaine hydrochloride was from McGraw Laboratories, Glendale, California and magnesium chloride, $6H_2O$ from Fischer Sci Co , Fairlawn, New Jersey.

‡Control cultures had no agents added. The benzidine-positive cell counts for Mg, Ca, Dibucaine, and Procaine control cultures were identical to the control counts noted above.

§Standard BME contains 8×10^{-4} M Mg^{2+} and 1.9×10^{-3} M Ca^{2+}. For the cases where additions were made the final concentrations were as indicated‡.

Effects of other inducers of differentiation on transition temperature

As shown earlier[1,2] DMSO, DMF, PNO, and TMU are all effective inducers of erythroid differentiation of FLC *in vitro* The results presented in Fig. 2 indicate that all these agents induced the appearance of a new transition at higher temperatures (upper T_c) which is similar to that produced by DMSO. The temperature of the upper transition did not always rise with increasing concentrations as observed with DMSO. The effects of the compounds on the lower peak varied somewhat with some compounds causing an increase (curve *b*) in the lower T_c with increasing concentration, while others caused little change (curves *c* and *d*) or a small decrease of the lower T_c (curve *e*). Butyric acid (data not shown) is unique among the effective inducers studied[14] in that at low concentrations (0 01 M) it raises the T_c while at higher concentrations (0.1 M) it lowers the T_c, and at even higher concentrations (1 0 M) it eliminates the transition in the temperature range tested It was not established whether butyric acid produced a new transition at much higher temperatures.

The urea family of compounds has been found to have varying effects on the induction of erythroid differentiation in FLC in the following order· TMU is an extremely potent inducer of differentiation, DMU is a moderate inducer and urea a very weak inducer[2] At concentrations of 30% (v/v) in the absence of Mg^{2+}, urea had no effect on the lower T_c and did not produce a new transition at higher temperatures.

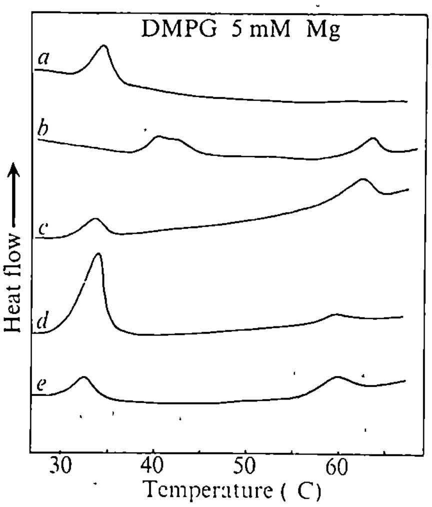

Fig. 2 Differential scanning calorimetry of DMPG vesicles in the presence of various inducers of erythroid differentiation. Vesicles were prepared in the presence of PBS with 5 mM magnesium chloride: *a*, Control. All further calorimetry thermograms were obtained in the same conditions except for the presence of: *b*, DMSO 15% (v/v), 1.95 M; *c*, DMF 15% (v/v), 1.95 M; *d*, PNO 10% stock solution (v/v), 0.81 M; *e*, TMU 10% (v/v), 0.86 M. PNO stock solution was 8.1 M, made by dissolving 100 g PNO in 130 ml of sterile water. The agents used in these studies were used as provided or dissolved in PBS (1 l contains: 900 ml 0.145 M NaCl; 80.40 ml 0.067 M Na_2HPO_4; 19.60 ml 0.067 M KH_2PO_4) and were obtained from the following companies: dimethylsulphoxide (DMSO), pyridine-*N*-oxide (PNO), tetramethylurea (TMU), dimethylurea (DMU), and butyric acid (BA), all from Eastman Kodak, Rochester, New York; dimethylformamide (DMF), urea, Fischer Sci. Co., Fairlawn, New Jersey.

On the other hand, both DMU and TMU were effective in abolishing the lower transition and producing one at much higher temperatures. TMU, which is the most potent inducer of differentiation in our system[2], in the presence of 5 mM Mg^{2+} caused the appearance of an upper transition at the lowest concentration tested (0.2% v/v), which is clearly within the range for inducing differentiation of FLC *in vitro* (0.1% v/v is optimal concentration).

Antagonistic effects of local anaesthetics and chemical inducers

It has previously been demonstrated that local anaesthetics increased the fluidity of acidic phospholipid membranes as indicated by a decrease of the T_c (ref. 11). Since the inducing agents were found to have the opposite effect on the T_c, we studied the interactions of these agents in the same system (Fig. 3).

As discussed above, the presence of DMSO results in an upward shift of the normal T_c and the appearance of a new transition of much higher T_c (Fig. 3, curve *c*). Dibucaine, on the other hand, lowers the normal T_c (curve *d*) When the vesicles were exposed simultaneously to dibucaine and DMSO, the upper T_c disappeared and the lower T_c was at midpoint between the peaks obtained when each agent was present alone (curve *e*) The disappearance of the upper T_c coincided with the disappearance of the DMSO-induced flocculation associated with the appearance of the upper T_c.

The addition of calcium to the mixture of DMSO and dibucaine not only restored the DMSO-induced upper peak, but also diminished the size of the lower transition compared with that shown by DMSO alone at that concentration (curve *f*). The exothermic (inverted) peak shown in curve *f* at 26 °C is usually obtained at higher concentrations of DMSO alone (30%). A more detailed study of the synergism of the effects of DMSO and divalent metals will be reported elsewhere[22].

Divalent cations and local anaesthetics on differentiation induction

The effects of inducing agents, divalent cations, and local anaesthetics on the properties of artificial phospholipid membranes led up to examine their effects on FLC growing in suspension culture. Friend leukaemic cells were grown in the presence of each of these agents alone or in combination (Table 1). DMSO 1% (v/v) induces a low degree of erythyroid differentiation. Increased concentration of calcium and, to a somewhat greater extent magnesium, seem to enhance the ability of DMSO to induce differentiation although they do not induce differentiation on their own at the concentrations used. Both dibucaine and procaine were found to inhibit to a large extent the development of benzidine positivity induced by DMSO and TMU in terms of both the proportion of benzidine-positive cells in the culture as well as the degree of positivity of the individual cells. Furthermore, calcium was able to restore and perhaps slightly enhance the DMSO-induced benzidine positivity previously inhibted by the local anaesthetics. None of these compounds alone or in combination, nor the addition of calcium, had any effect on the number or viability of cells present after 5 d of culture when compared with control cultures. Two additional observations are of interest. When FLC were grown in higher concentrations of DMSO or TMU (at 0.27 M or 8.6×10^{-3} M respectively) the topical anaesthetics produced little if any inhibition of benzidine positivity Additionally, although the addition of calcium had no effect on the rate of cell growth, the benzidine-positive cells in these cultures were vacuolated.

Membrane effects of cryoprotective agents

Cryoprotective agents which induce Friend leukaemic cell differentiation *in vitro* have variable effects on the normal T_c of phospholipid vesicles but consistently induce the appearance of a new endothermic peak at higher temperature. We interpret this as evidence for a stabilisation of the lipid bilayers indicating a decrease in membrane fluidity. Although high concentrations of inducing agents were frequently used, detectable effects on membrane fluidity were obtained with concentrations in the range used to induce differentiation in culture. Our previous studies with cryoprotective agents suggested that the ability of an agent to induce FLC differentiation paralleled the basicity of the agent[1]. Our current studies are in accord with these in that we have found that the effects of these agents in 'stabilising' phospholipid membranes are much more pronounced with acidic than with neutral phospholipids[22] it therefore seems that ionic charge interactions and perhaps hydrogen bonding[15] may be involved in the interaction of these compounds with phospholipid membranes.

The DSC studies demonstrated that agents, such as local anaesthetics[10,11,16] which increase membrane fluidity, inhibit the DMSO effect on membranes, whereas on the other hand, factors which decrease membrane fluidity such as Ca^{2+} and Mg^{2+} [17,18], enhance the DMSO effect An analogous relationship was found between the actions of divalent metals (enhancing) and a local anaesthetic (inhibiting) on cell differentiation induced by DMSO as judged by the development of benzidine positivity. But the inhibition of benzidine positivity by local anaesthetics[19] raises several questions in itself, since not only was the proportion of benzidine-positive cells decreased, but the degree of benzidine positivity of the differentiating cells was also reduced. This latter observation raises the possibility that the local anaesthetics may interfere only with the synthesis of haem and perhaps not inhibit at the same site where DMSO is involved directly in inducing FLC differentiation. For example, DMSO and other inducing agents have several different effects, whereas the local anaesthetics may merely inhibit mitochondrial synthesis of

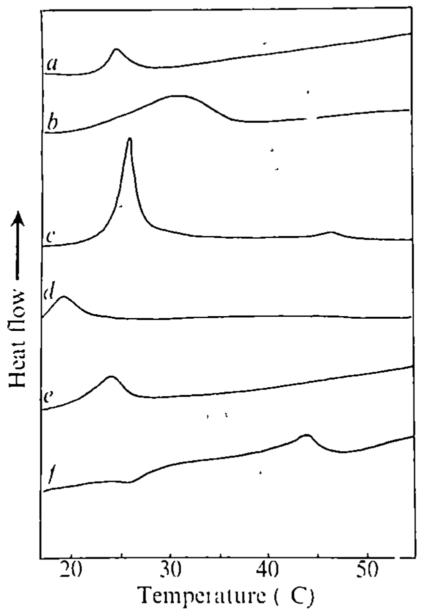

Fig. 3 Differential scanning calorimetry of DMPG vesicles in the presence of DMSO, dibucaine and calcium *a*, Thermogram obtained from vesicles prepared in the presence of PBS alone The remaining curves were obtained from vesicles to which were added: *b*, calcium chloride 5×10^{-4} M; *c*, DMSO 20% (v/v), 2.6 M; *d*, dibucaine hydrochloride 5×10^{-5} M; *e*, DMSO 20% (v/v), 2.6 M and dibucaine hydrochloride 5×10^{-5} M; *f*, DMSO 20% (v/v), 2.6 M, dibucaine hydrochloride 5×10^{-5} M, and calcium chloride 5×10^{-4} M Dibucaine hydrochloride was obtained from K and D Laboratories, Plainview, New York.; calcium chloride from Upjohn Co, Kalamazoo, Michigan.

haem. Other manifestations of differentiation may therefore not be inhibited by the local anaesthetics.

Our studies suggest that the cryoprotective ability of these compounds may also be related to their membrane effects. It is possible that a decrease in fluidity of the cell membrane could render the cell and its subcellular organelles more resistant to distortion during freezing. In fact, preliminary experiments in our laboratory suggest that local anaesthetics may inhibit DMSO cryoprotection of erythrocytes.

Although not ruling out a direct effect on transcription, the studies reported here suggest that in FLC line 745A interaction of the cryoprotective inducers with the cell membrane may play an important part in the induction of differentiation of murine erythroleukaemic cells. A decrease in membrane fluidity could alter the transport and permeability properties of the membrane or cause the 'release' of an intracellular messenger which would itself be responsible for initiating the transcription of those mRNAs necessary for erythroid differentiation. On the other hand, the same physical interactions which occur between the agents and the phospholipid membranes and the associated water molecules could also occur at other sites within the cell (including proteins, or nucleic acids). The conformational changes produced at such sites[20,21] could result in differentiation by directly effecting the transcription of mRNAs associated with differentiation. Although these lipid vesicle studies seem to be predictive of the effects of cryoprotective agents on FLC line 745A, they are not predictive of their effects on line 745D, a cell line which is refractory to DMSO and only minimally responsive to other cryoprotective agents[2]. It thus seems possible that the difference in responsiveness between lines 745A and 745D may be a result of differences in their cell membranes.

Similarity of the crystal and solution structure of yeast tRNA$^{\rm Phe}$

G. T. Robillard, C. E. Tarr*, F. Vosman & H. J. C. Berendsen

Department of Physical Chemistry, University of Groningen, Zernikelaan, Groningen, The Netherlands

A comparison of the crystal and the solution structure of yeast tRNA$^{\rm Phe}$ has been carried out by calculating the low field NMR spectrum from refined X-ray structure coordinates. The similarity between the computed and observed spectra show that the crystal and solution structure are virtually identical.

NUCLEAR magnetic resonance (NMR), in theory, can provide information on the solution structure of a macromolecule at the same level of resolution as obtained with X rays in solids. In particular, the chemical shift and relaxation parameters contained in an NMR spectrum are sensitive functions of the local environments of individual nuclei. Nevertheless, the transition from the theoretical argument to the practical task of attempting to extract such information from NMR spectra poses significant problems since the magnitude of individual effects are not precisely known and difficult to calculate.

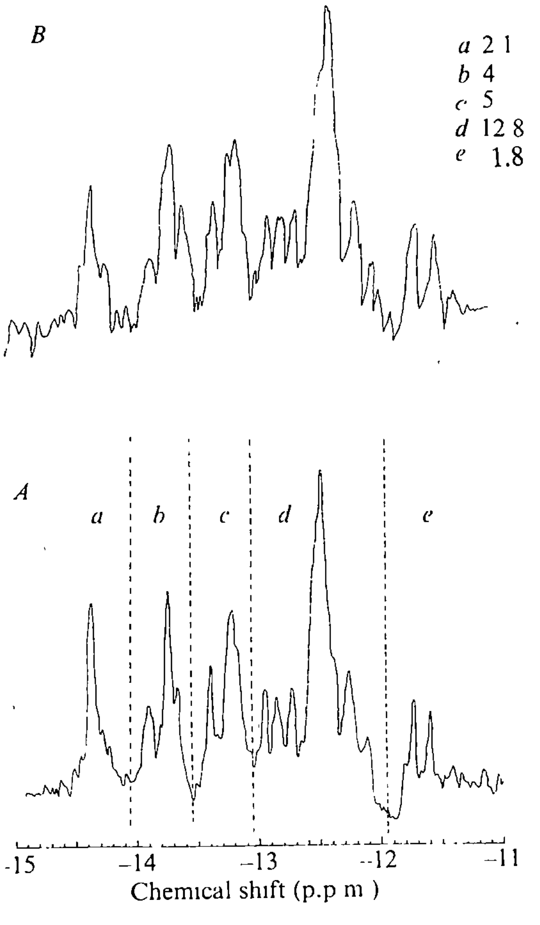
Table 1 Optimised ring current values

Nucleotide	Ring currents Giessner-Prettre and Pullman[6]	Optimised
Adenine		
Hexagonal ring	0.88	0.763
Pentagonal ring	0.67	0.580
Guanine		
Hexagonal ring	0.25	0.288
Pentagonal ring	0.63	0.725
Cytosine	0.27	0.210
Uracil	0.08	0.107

Calculation of magnetic ring currents, however, has reached a significantly high level of accuracy to be useful in predicting resonance positions if these positions, to a reasonable approximation, are determined only by ring current effects. In the case of NMR spectra of tRNA it is likely that ring currents are the dominant shift mechanism determining resonance positions.

Each ring NH · · · N hydrogen bonded proton in a Watson–Crick base pair generates a resonance in the low field region of the proton NMR spectrum of tRNA[1] The chemical shift of a proton in such an environment is a combination of three principal effects: (1) deshielding by polarisation of the NH bond due to the adjacent electronegative atoms of the hydrogen bond; (2) deshielding arising from the ring currents of the two aromatic rings between which this hydrogen bonded proton is located; and (3) shifts caused by the ring currents of bases stacked above and below the base pair containing the proton in question. The magnitude of these three effects may be as large as several parts per million. All other shift mechanisms generate shifts on the order of a few tenths of a part per million.

Fig. 1 360-MHz proton NMR spectra of yeast tRNA^{Phe} in H_2O solutions taken at 35 °C. The spectra represent 1-h accumulations in the continuous wave mode with a sweep rate of 12 s per 2,400 Hz. Solvent composition was: *A*, 1 mM tRNA, 1 mM EDTA and 10 mM sodium cacodylate *p*H 7; *B*, 1 mM tRNA, 1 mM EDTA, 10 mM sodium cacodylate *p*H 7, 15 mM $MgCl_2$, 0.1 M NaCl.



Since the X-ray structure of yeast tRNA^{Phe} has now been solved[2,3] and refined coordinates are available, we have calculated, directly from the coordinates, the ring current shift which each hydrogen bonded proton experiences from all other aromatic rings in the molecule. The results show that, on the basis of the resulting NMR spectrum, the X-ray crystal structure and the solution structure are virtually identical.

Ring current calculations

We have used the theory of Haigh and Mallion[4] to calculate the ring current shifts of the hydrogen bonded protons. In this theory, which is based on McWeeny's quantum mechanical treatment[5], all contributions to the ring current shifts are standard geometric terms that are calculated from the positions of ring atoms, multiplied by a factor proportional to the magnitude of the ring current. Haigh and Mallion used an empirical factor that is relevant only for in-plane protons attached to aromatic ring systems, but that should be scaled up by a factor of 2.6 for large distances. We have used this factor of 2.6 as appropriate for the distances occurring in tRNA. Our program for calculating the ring current shifts places a proton on a straight line between the donor and acceptor nitrogens at a distance of 1.02 Å from the donor It then sums the ring current contributions of every ring in the molecule excluding the donor and acceptor rings for the base pair of interest These rings are considered separately when determining starting positions for a hydrogen bonded proton in a given type of base pair.

Ring currents for the four isolated bases A, G, U and C have been calculated by Giessner-Prettre and Pullman[6] and are expressed relative to the ring currents in benzene (see Table 1). For several reasons calculated values of ring currents can be considered to be only approximately correct: (1) ring currents, derived from second-order perturbation theory, are sensitive to approximations used in the quantum mechanical treatment; (2) in hydrogen bonded base pairs the ring currents may deviate substantially from those in isolated bases; (3) the neglect of the effect of charges in heterocyclic rings; and (4) the inaccuracy of the geometric terms used in the calculation of shifts all may influence the apparent ring currents. Empirical adjustments for each of the ring currents should therefore be made to properly account for the observed shifts. We used the calculated ring currents[6] as starting values in an iterative procedure that successively refined each value. First, the A and G ring currents, and the difference between the AU and GC starting positions were varied and the computer was allowed to make a best fit between the nearest members of the calculated and the observed spectra. Then the C and U ring currents were refined keeping A and G fixed. These new values then provided the basis for a final slight refinement of A and G ring currents. In each case, the pentagonal and hexagonal ring currents of each purine were varied by the same factor, thus leaving only four ring currents to be refined. Because of the rapid convergence of this technique, no further iteration was required. A major advantage of this procedure is that one is not required to make detailed *a priori* assignments of given base pairs to specific resonances in the observed spectrum and thereby prejudice the outcome.

The values arrived at by this optimisation procedure are listed in Table 1. As can be seen, the optimum values for this calculation are only slightly different from the values calculated by Giessner-Prettre and Pullman[6]. Furthermore, the changes are consistent with those expected from hydrogen bonding between base pairs. During hydrogen bonding the electron density in the electron cloud, and hence the ring current, is expected to increase on the donor base and decrease on the acceptor base. This is precisely what occurs when the ring

Table 2 Base pair ring current shift

Helix	Base pair	Ring current shift (p.p.m)

currents are optimised. We are confident, therefore, that the optimisation procedure has not led to incorrect answers.

Yeast tRNA^{Phe} NMR spectrum

For the purpose of making detailed comparisons between observed and calculated spectra, it was necessary to use the most highly resolved spectra of tRNA^{Phe} available. Figure 1 shows the low field NMR spectra of yeast tRNA^{Phe} taken at 360 MHz in the absence or presence of Mg^{2+} (B R. Reid, personal communication). Except for slight shifts in resonance positions and the narrowing of the resonances in the absence of Mg^{2+}, the two spectra are identical. Because of the higher magnetic fields and the special solvent conditions, however, the resolution in the no Mg^{2+} spectrum (Fig 1*A*) reveals a number of features not observed in previously published spectra of this molecule[7–10]. There are seven well resolved resonances below −11.5 p.p.m. all of which have approximately unit intensity. When the total integrated intensity in the spectrum is calculated relative to any one of these individual resonances we find 26 ± 1 protons between −15 and −11.5 p.p.m. as shown in the table on the side of spectrum in Fig 1*B* (B. R. Reid and G. T. R., in preparation). Similar spectral resolution plus an independent calibration on the high field methyl resonances has led us recently to the same conclusion in the case of *Escherichia coli* tRNA$_1^{Val}$ (refs 11 and 12). The intensity in the low field region of yeast tRNA^{Phe} must then be attributed to the 20 secondary structure Watson–Crick hyrodgen bonded base pair protons (Fig 2) plus hydrogen bonded protons from tertiary interactions. There are five tertiary interactions involving ring NH· · ·N type hydrogen bonds which should account for five of the resonances in this region. Only one proton resonance is left unaccounted for and its origin will be discussed in the following section

Table 3 Proton resonance positions

Base pair	Chemical shift (p.p.m) Calculated	 Observed

Base pair offsets: Watson–Crick AU, −14 35; Watson–Crick GC, −13.54; reversed Hoogstein AU, −14.90; AΨ ≃ −13 50.

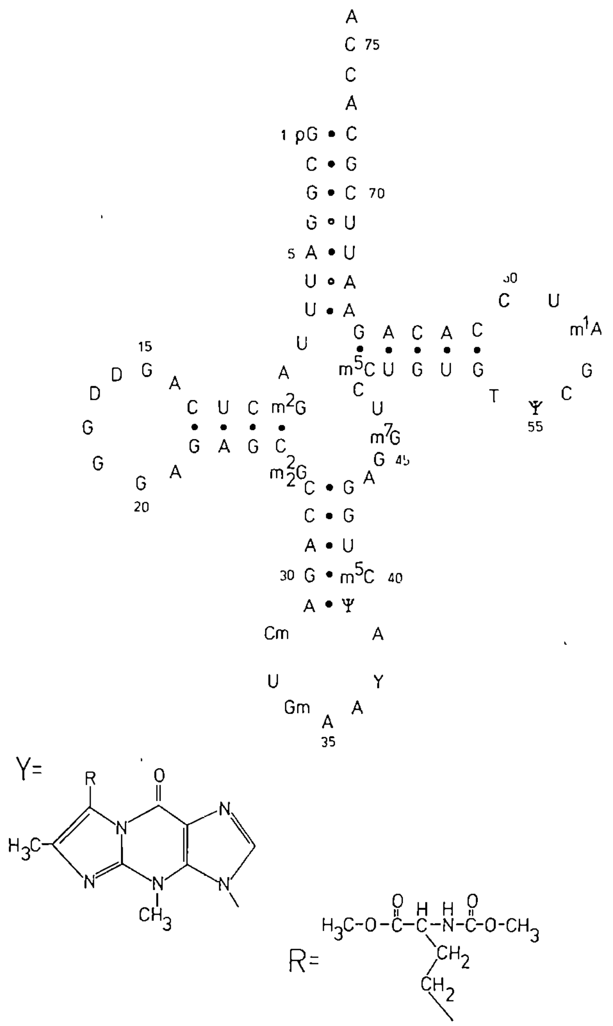

Fig. 2 Cloverleaf sequence of yeast tRNA^{Phe} (refs 14 and 15)

Figure 3*A* is a computer fit of the original spectrum in Fig. 1*A*. It was prepared by assigning a number of Lorentzian lines of equal intensity and linewidths to the positions where they occur in the original spectrum. Twenty-six lines were used to generate this spectrum and comparison with Fig. 1 demonstrates that the integration shown in this figure accurately reflects the number of protons in each peak of the original spectrum. The individual positions used in this fit were the same as those used in the ring current optimisation discussed above The optimised ring current values for the four bases obtained by this procedure (Table 1) have been used in the Haigh and Mallion ring current

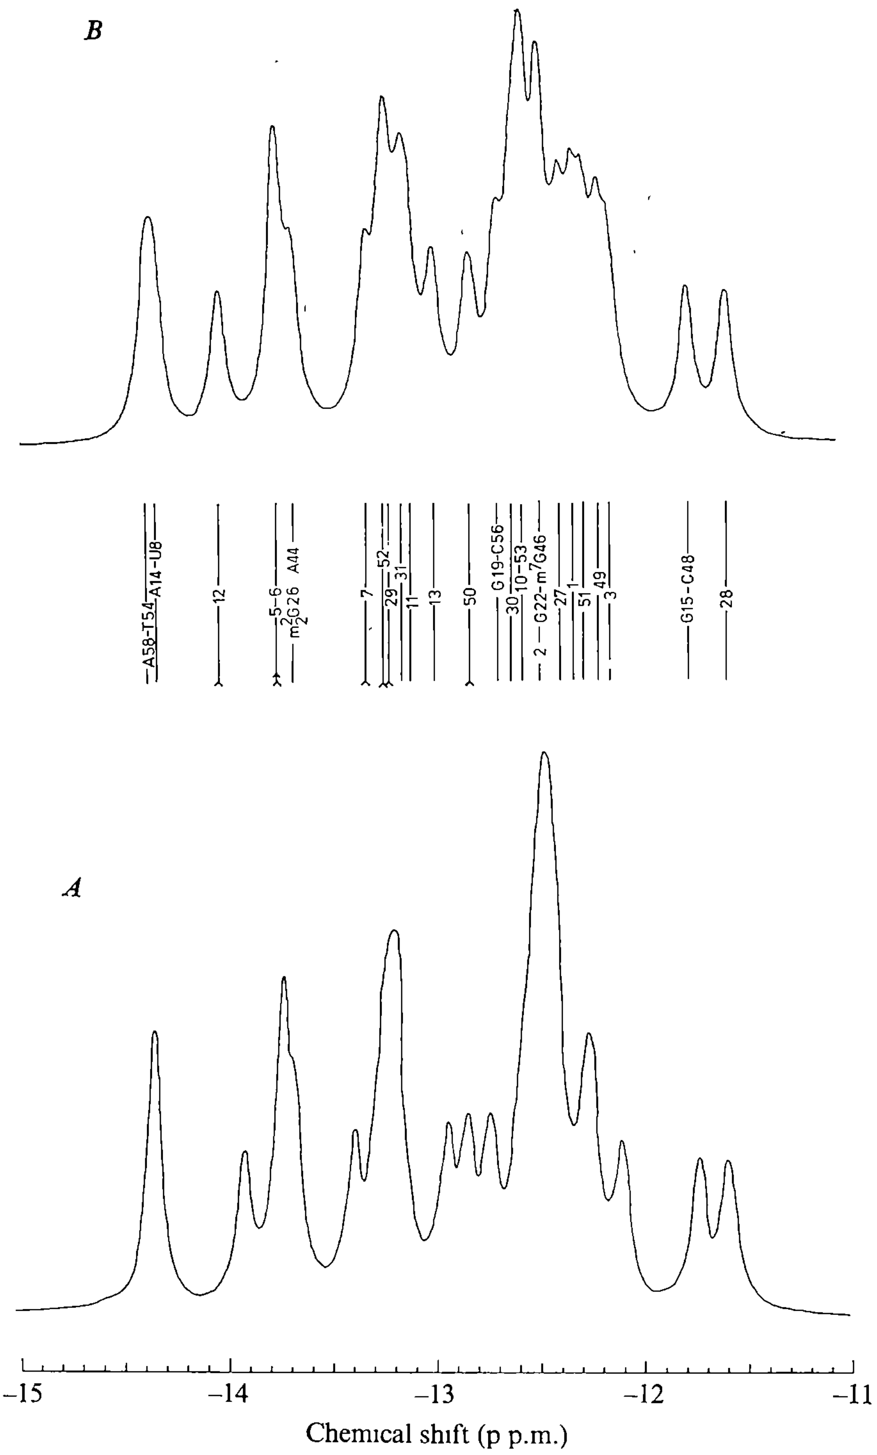

Fig. 3 *A*, Computer fit of the spectrum in Fig. 1*A* prepared as described in the text, *B*, spectrum calculated from the X-ray structure coordinate and optimised ring current values using the procedures and offsets described in the text and Tables 1–3. The indicated base pair positions are those assigned by the computer from the calculations. Secondary structure resonances are denoted by the normal conventions 1, 2 . . . . Secondary structure AU resonances are denoted by an ^ at the bottom of the line. Tertiary structure resonances are denoted by the full lettering and numbering of the base pair, that is, U8–A14 and so on.

calculation along with the X-ray crystal structure coordinates of yeast tRNA$^{\mathrm{Phe}}$ refined by Sussman and Kim (personal communication). The resulting spectrum (Fig. 3*B*) compares very closely with the original (Fig. 3*A*). Since the NMR spectrum of tRNA$^{\mathrm{Phe}}$ can be quite accurately calculated from the crystal structure coordinates simply by summation of the ring currents arising from each aromatic substituent in the molecule, there must be a very high degree of similarity between the solution and crystal structure

Resonances from secondary structure base pairs

A base pair hydrogen bonded proton will experience deshielding ring currents from the aromatic rings of the donor and acceptor bases. If the distance between the donor and acceptor bases varies slightly, as they do in the refined crystal structure coordinates (2.8–3.1 Å), there will be slight alterations in the ring current shift. Since it is not clear, however, that these differences are physically meaningful at the current level of resolution of the X-ray coordinates, they have been ignored in the present calculations Any error which results from this approximation will be small since the differences in degree of deshielding originating from these slight changes amount to only a few Hz. Deshielding also arises from the electronegative atoms of the hydrogen bond as stated previously. Since it is impossible to determine accurately the hydrogen bond strengths and correlate them with deshielding effects we have again assumed that the deshielding arising from the hydrogen bonded situation of the proton is the same for a given type of base pair. Thus the starting position for a proton in each type of isolated base pair is allowed to be a variable in the optimisation procedure discussed above. The parameters found were −14.35 and −13.54 p.p.m. for Watson–Crick AU and GC base-paired hydrogen bonded protons, respectively.

Resonance from AΨ base pair

The aromatic ring of the "Y" base is stacked in the anticodon loop, one ring removed from the Aψ base pair. In the present calculation the ring current shift arising from this base was calculated using the ring current value provided by B. Pullman (personal communication). The total ring current shift experienced by the Aψ hydrogen bonded proton is 0.24 p.p.m. In studies of the anticodon fragment of yeast tRNA^{Phe}, Lightfoot *et al.*[9] found the Aψ resonance occurring in region *c* of Fig. 2 and set the starting position at −13.5 p.p.m. We find that the Aψ could occur in either region *b* or *c* depending on the starting position and the magnitude of the ring current shift which the proton experiences. In the absence of other information, therefore, we prefer to rely tentatively on the fragment studies and assign the resonance to region *c* with the Aψ starting position in the region of −13.5 p.p.m.

Resonances from tertiary structure interactions

The calculated resonance positions marked in Fig. 3 show that the two protons in region *a*, and one each in regions *b*, *c*, *d* and *e* are not normal Watson–Crick AU or GC secondary structure resonances Having assigned AΨ 31 to region *c* in the previous section, the tertiary interactions must generate resonances in the remaining regions. The tertiary structure interactions involving U8–A14 and T54–A58 are of the reversed Hoogstein type (see Fig. 4*b*). These two tertiaries experience approximately the same ring currents as do the hydrogen bonded protons of AU5, 6 and 12 (see Table 2). If the AU offset is the same for both Watson–Crick and reversed Hoogstein base pairs, five protons fall into region *b* and none into region *a* of Fig. 1. It is probable, however, that protons in the reversed Hoogstein arrangement have a starting position to lower field than Watson–Crick AU protons. In the reversed Hoogstein arrangement (Fig. 4*b*), the hydrogen bond acceptor is N7 of the five-membered ring instead of N1 of the six-membered ring. It has been shown by calculations on the tautomeric forms of purines[13] that the ring currents in both the hexagonal and pentagonal rings are a factor of 2–3 higher if a proton is attached to the N7 compared with the N1. The change in ring currents on hydrogen bonding N7 in place of N1 is

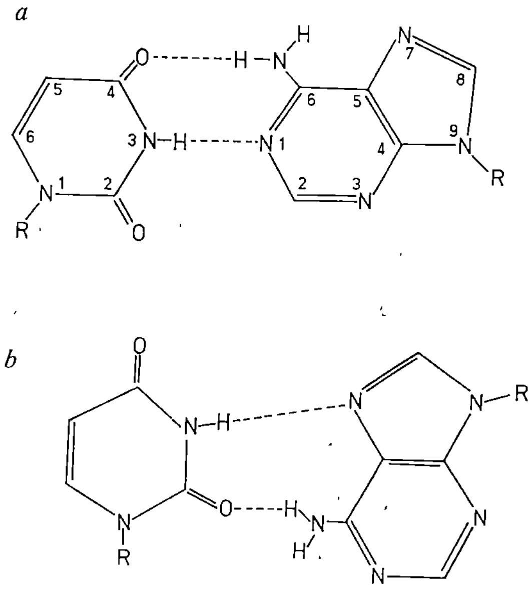

Fig. 4 Comparison of Watson–Crick AU base pairing (*a*) and reversed Hoogstein AU base pairing (*b*).

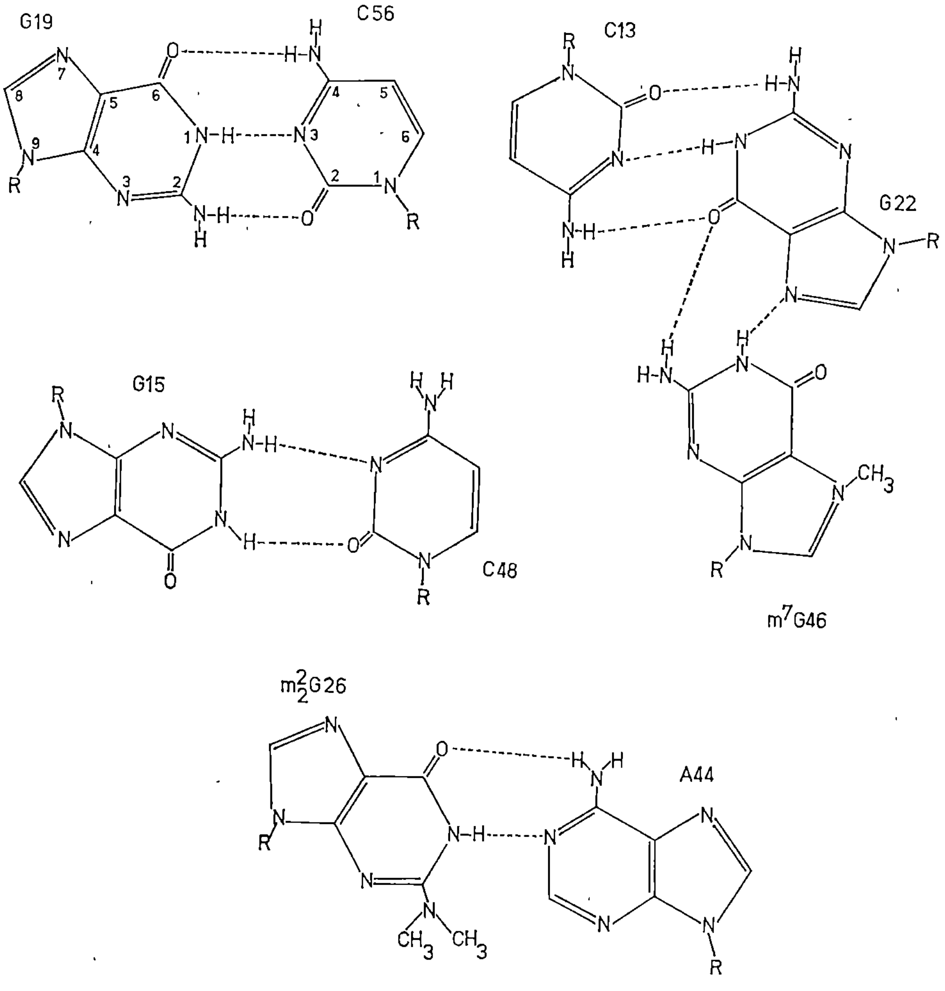

Fig. 5 Tertiary structure base pairing interactions, excluding the AU reversed Hoogstein, which are suggested to contribute resonances in the low field region of the NMR spectrum of yeast tRNA^{Phe} (refs 2 and 3).

expected to be in the same direction. Thus the deshielding experienced by the proton in the reversed Hoogstein pair is expected to be greater than in the Watson–Crick base pair and the starting position should occur at lower field. Setting the reversed Hoogstein AU offset at −14.9 p.p.m. places the two tertiaries U8–A14 and T54–A58 in peak *a* at −14.4 p.p.m. A lower field starting position for the reversed Hoogstein base pair may also arise from a localisation of positive charge on the five-membered ring when hydrogen bonding occurs at N7. In contrast, the positive charge which develops when hydrogen bonding occurs at N1 in a Watson–Crick arrangement may be withdrawn from the ring by resonance interaction with the NH_2 group. A higher degree of positive charge on the ring would result in greater deshielding and a lower field position for the reversed Hoogstein AU base pair proton.

Figure 5 shows the remaining tertiary structure interactions which are likely to give rise to resonances in the −15 to −11.5 p.p.m. region of the NMR spectrum. Since G19–C56 is a normal Watson–Crick base pair we have used the standard GC starting position of −13.54 p.p.m. which places the resonance from this base pair in region *d* (see Fig. 3). Only one proton each in regions *b*, *d* and *e* remain unaccounted for. Allowing for the strong deshielding ring currents which should arise from both rings in the tertiary base pair m^2_2G26–A44, the starting position for this resonance should certainly be lower than a normal Watson–Crick GC and may be more nearly the same as a Watson–Crick AU proton resonance. Therefore, we have tentatively placed m^2_2G26–A44 in peak *b* with a starting position of −14.2 p.p.m. The G22–m^7 G46 interaction (Fig. 5), is of the reversed Hoogstein type. By analogy with the arguments presented for the AU reversed Hoogstein resonance starting positions we expect this GG reversed Hoogstein offset to be to lower field than a Watson–Crick GC starting position. The difference between a Watson–Crick and a reversed Hoogstein AU offset is 0.55 p p.m. With the G22–m^7G46 resonance assigned to region *d* at −12.47 p.p.m. the GG reversed Hoogstein interaction has a starting position of −14.2 p.p.m. (0.65 p.p.m. to lower field than the Watson–Crick GC interaction). The ring NH of G15 hydrogen bonded to the exocyclic oxygen of C48 should be less deshielded than a normal Watson–Crick GC and we have tentatively assigned this proton to region *e* as indicated in Fig. 3 with a low field starting position of approximately −12.1 p.p.m.

Comparison with previous NMR data

The original analysis of the yeast $tRNA^{Phe}$ NMR spectrum was made with considerable help from NMR spectra of fragments of the individual helices[9]. Since the helical region structure was expected to be fairly stable in the presence or absence of the rest of the molecule, the spectra obtained were assumed to reflect the resonance positions of the base pairs for a given helix in the intact molecule. If one compares the fragment data with the assignments which have evolved from the present calculations of the secondary structure resonance positions, it is immediately evident that the present assignments are in very close agreement with the fragment data. The only noticeable deviation is the assignment of GC 13 in the DHU helix which was originally assigned to one of the two highest field resonances. Our calculations show, however, that GC 13 suffers very little upfield shift (see Fig. 3 and Table 2).

The major change which must be made as a result of these studies is that the Watson–Crick AU starting position is changed to −14.35 p.p.m. In the early studies, without knowledge of AU tertiary structure resonances it was necessary to set the offset to lower field to account for the resonances which occurred below −14 p.p.m. This, however, necessitated raising the A and G ring currents 20% above published values.

The results of removing the sulphur from thiouridine in *E. coli* $tRNA_1^{Val}$ (ref. 11) provide further support for assigning the resonances in region *a* of Fig. 1, to the tertiary AU resonances. When the sulphur was removed from s_4U8 by cyanogen bromide treatment the resonance which occurred at −14.9 p.p.m. in the NRM spectrum of *E. coli* $tRNA_1^{Val}$ disappeared and was replaced by a new resonance at −14.2 p.p m. This treatment should have changed a s_1U8–A14 tertiary base pair into a normal U8–A14 tertiary base pair as we have in yeast $tRNA^{Phe}$. The new resonance which appeared was located very close to that which we have assigned to the U8–A14 tertiary in the present spectra.

Kallenbach *et al.*[16] observed resonances at −13.8 and −13.2 p.p.m. when studying AMP interacting with oligo(U_{15}). Assuming the Watson–Crick AU offset of −14.6 p.p.m. originally used by Shulman *et al.*[8], the −13.8 p.p.m. resonance was assigned to ring NH · · · N Watson–Crick interactions while the −13.2 p.p.m. resonance was assigned to hydrogen bonded protons in the reversed Hoogstein interactions. The offsets proposed in this paper reverse the order of these assignments. Furthermore, when these offsets are used in conjunction with new ring current shift tables (Robillard *et al.*, in preparation) the position of the Watson–Crick and reversed Hoogstein resonance interactions for this polymer are predicted to occur exactly at the observed positions.

In their studies of ribosyl ApApGpCpUpUp double-stranded helix, Kan *et al.*[17] observed an AU resonance assigned to the internal AU base pair. At 0° the resonance occurred at −14.2 p.p.m. Since this base pair proton is expected to receive an upfield shift of approximately 0.5 p.p.m. from the neighbouring G, it would seem that the present starting position of −14.35 p.p.m. for a Watson–Crick AU base paired proton resonance is incorrect. It should be realised, however, that the temperature-dependent measurements of this fragment show a continuing shift as a function of decreasing temperature even after changes in the resonance line widths have ceased. As has been shown[17], this could arise from a structural change in the helix geometry (fraying effects). Thus it is likely that these fragments studies are not directly comparable with studies on larger polymers.

Conclusions

Table 3 contains the resonance positions of the protons in the observed spectrum and compares them with those which we have calculated using the offsets given at the bottom of the table and the ring current shifts in Table 2. The r.m.s. error between the resonances in the two columns is less than 0.05 p.p m. (18 Hz) when only the 20 secondary structure resonances are included. The agreement between the calculated and observed positions, which is even within the observed linewidth, can be considered as very satisfactory since in the optimisation procedure only five adjustable parameters were used to calculate 20 relative line positions. These parameters were the four ring currents and the difference between the AU and GC starting positions. The deviations which are still observed may well represent slight differences between crystal and solution structure. They may also arise from a slightly incorrectly refined structure in one part of the molecule. Further experiments are in progress to examine these possibilities as well as the accuracy of our optimised ring currents and starting positions for the individual base pair types.

We thank the ZWO (Netherlands Foundation for Pure Research) for support of the high resolution NMR facility at the University of Groningen, B. Pullman for providing the "Y" base ring current, R. Kaptein for assistance with the ring current calculation programmes, and R. G. Shulman and B. R. Reid for their stimulating ideas and suggestions. We would also like to thank S. H. Kim for providing refined coordinates as soon as they were available.

The 21-cm absorption line in NGC1275

De Young, Roberts and Saslaw[1] detected H I absorption in NGC1275 with a velocity of 8,120 km s^{-1}. This is ~ 3,000 km s^{-1} larger than the systemic velocity of NGC1275 and is the same as that of the enigmatic system of gas filaments extending 40″ from the nucleus[2,3]. The observations of De Young *et al.* were made with a single dish with insufficient angular resolution to determine which of the various radio continuum sources were being absorbed. They argue that the absorption is probably occurring in the components < 0.2″ rather than in the 5′ halo component, but they were unaware of an intermediate scale 30″ component[4]. Here we present observations made with sufficient angular resolution to decide unambiguously between these possibilities. Our data can also be used to place a limit on the H I mass of possible foreground objects which could be causing the absorption.

‡ With respect to the channels with the highest four velocities.

The observations were obtained with the Westerbork Synthesis Radio Telescope and its 80-channel filter spectrometer[5]. The measurements with the ten shorter baselines (36–684 m in 72-m increments) were made on August 11, 1974, and those with the 10 longer baselines (756–1,404 m in 72-m increments) on November 15, 1974. The eight frequency channels have a half-power bandwidth of 129 kHz ($c\,\Delta\lambda/\lambda_0$ = 27 km s^{-1}) and cover the range in $c\Delta\lambda/\lambda_0$ from 8,085 to 8,373 km s^{-1}. Table 1 gives the amplitudes in each channel averaged at the position of the continuum source. For the shorter baselines this corresponds to the flux density from a region ~ 50″×75″ in diameter (EW×NS) centred on the nucleus of NGC1275. For the longer baselines this is the flux density from components < (20″×30″) at the position of the nucleus.

For each observation, the variations in amplitude for the highest four velocities are consistent with that expected from receiver noise, so we have taken the average of these four channels to represent the mean continuum amplitude and have also tabulated the amplitudes relative to this value. To compare our result with that of De Young *et al.*[1], we have convolved their profile with our broader bandpass, and we have used the more accurate gain calibration of the 300′ antenna[6]. This gives an absorption of 0.26±0.02 Jy, in agreement with our value of 0.287±0.006 Jy in the 8,085 km s^{-1} channel.

Table 2 lists the angular sizes and flux densities of the main components of NGC1275 at the epoch of these observations. The deepest absorption seen by De Young *et al.*[1] corresponds to 1.4 Jy, so it is possible that this could have occurred in any of the three continuum components. Figure 1*a* shows the fringe amplitude of continuum emission in position angles 0° and 90°. The three angular size scales as described by Miley and Perola[4] are clearly seen. In Fig. 1*b* we show the difference between the channel containing the strongest absorption and the channels containing the continuum. It is clear from this plot that the absorbed component is unresolved and we can place a limit of < 6″ EW and < 9″ NS on its angular size. Furthermore, from the interferometer phase we can see that the position of the absorbed component is within 1″ of the position of the small diameter continuum source.

From this we can exclude the possibility that the major part of the absorption is occurring in either the 3′×4′ halo component or the 30″ intermediate component but it is still possible

Fig. 1 *a*, The fringe amplitude of the continuum emission from NGC1275 in position angles 0° (×) and 90° (●) plotted against the interferometer baseline in wavelengths. Note that the amplitude scale is offset from zero. *b*, The difference between the channel containing the strongest absorption and the average of the channels containing the continuum emission.

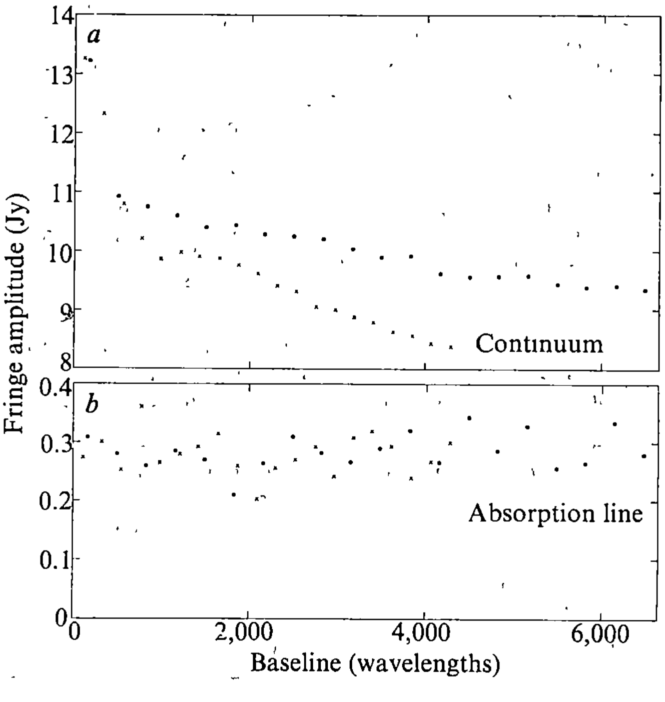

Table 2 Flux densities and absorption of the components

Component	Size*	Flux density (Jy)	Absorption (Jy)	Absorption %

Intermediate	35″×12″	2.2	<0.07	<3§
Halo	4′×3′	2.0¶	<0.05	<2

* Half intensity diameters of equivalent Gaussian distributions. Major axis position angle 170°.

† Average over our 27-km s^{-1} bandwidth.

‡ Variable—see text.

§ Upper limits are 3×r.m.s.

¶ The continuum fringe amplitudes in Fig. 1 also include a contribution from NGC1265 at the shorter spacings.

that a smaller fraction of the total absorption is occurring in these components. We can set limits on this fraction by fitting Gaussian components of the appropriate sizes to the absorption visibility in Fig. 1*b*. The resulting upper limits which correspond to 3×r.m.s. are also given in Table 2. Since the limits correspond to a fractional absorption in the larger scale components less than that seen in the compact component we can just exclude an absorbing cloud at 8,126 km s^{-1} uniformly covering the larger scale components, but we could not exclude a non-uniform cloud.

Table 3 summarises information from Westerbork on the variability of the continuum emission from the compact component at 1.4 GHz. The continuum emission has increased by 15% since 1971 and this is similar to the 10% increase between our present value of the absorption and that seen by De Young *et al.*[1]. The different calibration and velocity resolution of these two observations makes this result rather uncertain, however. Further accurate monitoring of the absorption line would indicate whether the continuum component responsible for the absorption is the variable component or some other part of the complex of small scale continuum structures known to be present[7].

One of the possible hypotheses to explain the absorption is that there is a foreground galaxy or H I cloud moving towards NGC1275 with a velocity of +3,000 km s^{-1}. Such a large positive velocity is not impossible if it is a member of the Perseus cluster, which has an r.m.s. velocity dispersion of 1,500 km s^{-1}. To detect such an object, we can either search for emission at velocities away from the absorption line velocity or search for emission from a larger region than that seen in absorption.

Since we do not see any feature in Table 1 exceeding the noise level we can set a 3σ limit of < 0.024 Jy in a 27-km s^{-1} channel on any emission feature in the velocity range 8,167 to 8,373 km s^{-1}. Comparison of the 50″ and 20″ data enables similar limits to be put on any emission at the absorption velocity coming from an area of ~ 50″ diameter centred on the galaxy. This corresponds to 18 kpc for an assumed distance of 75 Mpc for NGC1275.

For a foreground object smaller than or comparable with this size with a velocity dispersion ΔV in km s^{-1} our flux density limit gives a limit to the mass of neutral hydrogen, $M_{\rm H\,I}$, of

$$M_{\rm HI} < 3\times10^7\,(\Delta V)\,M_\odot$$

If ΔV is much greater than 200 km s^{-1} our limit is less well defined since the total profile would be wider than our velocity coverage. Thus a galaxy having the same distribution of H I velocities as the optical filaments ($\Delta V \simeq 250$ km s^{-1}) would have $M_{\rm HI} < 7.5\times10^9 M_\odot$. A late-type galaxy with this profile width would have $M_{\rm total} \lesssim 8\times10^{11} M_\odot$ and $M_{\rm HI} \simeq 6\times10^9 M_\odot$ (ref. 8), which is just below our present detection limit.

New limit on the size distribution of γ-ray bursts

SINCE the discovery of γ-ray bursts of non-solar origin in 1973 (ref. 1), about 42 events have been confirmed. All have been observed by X-ray and γ-ray detectors on various satellites, though a number of unconfirmed bursts have also been observed by balloon-borne instruments[2]. The lack of confirmation in the latter cases is not surprising, because of short exposure time and differing sensitivities. The detected flux ranges between about 3×10^{-6} erg cm^{-2} for the smallest burst to 5×10^{-4} erg cm^{-2} for the largest observed burst. The integral size distribution of these events above 10^{-4} erg cm^{-2} follows an $S^{-1.5}$ law, suggesting an isotropic distribution of the sources. For events with energy of less than 10^{-4} erg cm^{-2}, however, the observed distribution seems to flatten out, and the choice of number index ($\alpha=0.5$, 1.0 or 1.5) in this region is not strongly supported by experimental results.

We present here a new upper limit for the number of bursts which deposit more than about 2×10^{-7} erg cm^{-2} in the energy range 100–1,000 keV. The result indicates the direction in which future γ-ray burst experiments might go.

Our instrument comprised a 125-mm NaI(Tl) detector 10 mm thick, shielded from photons originating in the lower hemisphere by a graded shield. The pulses were analysed in four integral channels between 40 and 1,000 keV. The prescaling factor and the sampling rate for each channel was matched to the available telemetry capacity. The counting rate between 100 and 1,000 keV was sampled every 0.6 s, for 300–1,000 keV and 600–1,000 keV every 2 s, while counts between 40 and 1,000 keV were read out 6 times in 5 min. The instrument was flown as a piggy-back experiment on the first transatlantic balloon flight launched at 0505 UT on August 15, 1975 from Trapani, Sicily (38°N, 13°E). The balloon reached a ceiling altitude of about 3.0 g cm^{-2} at 0740 UT, and floated for 78 h before being cut down over Kentucky, USA[6]. The data were transmitted using a high-frequency radio link and were recorded at two ground stations, one in Sicily and the other in Chesapeake Beach, USA. The region of sky observed during this flight included a complete band across the celestial sphere defined by $\delta=+38\pm60°$.

The counting rates observed in each energy channel indicated the perfectly normal behaviour of the instrument. The changes in the detector counting rates from time to time were well understood in terms of variations in the residual atmospheric depth and other detector parameters. Since this transatlantic flight was the first of its kind, good scientific data were obtained for only about 70% of the time at float altitude. The loss of data arose mostly from the particular configuration of the high frequency communications system used on this proving flight. The criterion

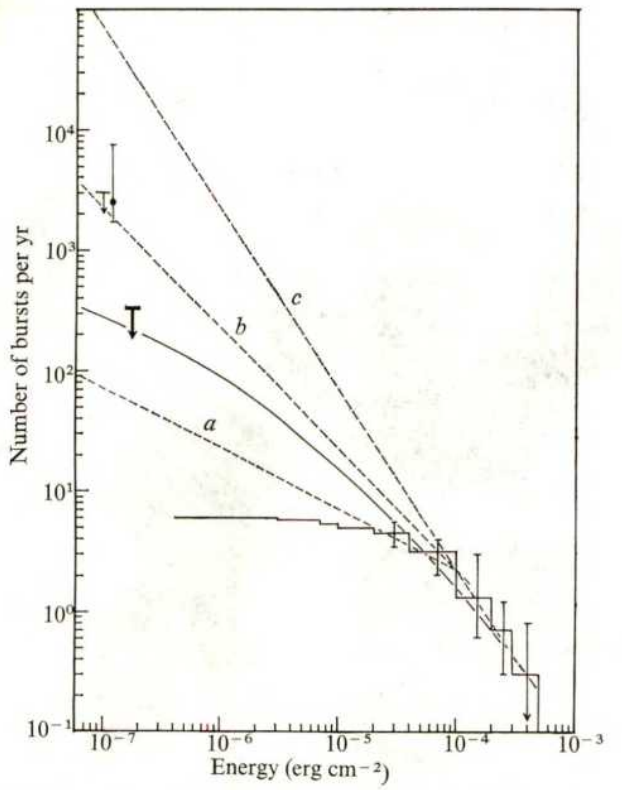

Fig. 1 Observed data of γ-ray bursts along with the results reported here. The limits defined by Cline *et al.* are those presented in ref. 5. Solid line, modified galactic distribution, $S^{-1.0}$ with a break point around 5×10^{-5} erg cm^{-2} and the dotted lines represent the form $N \propto S^{-\alpha}$ where $\alpha = 0.5$ (*a*), 1 (*b*) or 1.5 (*c*) for one-two- and three-dimensional distribution; stepped line, Vela events; ●, ref. 2; thin arrows, ref. 4; thick arrows, our results.

for the detection of a burst was that the counting rates per interval should each increase by more than 3σ above the background rate in at least three successive 0.6-s intervals. No candidate burst event could be found in the data. Such an excess would have corresponded to a signal strength of 0.36 photon cm^{-2} in the energy region 100–1,000 keV. This is equivalent to 0.1 photon cm^{-2} in terms of the Vela detector threshold, assuming an E^{-2} differential photon spectrum. Figure 1 shows the log*N*–log*S* distribution observed for Vela events along with the upper limit derived from this experiment. It can be seen that the limit is a factor of 5 lower than that expected from an S^{-1} distribution and about 100 times smaller than the value expected from an $S^{-1.5}$ number distribution. A 95% confidence upper limit would be higher than the plotted value by a factor of 3. That limit is still lower than that expected, even on the assumption of a two-dimensional distribution of burst sources. The present results favour the $S^{-0.5}$ spectrum for γ-ray bursts.

The results seem to demonstrate that the bursts are not of extragalactic origin, otherwise they would give an isotropic distribution. Similar conclusions have been suggested by Strong *et al.*[3] on the basis of the general features of observed γ-ray bursts. A galactic distribution of nearby sources would follow an $S^{-1.5}$ distribution for sources up to 300 pc, which is typical of the thickness of the galaxy. It would then change to an S^{-1} distribution for sources up to 3 kpc, which is the distance to the galactic anticentre, and then tend towards an $S^{-0.5}$ distribution beyond that point. If the break point at 10^{-4} erg cm^{-2} in the Vela data is genuine, and occurs because of the limited thickness of the galaxy, then one would also expect to find a less defined change of slope at about 10^{-6} erg cm^{-2}. On this basis, the expected number of bursts would be about 3 times greater than the upper limit obtained in our detector. But a pure disk population of burst sources with an S^{-1} distribution, and with a Gaussian distribution in its intrinsic source luminosities, would have a steeper slope on the log*N*–log*S* curve for energies greater than that expected from the mean luminosity. A log*N*–log*S* distribution has been calculated for such a disk population with a mean luminosity corresponding to a detected energy of 10^{-4} erg cm^{-2}. This also includes a further flattening between 10^{-5} and 10^{-6} erg cm^{-2} which arises when sources are at a distance of 3 kpc.

We believe that our results are consistent with a size distribution of $S^{-1.5}$ above 10^{-4} erg cm^{-2} and $S^{-0.5}$ below this energy, as determined for the Vela bursts. A distribution function obtained from a galactic population with a Gaussian spread in intrinsic luminosities having a break point at $\sim 5 \times 10^{-5}$ erg cm^{-2} would, however, also be compatible with our data. The break point at 10^{-4} erg cm^{-2} in the case of the Vela events may arise because of the characteristics of the Vela detection system, since it is optimised for events having a fast rise time. A slowly rising burst could escape detection. For example, the event of April 27, 1972 was seen by Apollo 16 but was not detected by the Vela satellites.

In view of the two competing spectra, $S^{-0.5}$ and S^{-1}, modified by a Gaussian distribution in luminosities, a reduction by a factor of about 10 in the limit obtained by this experiment is needed to establish the true nature of the source origin. Clearly, reducing the threshold sensitivity much below that of the present detector has little advantage, whereas the extension of the observation period reduces the limit in direct proportion to the flight length. Exposure times of up to 500 h could be obtained in relatively few flights using the techniques developed for the transatlantic balloon facility. It is important that some of the future long duration flights should be made in the Southern Hemisphere, where the galactic centre would pass within the field of view of the detectors. When quasi-omnidirectional detectors are used, it will be necessary to qualify any result on the size spectrum of γ-ray bursts with information on the sky coordinates of the region observed. The true form of the size spectrum is of extreme importance in the development of theories to explain γ-ray bursts. Some attempts at a theoretical explanation of this class of event have been made, but any quantitative picture will change drastically if the size spectrum follows either of these two distribution or, in the extreme case, if the distribution has a cutoff at lower energies.

We thank the SRC, Consiglio Nazionale delle Richerce and US National Scientific Balloon Facility for help with the first transatlantic balloon flight. We also thank the Naval Research Laboratories (Washington) for the use of their Chesapeake Beach radio receiving station.

Palynomorphs indicating Permian rocks in Ethiopia

Karroo (Carboniferous to Triassic) strata have been reported in Ethiopia[1,11,12], but without firm documentation. Other sediments lying on the crystalline basement but beneath the Jurassic Adigrat Sandstone[2] may also be of Karroo age[3–5]. To our knowledge, however, the occurrences reported here are the first palaeontologically substantiated records of Permian strata in Ethiopia. Localities are shown in Fig. 1.

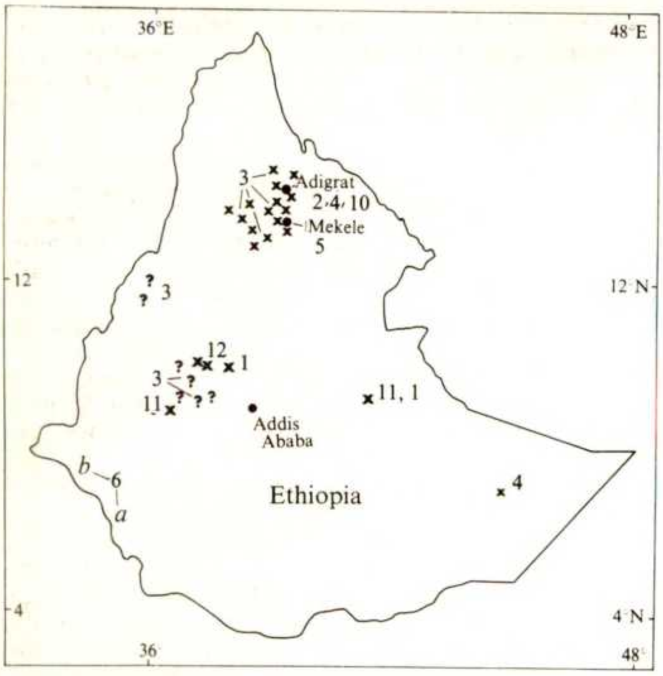

Fig. 1 Localities of post-Precambrian and pre-Jurassic (pre-Adigrat) strata in Ethiopia. *a*, Kari sandstone; *b*, Gilo sandstone; **x**, probable Karroo; x, pre-Adigrat; ?, Adigrat ?; numbers, references.

Several outcrop areas of apparently unfossiliferous fluviatile sandstones and conglomerates were discovered in western Kefa and Ilubabor Provines, south-western Ethiopia, in 1974 during reconnaissance mapping[6] The sediments are consolidated, tilted, and faulted; they lie unconformably on late Precambrian(?) crystalline basement and are overlain by mid to late Tertiary basalts with shallow angular unconformity. They differ distinctly in facies and thickness from the red, residual conglomeratic sandstone, generally less than 10 m thick and of unknown age, that marks the basement–basalt unconformity to the south-east[6,13,14]. Samples suitable for palynological analysis, taken from two localities 125 km apart (Fig. 1, *a* and *b*), yielded identifiable Permian miospores. At locality *a*, the Kari sandstone, comprising at least 30 m of fluviatile sandstones with minor conglomerate and siltstone, occurs in several small outcrop areas, in part fault bounded, in which the strata dip gently south-westwards. Miospores are common, but most are corroded, broken, and dark brown to black, indicating a relatively high degree of thermal metamorphism of the organic material, and some post-depositional oxidation. On prolonged laboratory oxidation they became sufficiently translucent to allow identification of the following: *Alisporites* sp.; *Granulatisporites micronodosus* Balme and Hennelly; (?)*Horriditriletes ramosus* (B. and H.) Bharadwaj and Salujha; *Klausipollenites schaubergeri* (P. and K.) Klaus (Fig. 2*c*); *Kraeuselisporites* sp.; *Parasaccites* sp. (Fig. 2*a*); *Protohaploxypinus* sp. (Fig. 2*b*); *Striatopodocarpites* sp.; *Vittatina* sp. (Fig. 2*d*); and *V.* (?) *costabilis* Wilson. As the fossils were difficult to identify because of rather poor preservation, no information on the quantitative composition of the assemblage was obtained. On broad comparisons, the assemblage is like those from the Lower and Upper Permian of Gondwanaland in its relatively high percentage of *Striatiti*. It also resembles those from the Upper Permian of Europe in the presence of *Klausipollenites schaubergeri*. Thus, like Upper Permian assemblages of Gabon[7], it seems to be somewhat transitional in composition between Gondwana and European assemblages.

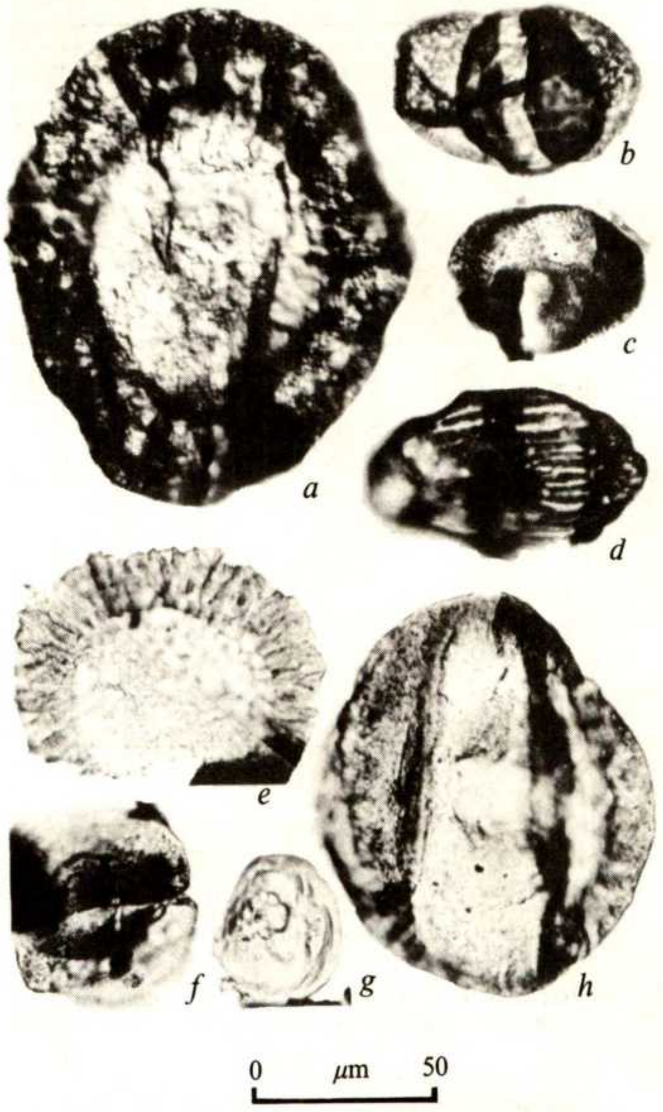

Fig. 2 *a–d*, Miospores from the Kari sandstone: *a*, *Parasaccites sp*. (GSC 45731); *b*, *Protohaploxypinus* sp. (GSC 45732); *c*, *Klausipollenites schaubergeri* (P. and K.) Klaus (GSC 45733); *d*, *Vittatina* sp. (GSC 45734). *e–h*, Miospores from the Gilo sandstone: *e*, (?)*Nuskoisporites gondwanensis* (B. and H.), (GSC 45735); *f*, (?) *Pallidosporites magnus* Schaar. (GSC 45736); *g*, (?) *Marsupipollenites* sp. (GSC 45737); *h*, (?)*Divarisaccus* sp. (GSC 45738). Numbers in brackets refer to specimens in the National Type Collection, Geological Survey of Canada, Ottawa.

At locality *b* (Fig. 1), the Gilo sandstone occurs in two basins separated by a north-westerly-trending basement arch. The poorly exposed south-western occurrence, 100 km^2 in area, is a homocline faulted against basement on its south-west side, and may contain as much as 1,500 m of strata, unless it is repeated by unrecognised faults. The north-eastern basin plunges gently north-westwards, and contains at least 300 m of strata, sparsely exposed within a 250 km^2 area. Calcite-cemented feldspathic quartz sandstones predominate, with interbedded arkosic conglomerate in the basal part. The transportation direction in both basins is mainly to the south-west. Miospores are relatively rare in the available sample from the north-eastern basin. In contrast to those from the Kari sandstone, they seem to have been little affected by thermal metamorphism, being brownish yellow without laboratory oxidation. The following were recognised: *Alisporites* sp.; *Cordaitina* sp.; (?)*Divarisaccus* sp. (Fig. 2*h*); *Kraeuselisporites* sp.; (?)*Marsupipollenites* sp. (Fig. 2*g*); (?)*Nuskoisporites gondwanensis* Balme and Hennelly (Fig. 2*e*); (?)*Pallidosporites magnus* Schaarschmidt (Fig. 2*f*); *Parasaccites* sp.; and *Protohaploxypinus* sp. Most specimens are corroded, and this, coupled with their relative rarity in the studied sample, makes precise age determination difficult. Therefore, as with the Kari sandstone sample, it is only possible to determine the age in broad terms from the palynological data. Striate pollen are rare, and large, radially symmetrical monosaccate forms comprise a greater proportion of the assemblage than in the Kari sandstone, suggesting a closer affinity with Lower rather than Upper Permian assemblages of the Gondwana region[8,15]. This suggestion is supported by the observation of a single specimen of (?)*Nuskoisporites gondwanensis* Balme and Hennelly (Fig. 2*e*; (?)=*Parasaccites* sp. of Segroves[9]).

The limited miospore assemblages we have studied from the Kari and Gilo sandstones, although evidently Permian and similar to those of the Gondwana Province, can be cautiously dated more precisely as late and early Permian, respectively. Considering that the samples reported here were not collected specifically for palynological studies, however, it seems reasonable to predict that samples collected primarily for that purpose would give a better yield of palynomorphs and enable a more precise determination of the age and geological history of Permian strata in this part of Ethiopia.

In western central Ethiopia, 300–400 km north-east of the Kari and Gilo sandstones, large tracts of clastic sediments have been mapped as Adigrat Sandstone[3], although pre-Adigrat sediments are known[1,12] or suspected to be present locally. The term Adigrat Sandstone was at first applied collectively to sandstones lying in the same stratigraphic position in northern Ethiopia[10], but later work[2,5] has shown that parts of the original unit, namely the Enticho Sandstone, the Edaga Arbi Tillite, and the Enguya Sandstone, are older than the basal clastic sediments of the Mesozoic marine transgression, to which the name Adigrat Sandstone has now been restricted[2]. The Adigrat Sandstone as redefined is Jurassic and is known to thin westwards beneath its cover of marine limestones[4], although its rapid thinning to the west where overlying limestones are absent may be attributable in part to later erosion. On the basis of the occurrence of Permian strata in south-western Ethiopia reported here, and the recognition of pre-Adigrat sediments to the north-east, it seems likely that much of the apparently thick sedimentary succession mapped as Adigrat Sandstone in western central Ethiopia may also be of Karroo age. If so, Karroo sediments are more widespread north of their formerly recognised northern limit than was previously suspected.

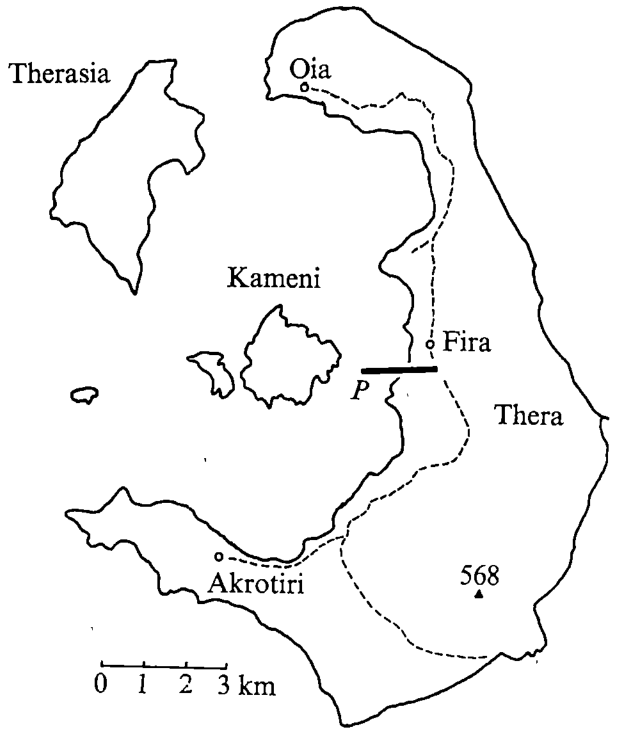
Radiocarbon dates of Santorini volcanics

THE caldera walls of the ring-islands Thera and Therasia, belonging to the Santorini Group (Fig. 1) in the southern Aegean, are built up of lavas and pyroclastics, among which pumice layers are particularly striking (Fig. 2). The top layer (Bo, abbreviated from the German term "oberer Bimsstein"[1]) comprises air-fall pumice and ashes, overlain by thick pyroclastic flows[2,3]. It was produced by the catastrophic outburst of the Thera volcano in late-Minoan time, which culminated in the collapse of the Santorini caldera[4]. The decline of the Minoan civilisation around 1500 BC has been attributed to these volcanic events[5]. The Upper Pumice Series buried late-Minoan settlements on Thera and Therasia, and an important settlement near Akrotiri in the southern part of Thera is still being excavated[6]. The Upper Pumice Series rests on an old soil horizon (black layer in Fig. 2) in which remnants of late-Minoan houses were found in 1869 (ref. 7). Wood from such houses found at the base of the pumice quarries south of the town of Fira has provided radiocarbon dates of 3,370±100 yr b.p. (ref. 8). This age coincides exactly with archaeological data for the destruction of late-Minoan settlements on Santorini[6].

The Bo palaeosol is spread all over Thera and Therasia. Its thickness locally reaches 3–4 m, for example, on Therasia, where carbonised plants have been found in its lower parts. ^{14}C dating of these plants has given an age of 12,950±756 yr b.p. The palaeosol horizon rests unconformably on a small sequence of welded tuffs and slightly welded pumice flow deposits. A maximum thickness of 12 m for these ignimbrites occurs in the southern part of Thera. The walls of the partly excavated late-Minoan town near Akrotiri are founded on these ignimbrites. ^{14}C ages of charred trees which sporadically occur in the pumice flow deposits forming the lower part of the ignimbrite series have provided ^{14}C dates of 18,050±340, 18,165±210 and

Fig. 1 The Santorini Group in the Aegean Sea, Greece. The old ring-islands Thera and Therasia surround the late-Minoan Santorini caldera and the post-Minoan Kameni islands. *P*, location of the schematic profile (Fig. 2).



18,880±230 yr b.p. (ref. 3). The ages show that an exceptionally long interval of about 15,000 yr without any volcanic activity on Santorini preceded the late-Minoan outburst. During this interval the contemporaneous volcanic top layers were deeply decomposed and altered to a thick palaeosol.

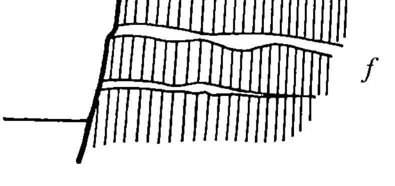
The ignimbrite series is underlain by a stratigraphic sequence of at least 19 alternating pyroclastic strata comprising mostly dark ashes, cinders, scoriae, pumice, bombs, xenolithic lapilli, blocks, and so on. Many of these strata can be subdivided into numerous small beds and horizons. The total thickness of the complete sequence underlain by the Middle Pumice Series (Bm, "mittlerer Bimsstein") amounts to about 30 m. The sequence represents a long period of volcanic activity of the Thera and adjacent volcanoes with some overlap of their products. Intervals of quiescence are marked by some decomposed ash layers and fossil soil horizons, four of which are rich in plant fossils (*Chamerops, Olea, Pistacia, Phoenix,* and *Tamarix*). All of these genera still exist among Mediterranean flora. This means that during that time the Mediterranean climate was the same as at present.

Radiocarbon dating of a carbonised piece of tree found about 1.5 m under the lower plant horizon in the lower part of the pyroclastic sequence, has given an age of 36,700± 1,025–950 yr b.p. (determination by the Niedersächsisches Landesamt für Bodenforschung, Hannover). Another ^{14}C dating of the same sample (performed in the Geochron Laboratories, Cambridge, Massachusetts) has shown an age of more than 37,000 yr b.p. Therefore, the plant horizons of Santorini can be correlated with the Kalabaki I and II interstadial (between 37,000 and 35,000 yr b.p.) demonstrated by palynological studies near Thessaloniki in northern Greece[9].

Twenty distinctive tephra layers, derived from various sources[10], have been identified in Quaternary deep-sea cores of the eastern Mediterranean[11]. Mellis[12] has correlated the upper tephra layer in the cores collected on the Albatross with the Upper Pumice Series on Santorini.

His correlation has been confirmed by Ninkovich and Heezen[13], who have identified the Upper Tephra Layer in 14 cores collected on the Vema. The Middle Tephra Layer, which has been detected in Vema core 10–58, has been correlated with the Lower Pumice Series (Fig. 2, Bu, "unterer Bimsstein") on Santorini. Based on a ^{14}C age of 17,860 yr b.p., taken from carbonised pumice found on the neighbouring island of Anaphi, the Lower Pumice Series was deposited[14], probably 17,000–18,000 yr b.p. This is inconsistent, however, with the age of the Lower Pumice Series if the plant horizons (37,000 yr) and their stratigraphic position (Fig. 2) are taken into account. According to that evidence, that part of the volcanic sequence on Santorini which underlies the plant horizons, including the Middle (Bm) and the Lower Pumice Series (Bu), must be older than 37,000 yr.

Fig. 2 Schematic profile (*P* in Fig. 1) of the caldera walls of Thera, south of Fira. For explanation see text. *a*, Upper Pumice (Bo); *b*, palaeosol; *c*, ignimbrites; *d*, Middle Pumice (Bm); *e*, Lower Pumice; *f*, lavas. Figures denote radiocarbon ages (yr b.p.)



The Middle Tephra Layer of the Vema 10–58 core, however, can more appropriately be correlated with the ignimbrite series, for which an age of between 18,000 and 18,500 yr can be fixed. Mineralogical and petrochemical characteristics of the Middle Tephra Layer[14] correspond exactly to the pumice in the lower part of the ignimbrite series. The refractive index of the glass is 1.514 (ref. 15), about the same as in the Lower Pumice Series. Therefore, the refractive index cannot be used as a discriminative factor[14] between the two pumice series. It may also be noted that a layer in the Albatross core 189 has provided an age of 17,200±500 yr b.p. (ref. 16), which roughly fits with the age of the ignimbrite series.

Based on the fact that the Middle Tephra Layer is not to be correlated with the Lower Pumice Series but corresponds to the stratigraphically younger Ignimbrite Series, the position of the Lower Pumice Series in the deep sea cores is still unknown. In any case, the corresponding tephra layer must be situated below the "Ischia Tephra"[14] (or "Lower Tephra"[13]), which has an age of 24,000 yr b.p.

We thank the Deutsche Forschungusgemeinschaft and the Carlsberg Foundation for financial support, the Niedersächsisches Landesmat für Bodenforschung, Hannover and the Institut für Umweltphysik/University of Heidelberg for ^{14}C determinations. Formation of Hercynian subplates, possible causes and consequences

WITH the exception of the microplate models of Badham and Halls[1] and Riding[2] models of Hercynian plate tectonics[3–7] have assumed the existence of only one plate, that is, South Europe, between Africa and the Tethys in the south and North America–Europe and the Mid-European Ocean in the north. The South European plate has generally been considered as a stable unit. Studies of the Alpine

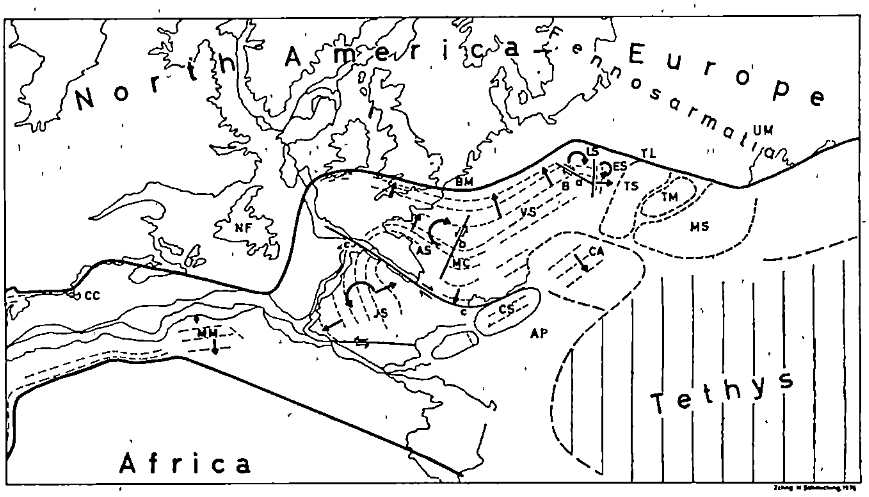

Fig. 1 Schematic map of the South Europe plate and neighbouring plates for the late Hercynian time showing subplates, major wrench faults, and general structural trends within South Europe. Base map after Bullard *et al.*[24] and Dewey *et al.*[8]. Thick lines = continental margins of bordering plates; thick arrows = direction of migrating fold-belts; thick curved arrows = direction of rotation of subplates in respect to Variscan subplate. Key to abbreviations: AP = Apulia; AS = Amorican subplate; B = Bohemia; BM = Massif of Brabant; CA = Carnics; CC = Cape Cod; CS = Corsica–Sardinia; ES = East Sudetan subplate; IS = Iberian subplate; LS = Lugian–Silesian subplate; MC = Massif Central; MM = Moroccan Meseta; MS = Moesian subplate?; NF = Newfoundland; TL = Tornquist Line; TM = Tirgu–Mures subplate?; TS = Tatride subplate?; UM = Ukrainian Massif; VS = Variscan subplate; a = Elbe wrench fault; b = Sillon Houiller wrench fault; c = Biscaya–Pyrenees wrench fault.

system[8], however, suggest that such an assumption may not be valid. I assume here that during the Carboniferous, South Europe was originally an elongated plate with nearly straight margins and internal structures. Collision with the irregular continental margins of the bounding plates North America–Europe and Africa induced subdivision of South Europe into semi-independent subunits, that is, into subplates, and formation of major arc-like structures and wrench faults.

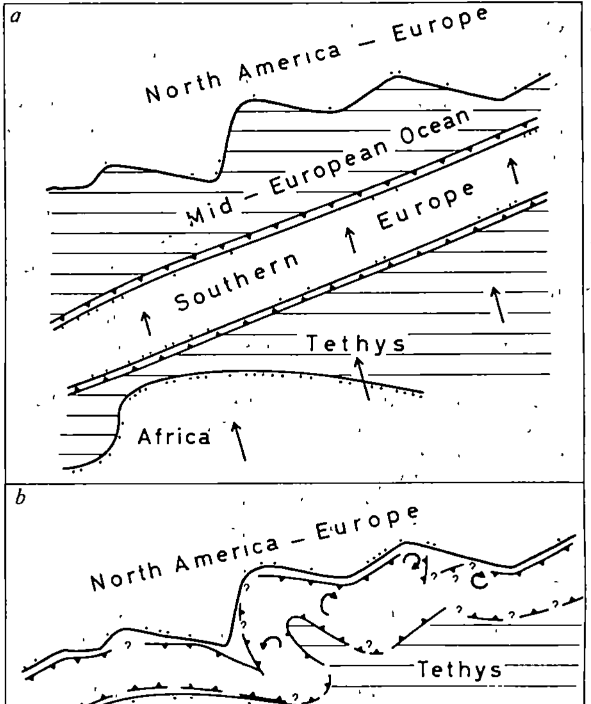
Both North America–Europe and Africa were large plates. The postulated South Europe plate in contrast was characterised by great length and small but variable width compatible with an origin by accretion of new crust at an island arc system. In general, the oldest rocks of the plate occur within a central ridge that extends from Bohemia through the Massif Central, Brittany into Iberia and the Moroccan Meseta. Distribution of younger rocks to either side has been taken to indicate that two fold belts migrated away from the central ridge, one towards the north and the other towards the south[7,9–12] (Fig. 1). This process has been ascribed to the oceanward movement of two opposed subduction zones[3,13]. Metamorphism and emplacement of granites also began in the central ridge and became progressively younger towards the plate margins.

Dehydration and partial melting of former oceanic crust subducted beneath South Europe during the Carboniferous may have led to the formation of zones of hot partially molten upper mantle material above the opposed subduction zones. Diapiric uprise and lateral spreading of this material may have in turn caused widespread partial melting in the lower crust of South Europe and high temperature–low pressure metamorphism of upper crustal rocks[13]. As a consequence South Europe during the greater part of the Carboniferous was probably a rather thin and hot plate with a rigid crust ~ 20 km thick. In contrast the adjacent parts of both North America–Europe and Africa did not experience extensive granite emplacement and high temperature–low pressure metamorphism during the Carboniferous. It can therefore be assumed that the heatflow within both plates was lower than under South Europe and that both plates were cooler and consequently characterised by thicker lithosphere than South Europe. Applying this concept, which is of critical importance to the model given below, it is likely that the mechanical properties of the thin and hot South Europe plate were quite unusual and very different from those of the two major plates bordering it.

Uplift of the crust of South Europe, regional erosion of the central zone, formation of intermontane troughs and associated volcanism were also probably related directly to the uprise of hot upper mantle material. Spreading of this material caused migration in the onset of uplift, erosion, trough formation and volcanism[13]. This activity persisted into the Lower Permian in spite of the cessation of subduction in Upper Carboniferous time because of the collisions between the South Europe plate and the bounding North America–Europe and Africa plates.

According to McKerrow and Ziegler[14] and Dewey and Kidd[15] the pre-Hercynian margin of eastern North America and southern Britain was formed by rifting during the Devonian when northern South America and North America–Europe collided and then separated again soon after. Subsequently, South Europe and Africa were sutured to North America–Europe by continent–continent collisions[5,6,13], events which also apparently caused the ter-

Fig. 2 *a*, Sketch map of the pre-collision South Europe plate with its two subduction zones (thrust lines), the bordering oceans and the irregular continental margins of North America–Europe and Africa. Arrows indicate potential direction of drift. *b*, Sketch map of the South Europe plate near the end of the continent–continent collisions. The South Europe plate adjusted to the irregular continental margins of the neighbouring plates by distortion, that is, formation of subplates. Curved arrows indicate sense of rotation of subplates.



mination of subduction of oceanic crust of the Tethys further to the east. The suture line, represented by Hercynian fold belts, is not straight, but probably reflects the pre-existing form of the North America–Europe continental margin. Assuming that the southern continental margin of North America–Europe underwent little modification during suturing it is likely that its previous form was irregular and of a configuration typical of rifted margins. There are projections and embayments. Long relatively straight segments meet at rather sharp bends in the manner described by Dewey and Burke[16].

During its northward approach, South Europe eventually managed to fit into the irregularities of the southern continental margin of North America–Europe. South Europe is unlikely to have possessed the required configuration to fit the irregularities of the continental margin of the northern plate in the manner of a jig-saw puzzle. A more reasonable assumption is that the original configuration of South Europe was one of almost straight structural trends within the plate and also an originally straight northern plate margin (Fig 2) This form would be favoured by an origin of the plate as a series of island arcs. During collision South Europe would have needed to adjust until it eventually fitted all irregularities of the southern continental margin of the North America–Europe assuming these were relatively unmodified by the collision. Progressive subduction of the Mid-European ocean crust between North America–Europe and South Europe would have allowed the latter plate to collide first with the southernmost projections of the former, then through internal deformation and wedging aside of large slices to advance further northwards and finally fit into the embayments of the continental margin of North America–Europe.

During this process, South Europe probably collided first with the Ukrainian Massif of Fennosarmatia. Along newly forming wrench faults subplates were driven aside and rotated, and were left behind by the main part of South Europe, which was able to proceed further northwards, west of the Tornquist line. Such subplates are the Lugian–Silesian and East Sudetan subplates, probably also the Hercynian massifs in the realm of the Carpathians, that is, the Tatride, Tirgu–Mures, and Moesian subplates (Fig. 1). Palaeomagnetic studies of Upper Carboniferous rocks from the Bohemian Massif and the Inner Sudetic basin separated by the Elbe wrench fault indicate a late Hercynian rotation of 17° between these areas[17]. This relatively small rotation is believed to represent only part of the total rotation which is assumed to have commenced before the Westphalian. Evaluation of deep boreholes clearly shows that a postulated connection between the Rhenohercynian zone and Westphalian coal measures of the Ruhr district with equivalent zones of the Sudetic Mountains and the Upper Silesian coal basin[18] does not exist[19]. This is believed to be caused by the disruption of the originally continuous fold belt during its formation by collision with Fennosarmatia. In spite of this disruption, later development of both areas followed similar paths, for example in the deposition of the Upper Carboniferous coal measures.

Another important bend in the southern continental margin of North Europe existed at the south-eastern margin of the Massif of Brabant, Belguim. South of this, nappe structures, unique in the Rhenohercynian zone, were probably developed in response to a local concentration of compressional forces. To the west of this bend there extended a large embayment bounded to the west by Newfoundland. It is postulated that the South Europe plate reacted to contact with this embayment by formation of several subplates. West of the Variscan subplate, the Amorican and Iberian subplates formed, separated from each other by major wrench faults, that is, the Sillon Houiller and the Biscaya–Pyrenees wrench faults[20]. The Amorican subplate rotated clockwise relative to the Variscan subplate and Iberia in turn rotated anticlockwise relative to both the Variscan and Amorican subplates, these rotations, together with translations, finally resulted in the closure of the embayment. This process of rotation of both subplates in opposite directions would have caused intense shearing stresses and consequent intense internal deformation of both subplates. It is assumed that the partially molten and thus relatively soft lower crust could have reacted by plastic deformation recorded by the two large basement arcs in the Massif Central and in Brittany–NW Iberia whereas the more rigid upper crust could have reacted only through formation of many wrench faults within both subplates[20]. Further analysis of the wrench fault system should clarify the mechanism by which the two subplates moved into the embayment.

Another consequence of this major tectonic event was that the south-eastern continental margins of both subplates which were originally colinear, were rotated until they finally came into contact. In addition, the two fold belts situated north-east of the Iberian ridge and south of the Massif Central were probably also initially colinear, and only during the later part of their evolution, that is, during collision of South Europe with North America–Europe, did they rotate to face each other, migrate towards each other and eventually come into contact in the general region of the Pyrenees. It seems quite possible that some crustal slices from the southern margin of South Europe were driven aside during this subplate collision. Van der Voo[21] recently discussed palaeomagnetic data from some Palaeozoic Iberian rocks and concluded that Iberia rotated for at least 40°, that is the total value of the anticlockwise rotation of Iberia exceeds its Mesozoic value of 35°.

To the south-west of the large embayment, the Newfoundland projection and the bend in the continental margin near Cape Cod may have induced formation of major wrench faults, and thus the formation of several subplates, now located in Morocco, Algeria, and Southern Spain. In western Morocco, the general structural trend of the Hercynian fold belt is NE–SW to N–S. At the northern margin of the Moroccan Meseta, between Rabat and Tiflet, however, there is a sharp bend in the structures towards the east[22,23]. Varied structural trends in the Hercynian Massifs of NE Morocco and Algeria may in part be due to formation of Hercynian subplates. The Iberian and North African subplates must have been separated by major wrench faults across which large changes in the structural trends took place. Collision of the Moroccan, Algerian, and Iberian parts of South Europe with Africa probably also facilitated the squeezing of South Europe into the large Brabant–Newfoundland embayment.

During collision with elongated South Europe the irregular rifted continental margins of North America–Europe and Africa are believed, as argued above, to have induced formation of major arc-like basement structures and many wrench faults, some of which form the boundaries of subplates and thus to have produced the diversity in major structural trends of the Hercynian fold belt. The postulated mechanical properties of the South Europe plate, in contrast to those of the two large plates that flanked it, are believed to have enabled South Europe to react in the manner outlined. The force that drove South Europe against the flanking plates was apparently not as great as during collisions associated with the Alpine system. The scarcity of large nappes and lack of areas of strong post-collision uplift arising from one continental plate overriding another lend support to this model. A reason for this could have been a reduction in the velocities of the approach of the two large plates because of the spread of hot mantle material beneath the South Europe plate.

Late Hercynian formation of intermontane troughs, many of which are located on wrench faults, and associated volcanicity commenced in uppermost Viséan time. These late

Hercynian processes were very similar on the postulated subplates of South Europe, even in post-collision Lower Permian time. Thus crustal spreading of South Europe took place in a number of different directions simultaneously as the subplates in this respect behaved as individual units. This again seems to have been possible only if the force driving South Europe against the adjacent plates was not very great.

Two other possible consequences of the model are that the formation of the irregularly rifted continental margins of North America–Europe and north-western Africa might have influenced the pattern of subsequent opening in the relevant area of the North Atlantic, and ultimately may have played a part in the behaviour of South Europe during the Alpine cycle of plate tectonic processes. Some of the major wrench faults between the Hercynian subplates, being major zones of weakness may have been reactivated during the opening of the North Atlantic and during the Alpine cycle. Some of the subplates were probably blocked out and developed into microplates. Thus the heritage from the rifted continental margin of North America–Europe and the Hercynian plate tectonics may, in part, have caused some of the peculiarities of the Alpine orogenic belts, for example the numerous microplates described from the Mediterranean area[8] and some of the arc-like fold belts as in the Carpathians.

Revision of an earlier version of the manuscript by I. A. Nicholls is acknowledged.

Age relationships along the Hermitage Bay–Dover Fault System, Newfoundland

WE present here geochronological evidence that parts of the Central Mobile Belt and the Avalon Zone of Newfoundland have been contiguous since the Ordovician or earlier, and that some time after about 4 Myr, significant movement took place along part of the boundary.

Wilson[1] has used fossil, lithological, and palaeoclimatic evidence to suggest the existence of a Lower Palaeozoic Proto-Atlantic Ocean close to, but not coincident with, the site of the present Atlantic. The fossil evidence he cited showed that the Avalon Zone (Fig. 1) of the island of Newfoundland was on the European side of the Proto-Atlantic ocean in Cambrian and Lower Ordovician times, whereas the Western Platform (Fig. 1) was on the North American side of the ocean. The same evidence also suggested that the Proto-Atlantic ocean became narrower later in the Ordovician, although to what extent is very much a matter of debate. Wilson proposed that closure of the ocean and the consequent collision of the opposing continental margins was the mechanism responsible for much of the orogenic activity in Europe and eastern North America during Palaeozoic time, and that the opening of the present Atlantic resulted in transposition of fragments of the continents, such as is found in Newfoundland. Others (see ref. 2) have extended Wilson's original idea.

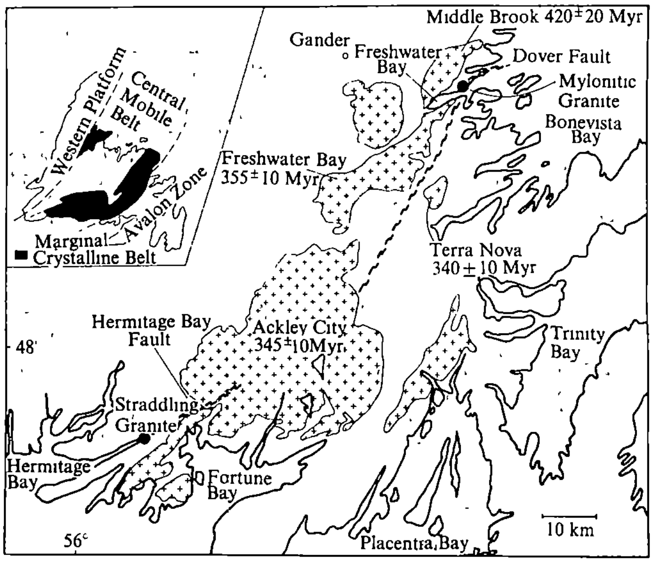

Fig. 1 Diagram showing the relationship of the Mylonitic and Straddling granites to the Hermitage Bay–Dover Fault System. The Rb–Sr age data are taken from ref. 8.

The site of closure of the Proto-Atlantic ocean may be marked in Newfoundland by the boundary between the Central Mobile Belt (Fig. 1) and the Avalon Zone[3,4], though alternative proposals have been made[5,6]. The boundary separates a long strip of gneissic rocks and metasedimentary sequences (the Gander Zone) from the much less deformed, late Precambrian volcanics and sediments of the Avalon Zone[4]. The proposal has been made that the Hermitage Bay–Dover Fault System, a supposedly continuous fault system with a length of over 200 km, marks the boundary[7]. Unfortunately, a large part of it is obscured by the Ackley City Granite (Fig. 1), which has been dated at 345±10 Myr (ref. 8).

Our geochronological evidence is provided by Rb–Sr, total-rock ages from two granites intimately associated with the Hermitage Bay–Dover Fault System. The "Straddling" Granite, at the head of Hermitage Bay, gives an isochron age of 490±10 Myr (Fig. 2*a*), and the "Mylonitic" Granite, adjacent to the Dover Fault, gives an age of 400±30 Myr (Fig. 2*b*). (Both intrusions have yet to receive formal names.) The analytical information is provided in Table 1.

The "Straddling" Granite, as its name implies, straddles the boundary between the Gander and Avalon Zones, and is cut by a breccia zone 50–100 m wide, which is the most southerly expression of the Hermitage Bay Fault. The pluton intrudes both the Garrison Hills Gneiss of the Gander Zone, and volcanics of the Connaigre Bay Group of the Avalon Zone. Although the granite is brecciated, (O'Driscoll, private communication) there is no sign of mylonitisation.

The "Mylonitic" Granite[7,9] occurs adjacent to the trace of the Dover Fault, which is marked by a zone of mylonitisation 300–500 m wide and at least 20 km long[7]. The fault separates the Bonavista Bay Gneiss Complex (Gander Zone)

Table 1 Analytical results

Sample	Petrographic notes	Rb (p.p.m.)*	Sr (p.p.m.)*	^{87}Rb/^{86}Sr (atomic)†	^{87}Sr/^{86}Sr (atomic)‡
Straddling Granite	Medium to fine-grained granite, alkali feldspar mainly microcline, some perthite. Euhedral to subhedral plagioclase (~An_{34}), altered to sericite and epidote. Anhedral quartz with some serrate boundaries, undulose extinction. Some polygonised grains Accessory minerals: epidote, sericite, carbonate, sphene, apatite, chlorite				
SG–1		130	214	1.75	0.7158
SG–2		119	19	18.0	0.8367
SG–3		73	20	10.5	0.7779
SG–4		23	92	0.72	0.7094
SG–5		20	92	0.62	0.7087
SG–6		29	132	0.63	0.7087
Mylonitic Granite	Medium to fine-grained granite, alkali feldspar mainly microcline, some perthite Granitic texture still evident in all but two of the samples. Plagioclase (An_{21}–An_{32}) altered and fractured, quartz usually anhedral, polygonised grains common, undulose extinction. Pronounced cataclastic deformation in MG–4 and MG–5; foliation defined by alternating bands of muscovite and fine-grained quartzofeldspathic material. Some feldspars augened, accessory minerals include sericite, epidote, chlorite and sphene				
MG–1		129	113	3.3	0.7255
MG–2		102	105	2.8	0.7234
MG–3		92	89	3.0	0.7245
MG–4		72	161	1.30	0.7146
MG–5		55	160	0.99	0.7117

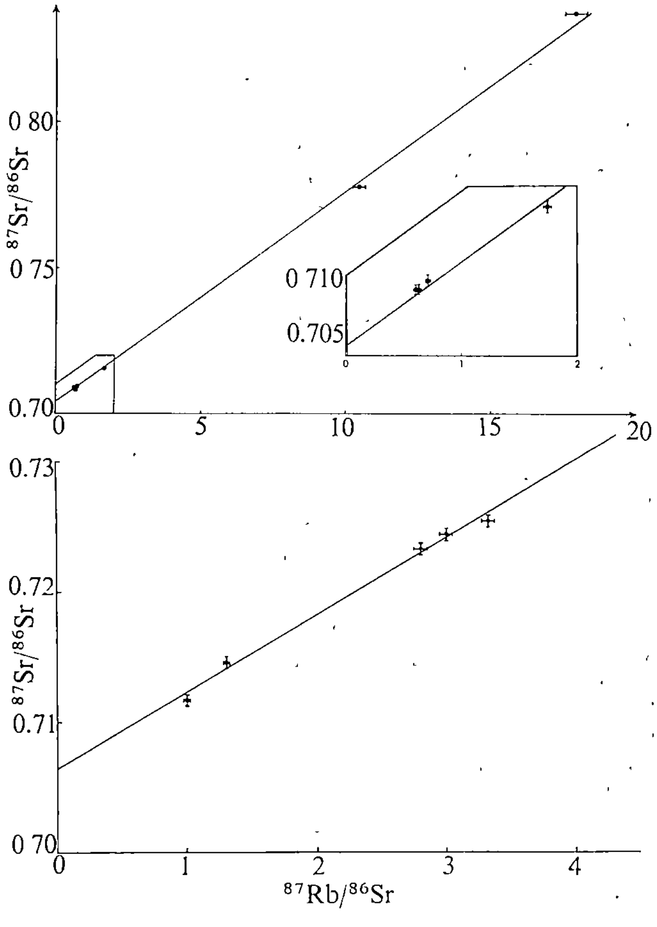
} at 99% confidence level; $\lambda^{87}Rb = 1.47\times10^{-11}$ yr^{-1}

from volcanics of the Love Cove Group (Avalon Zone); the latter are considered to be unconformably overlain by sediments of the Musgravetown Group (Avalon Zone). The granite exhibits a mylonitic fabric close to the fault, and there is some evidence for later brecciation. The age of 400±30 Myr, we feel, represents the emplacement age of the granite and not the age of mylonitisation, since the samples dated were cataclastically deformed to markedly different degrees, yet still define an excellent isochron. Samples MG-4 and MG-5 (see Table 1) are the only true mylonites; the rest retain their granitic textures.

Fig. 2 *a*, Rb–Sr isochron for the Straddling Granite: $t = 490\pm10$ Myr; $R_i = 0.7039\pm0.0006$; MSWD, 2.7. *b*, Rb–Sr isochron for the Mylonitic Granite: $t = 400\pm30$ Myr; $R_i = 0.7064\pm0.0012$; MSWD, 1.4. (Uncertainties given at 95% confidence level). (MSWD, Mean square of weighted deviates)



The isotopic data from the Straddling Granite are consistent with the geological evidence which suggests that the Garrison Hills Gneiss and the Connaigre Bay Group are both Precambrian[10,11]. The significant finding, however, is that the southern portions of the Avalon and Gander Zones were in contact by the Ordovician, and it therefore seems extremely unlikely that the boundary between the Avalon Zone and the Central Mobile Belt represents the suture of the Proto-Atlantic Ocean.

We thank R. F. Blackwood, C. F. O'Driscoll, and D. F. Strong for discussion and for samples, J. S. Stevenson for technical assistance, and T. J. S. Cole, D. P. Menagh for help with the mass spectrometry. The study was funded by the National Research Council of Canada.

Upper limit to earthquake size

Chinnery and North[1] have used data relating surface wave magnitude to seismic moment, M_0, to convert magnitude–frequency statistics for the Earth into a seismic moment distribution. For M_0 values ranging from about 2×10^{25} to 2×10^{30} dyne cm they found that their data could be represented by

$$\log N = 17.47 - 0.61 \log M_0 \qquad (1)$$

where N is the number of shallow earthquakes (depth < 70 km) each year with seismic moment greater than or equal to M_0. On

Table 1 Data on relative plate motion (adapted from Kaula[6])

Boundary type	Length (km)	Assumed width (km)	Mean transverse velocity (cm yr^{-1})	μ (dyne cm^{-2})	Contribution to M_0(tot) (dyne cm)
Ocean subducted under ocean	13,100	200	4.07	6×10^{11}	0.64×10^{29}
Ocean subducted under shelf	22,400	200	5.37	6×10^{11}	1.44×10^{29}
Ocean subducted under cordillera	10,700	200	8.32	6×10^{11}	1.07×10^{29}
Continent–continent collision	9,100	200	2.66	6×10^{11}	0.29×10^{29}
Oceanic fracture zone	16,900	5	1.32	3×10^{11}	3.4×10^{26}
Continent or island fracture zone	9,600	20	0.35	3×10^{11}	2.0×10^{26}
				M_0(tot)	3.44×10^{29}

the basis of the remarkably good fit of equation (1) to their data, they argued that seismic moments considerably in excess of 2×10^{30} dyne cm were likely to occur as they did not consider it probable that the linear trend stopped immediately beyond the last data point. I have used recent results on the movement of lithospheric plates in conjunction with equation (1) to estimate an upper limit for M_0. It turns out that this upper limit is probably not much in excess of the moment of the Chile earthquake of 1960 ($\sim2\times10^{30}$ dyne cm) (ref. 2).

Nearly all of worldwide seismic deformation occurs at plate boundaries (see, for example, ref. 3). Most of the seismic deformation occurs in subduction zones and nearly all of the remainder in fracture zones. Brune[4] and Davies and Brune[5] have shown that seismic failure could account for essentially all of the relative motion at these plate boundaries. Accordingly, aseismic failure is assumed to be of little importance over the interplate boundaries defined by large shallow shocks.

According to Brune[4], the total seismic moment each year, M_0 (tot), that is consistent with the relative motion of all of the tectonic plates is

$$M_0\,(\text{tot}) = \Sigma\mu_i D_i L_i W_i \qquad (2)$$

where the summation is over all of the plate boundaries that are associated with large earthquakes. At each boundary, μ_i is the modulus of rigidity, D_i is the annual relative displacement, and L_i and W_i are the length and width, respectively, of the boundary. Because the material comprising the interplate boundaries has a finite strength, there can be no worldwide secular increase in elastic strain energy at these boundaries. Thus M_0 (tot) represents the average annual amount of seismic deformation that must occur to accommodate the observed interplate motion. Equating the total seismic moment to M_0 (tot) leads to

$$\int_0^{M_0(\text{max})} M_0\,[-(\mathrm{d}N/\mathrm{d}M_0)]\mathrm{d}M_0 = M_0\,(\text{tot}) \qquad (3)$$

where the integrand is calculated from equation (1), and M_0 (max) is the maximum possible seismic moment. From equation (3)

$$M_0(\text{max}) = [M_0(\text{tot})/4.62\times10^{17}]^{2.564} \qquad (4)$$

(Equation (4) is a statistical relationship in that equation (1) was based partly on worldwide magnitude–frequency statistics.)

To perform the integration of equation (3) it is necessary to assume that equation (1) is the correct distribution of M_0 up to M_0 (max). If M_0 (max) is not much in excess of 2×10^{30} dyne cm (the upper limit of the data presented by Chinnery and North[1]) then this assumption is reasonable. From equation (4), then, an upper bound to earthquake moments can be calculated if M_0 (tot) can be estimated from the results of studies of the motions of plates of lithosphere. The calculation of M_0 (max), (equation (4)) does not depend on the time interval of one year, which was chosen for convenience.

Kaula[6] presented data on relative plate motions in a convenient form for the calculation of M_0 (tot). Table 2 of his paper lists the total lengths and mean transverse velocities of various types of interplate boundaries. His data for boundaries associated with large shocks are relisted here (Table 1) along with assumed widths for the zones of contact between plates, rigidities and the corresponding moments calculated from equation (2). The last column of Table 1 shows that in calculations of M_0 (tot) the contributions from the fracture zones are negligible.

The most critical assumption in the estimation of M_0 (tot) is the width of the zones of contact for shallow underthrusting. An average width of 200 km (Table 1) was chosen here on the basis of evidence reviewed by Kelleher *et al.*[8]. It does not seem likely that the average width of contact is less than 150 km or greater than 250 km.

From equation (4) M_0 (max) $= 2.75\times10^{30}$ dyne cm, which is not much greater than the moment of the Chile earthquake of 1960. For average widths of shallow underthrusting as little as 150 km or as great as 250 km the corresponding maximum moments (equation (4)) are 1.3×10^{30} and 4.9×10^{30} dyne cm. Thus, earthquakes substantially larger than the Chile shock of 1960 do not seem possible in view of the bounds associated with the relative motion of tectonic plates if equation (1), based on about 40 yr of seismic data, is the correct distribution of M_0 for the past 30,000 yr or more; the time resolution of the boundary rates in Table 1 is probably no better than 30,000 yr (Kaula, private communication). There is a possibility that the worldwide seismic-slip rate has decreased over the past 70 yr (ref. 5). This possibility introduces some uncertainty into the use of equation (1) for periods of time much greater than 40 yr.

I thank L. O. Nicolaysen, S. M. Spottiswoode and D. O'Connor for helpful suggestions.

Ball lightning in Smethwick

BALL lightning has been observed on many occasions, but there have been few events[1–5] which have provided evidence with which to test any of the available explanations of the phenomenon. Consequently considerable weight has been placed on the "tub of water" event[1]. The occurrence reported by Stenhoff[6] has presented unique evidence which enables us to carry out a number of simple calculations. The lady concerned describes the fireball appearing 39–40″ above the floor, then dropping 2 or 3″ when she tried to stop it with her hand. It was apparent for ~1 s and had a diameter of ~4″ but also had a halo.

The position of the hole in the dress is consistent with the fireball being ~700 mm above the floor when it struck. The hole is 100×70 mm, but the narrowest part indicates that the core of the fireball was ~20 mm in diameter. The surface of the fabric had melted over an area about 300 mm across.

The material seems to be a polyester which would melt at 250 °C and have a specific heat capacity of 1.2 J g^{-1} K^{-1}. To melt the material where there is now a hole would require 200 J and to melt the surface to a depth of 0.1 mm, 240 J. Even if this were only 10% of the total energy, it is $<10^{-2}$ of the values quoted previously. Very little charring had occurred.

An estimate may be made of the energy radiated by the fireball since the lady said that "she seemed to glow all over" as the fireball approached. Assuming this sensation to be equivalent to a 1-kW radiator at a distance of 0.5 m, the flux would be 0.6 kW m^{-1}. A body area of 0.6 m^2 would receive 400 J in 1 s. An equivalent power would be radiated by a spherical black body of 10 cm diameter at 950 °C or at 3,500 °C for a diameter of 1 cm. The thermal energy contained in the sphere would then be 2 kJ. In a dense plasma, radiation trapping reduces the rate of loss of energy and thus implies a higher temperature[10]. Since the ball did not convect rapidly, its mean density must have been close to that of the ambient air, indicating a confining force which if magnetic would require a field ~1.5 T. It is interesting to note that Brand[7] concluded that there was no heat effect with "the type of ball lightning that floats free in the air"[8].

It has been proposed that ^{15}O and ^{17}F are formed during a lightning discharge[9,10] but their half lives are 2.1 min and 66 s respectively, so there was no point in measuring β activity when the dress became available for examination 10 weeks after the event. A γ spectrum taken over a period of 1,000 min for energies from 0 to 3.6 Mev produced a total count over 400 channels of 1.1 c.p.m. above background, implying an activity of 1.6 pCi. No signs of chemical reaction were apparent.

The lady is alive and healthy, so we know that she has not been subjected to harmful ionising radiation. Taking a figure of 500 rad as the maximum exposure that may be suffered without apparent physiological effect, an upper limit of 250 J may be placed on the whole body radiation. This energy would be produced by the annihilation of 10^{-11} g of antimatter at a distance of 10 cm, a figure which is $<10^{-2}$ that discussed in an antimatter theory of ball lightning[5].

The burn suffered in the vicinity of the gold wedding ring permits another estimate of energy to be made. The burn was described as being lighter than a scald, so it is assumed that the skin temperature rose no more than 100 °C. About 3 kJ would heat the surface of the hand (10×10 cm^2) to a depth of 1 mm. To heat the ring up to 100 °C by an electromagnetic field[11] would require a current of 10^3 A and imply an electric component of the e.m. field of 10^4 V cm^{-1}. The resonant frequency would be 10^9 Hz, assuming an inductance of 10^{-9} H and capacitance of 10^{-11} F. Although large d.c. electric fields are present during thunderstorms, only small electromagnetic fields at GHz frequency have been measured[12].

These orders of magnitude 'guesstimates' suggest that the energy associated with this fireball is $\sim10^{-3}$ of that calculated previously[13]. Nothing can be found to support the theories based on radioactivity, antimatter or magnetic fields Furthermore, the low energies estimated are inconsistent with the assumptions on which some models of ball lightning are based.

I am grateful to Miss Stephanie Pearson for drawing my attention to this event, to the lady who suffered the alarming experience, to Dr Desmond MacMahon, Dr R. S. Higginbotham, Dr Colin Whitehead for advice and assistance with measurements, and to Mark Stenhoff for discussions.

Non-crystallinity of ion-irradiated metals

The preparation of various metals and metallic alloys in a non-crystalline state using splat cooling, vapour quenching or electrochemical deposition techniques has been reported by many authors. A distinguishing characteristic of such amorphous films is a severe modification of the structure factor from that of the crystalline state. Although usually formed only at low temperatures the non-crystalline state may in some cases be metastable to above room temperature, this being particularly true for alloys near the eutectic. We examine here evidence for metastable non-crystalline alloys resulting from ion irradiation.

The structural modifcation of metals by ion irradiation has traditionally been treated in terms of replacement collision sequences or thermal spikes followed by a return to crystallinity with the freezing-in of point defects. At high ion doses the agglomeration of point defects may occur, but the final structure is considered to be that of a defected crystal. This is in contrast to the behaviour of ion-irradiated semiconductors, in which demorphisation occurs. Since, however, each collision cascade causes the temporary displacement of a large number of metal atoms and energy dissipation is rapid, the situation locally may well be compared with splat cooling, and the formation of a non-crystalline state in suitable cases might be anticipated. Stephens *et al.*[1] have reported that Rutherford backscattering and channelling analysis of Dy^+ implanted into single-crystal Ni produced a disorder peak structure which is uncharacteristic of metals, but which can usually be obtained with semiconductors rendered amorphous by ion bombardment. The Dy-implanted Ni system was consequently chosen for more detailed transmission electron microscopy examination, the results of which are reported here.

In our experiments, high purity Ni samples prepared for transmission electron microscopic examination were irradiated at room temperature with 20 keV Dy^+ ions to doses of 10^{16} ions cm^{-2}, thus giving a peak implant concentration of ~ 30 atom% as confirmed by Rutherford backscattering. Analysis using electron diffraction in the TEM shows, in addition to Ni matrix reflections attributable to the undamaged crystal lying beyond the ion range, a single diffuse scattering maximum with a peak intensity scattering parameter $s = 2.99 \pm 0.01$ Å^{-1}, and a half intensity width $\Delta s = 1.1 \pm 0.2$ Å^{-1}. This should be compared with the value $s = 3.085$ Å^{-1} for ⟨111⟩ Ni. Dark field images using the diffuse ring show a generally high background intensity with occasional resolved crystallites in the 30–100 Å range. The former should be expected since application of the Scherrer particle size broadening equation to the measurements quoted already indicated particle dimensions of <10 Å, which is below the resolution limit of the microscopy. On annealing above ~ 400 °C the diffuse ring sharpens and widens to a good Ni ⟨111⟩ fit concurrent with the appearance of additional sharp rings attributable to higher order Ni reflections. Dark-field microscopy confirms the presence of large numbers of Ni crystallites 50–200 Å in size.

Various models of amorphous solids based on the random packing of hard spheres with no appreciable order beyond first neighbours have been proposed; an alternative model for a quasi-amorphous solid is a microcrystalline arrangement in which isolated groups of atoms adopt the parent crystal structure but are separated by localised energy barriers to recrystallisation. In particular, Wang and Merz[2] have proposed a microcrystalline arrangement in which atomic groups may take up the crystal structure of any one of a number of polymorphic forms, and have correlated the occurrence of noncrystallinity with bonding anisotropy and polymorphicity. According to this classification, Ni, with three polymorphs, should be one of the least structurally stable metals. For very small crystals the difference between a microcrystalline solid and a true amorphous solid becomes increasingly indistinct, although it is interesting to note that the observed increase in nearest-neighbour distance in our experiments has also been observed by Davies and Grundy[3] in amorphous Ni films where a dense random packing model seemed justified.

Numerous authors have noted the enhanced stability of non-crystalline metals when alloyed with other metals or metalloids, and Nagel and Tauc[4], using a nearly free electron approach, have suggested that this stability is attributable to a shift in the effective valency, causing the Fermi level to lie at a dip in the density of states function. Thus, an alloy with concentration x of element valency z_2 in z_1 should be most stable against recrystallisation when

$$1.7 \approx z_1(1-x)+z_2x$$

Substitution of $z_1=1$ for Ni, which as a group VIII element may be treated as having only one free electron per atom in the liquid, and $z_2=3$ for Dy gives $x=35\%$, similar to the peak concentrations achieved in the implantations reported here.

Of interest here are the data of Cullis, Poate and Borders[5] who have observed a diffuse diffraction maximum following ion implantation of W^+ into Cu at concentrations in excess of 10 atom%. This figure may be compared with a most stable concentration of 14 atom% predicted by the equation given here.

Finally, we have noted the complete absence of a noncrystalline phase in Pb^+ irradiated Ni up to concentrations of ~ 35 atom%, where $z_2=2$ gives $x=70\%$.

Financial support from both NATO and the Science Research Council is gratefully acknowledged. The authors also acknowledge G. Carter for suggesting the study and possible interpretation, and discussions with C. E. Christodoulides and G. A. Stephens have been most helpful.

Effect of roughness on rubber friction when waves of detachment are present

IN some circumstances, when rubber moves over a hard surface no true sliding occurs. Instead, the contact area is crossed by waves of detachment[1]; and it is only in these regions, where contact has temporarily been lost, that there is any relative motion of the two surfaces. The effect resembles the motion of a caterpillar on a leaf. It is now well established that when an elastometer slides over a smooth surface in these conditions, the frictional force may be accounted for in terms of the net work required to peel the rubber away from the counterface and readhere it[2,3]. We have now found that waves of detachment may be present when the counterface is rough, and that the same explanation of the friction force applies.

The adhesion of rubber depends markedly on the roughness of the surface with which it is in contact[4,5]. Slight roughness can increase the adhesion compared with an ideally smooth surface, while larger values of roughness can greatly reduce it[6]. When a cylinder rolls on clean rubber, the two surfaces are adhering together at the front of the contact and peeling apart at the rear. The net work for this process at a given velocity may be measured by rolling cylinders down an inclined plane.

For the friction experiments, silicone rubber was moulded to be optically smooth. The counterface was Perspex, which was roughened by blasting with fine particles. The two surfaces were brought together in a crossed cylinders configuration with a sliding speed of 1 mm s^{-1}. The frictional force was recorded, and the waves were filmed at 200 frames s^{-1}.

If Γ is the net work required to peel apart and readhere unit area, A the observed area of contact, and f the number of waves crossing the interface per s; then the energy required in 1 s may be equated to the work done by the frictional force F moving at the sliding speed V thus

$$FV=\Gamma fA$$

Thus, a value of Γ may be deduced and compared with Γ measured directly from rolling experiments for the same surface at the velocity of the waves. This is done in Table 1, and the agreement is fairly satisfactory for a friction experiment.

Table 1 Correlation between the adhesion energy required to account for the frictional force in terms of waves of detachment (Γ_1), and the adhesion energy deduced directly from rolling experiments (Γ_2)

Ra (μm)		*F* (N)	*f* (s^{-1})	*V* (mm s^{-1})	Γ_1 (J m^{-1})	Γ_2 (J m^{-2})

9.20	‡	0.184	6.05	10.17	2 38	1.36

The normal load was 0 1 N and the imposed sliding speed 1 mm s^{-1}. The results are for a range of roughness measured in terms of the centre line average (*Ra*). *F* is the frictional force, *f* the number of waves crossing the interface per second, and *V* the mean wave velocity. The rubber was Dow Corning XF-13-523 dielectric gel. The surfaces were prepared by blasting with fine particles as follows: *, untreated; †, glass beads; ‡, metal particles; §, sand. The correlation coefficient for the last two columns is 0.79.

At the highest roughness it became difficult to see exactly where contact existed. Waves were clearly observed to propagate, but it may be that with the low true contact area here there is also some interfacial sliding.

It is interesting to note that the coefficient of friction does not vary markedly with roughness. This is because of two competing factors. A Burgers vector, b, may be defined for a wave as the interfacial displacment which results when it passes. The total displacment per s is

$$V=fb$$

When Γ increases, bigger waves form, and they have a larger Burgers vector. Therefore they do not form so often and f decreases, so that F does not change very much.

It has similarly been observed that F may be insensitive to change in V, even though Γ is markedly velocity dependent. This may represent a general result for rubber friction when waves of detachment are present, that although the frictional force is to be accounted for in terms of the net adhesion energy Γ, changes in Γ may have little effect on the coefficient of friction for a particular elastomer.

A theoretical account, which is in preparation, provides a more detailed explanation of these observations. We are grateful to Professor D. Tabor for help and encouragement, and also to the SRC for an Assist award to G.A.D.B.

Learning-like phenomena in stereopsis

WHEN confronted with Julesz random-dot stereograms[1] for the first time, naive observers often need as long as a minute or more to see a global figure in depth. With repeated exposure to the stereograms this perception time is progressively reduced until they begin to see depth almost instantaneously[2]. This acceleration of the stereoscopic process over successive trials is a remarkable example of perceptual learning[2,3], and unlike many other kinds of perceptual learning it seems to be a purely visual effect. Further, stereopsis is a basic visual function for which much of the processing may occur as early as the prestriate cortex[4]. It is important to note that learning-like changes can affect such a process, and knowledge of elementary visual function may be helpful in determining just what is learned. Here I explore the position specificity of stereo-learning, and find that in most observers a significant proportion of the learning that is acquired in one retinal area does not transfer to neighbouring areas. One question raised by this finding is whether such position specificity necessarily implies localisation of the learning process to specific anatomical areas in the brain.

The stimulus used (Fig. 1) was a Xerox of Fig. 4.5–3 from Julesz's book[5]. The global figure portrayed (Fig. 3) was a 'saddle' with a 'doughnut' threaded through it (hyperbolic paraboloid with torus) and the pattern was composed of 1,000×1,000 disparity elements, of which 90% were white and 10% black. The maximum disparity was in the range of 30′.

The stereogram was displayed through a three-channel tachistoscope (Electronics Developments). The two half images were carefully aligned before the experiment so that the surround had zero disparity, and crossed polaroids were used to separate the two eye pictures. The whole stereogram subtended 9° at the viewing distance used.

A tiny yellow fixation rectangle was displayed (to both eyes) through the third channel of the tachistoscope. This ensured that the observer was converging on the plane of zero disparity in the stereogram. The stereogram was mounted in such a way that the fixation spot occupied a position between the 'saddle' and the 'doughnut' portions of the global figure as shown in Fig. 2. This will be explained below in greater detail. During the experiment the observer was asked to fixate this spot and never to move his eyes away from the spot. He was also encouraged to move his eyes very slightly within the spot to prevent the image from fading.

Each trial began with the exposure of the fixation rectangle. The subject initiated the exposure of the patterns by pressing a button on command which also started a timer. He was instructed to hold the button pressed until he could clearly see the curved three-dimensional surface of the saddle surrounded by the doughnut. A pencil sketch of the figure was shown to him. It was emphasised that he should use a constant criterion for reporting the emergence of the figure. His release of the button stopped the timer and recorded his perception time on that trial. The button release also switched off the stereogram. There was then a 10-s interval before he was required to initiate the next trial.

Trials were begun with the 'saddle' portion of the global figure occupying a position either to the right (seven observers) or to the left (seven observers) of the fixation point. They were continued until the perception time reached an asymptotic value. After the normal intertrial interval the whole stereogram was shifted by 2.5°, so that the saddle now came to lie on the opposite side of the fixation spot. To ensure that the observer knew exactly where to expect the global figure he was told that the stereogram had been shifted. The time course of his learning was then followed over a number of trials for this new position to the stereogram.

Fourteen subjects were used and all were naive as to the purpose of the experiment. Some of them had seen the 'standard' Julesz stereogram before, but not complex three-dimensional surfaces.

In Fig. 3 the perception time is plotted as a function of trial number for each subject. The line joining the points is broken where the stereogram was moved to a new position. The graphs clearly show the decrease of perception time over trials with the initial position of the stereogram.

Change in position produced an increase in perception time for 13 of the 14 subjects. In most of these 13 cases the time on the first trial for the new position was far outside the range of the preceding asymptotic trials. On subsequent trials there was a steady decline in perception time usually down to the original asymptotic value. In at least nine of the observers the magnitude of change was large (20–50 s change from the original asymptotic level) and a 'criterion' shift seems very unlikely. Most of them, on being questioned, reported unhesitatingly that they had not in fact seen anything during the long latent period on the first trial for the new position of the stereogram and that they had seen the figure emerge only just before button release. These results suggest that a significant proportion of the learning that is acquired in a particular retinal area, remains confined to that area.

When interpreting this lack of transfer, however, the possible role of nonspecific 'distraction' effects must be considered. The involvement of such effects seems unlikely for the following reasons. The same result was obtained on four additional subjects when a 'distributed practice'

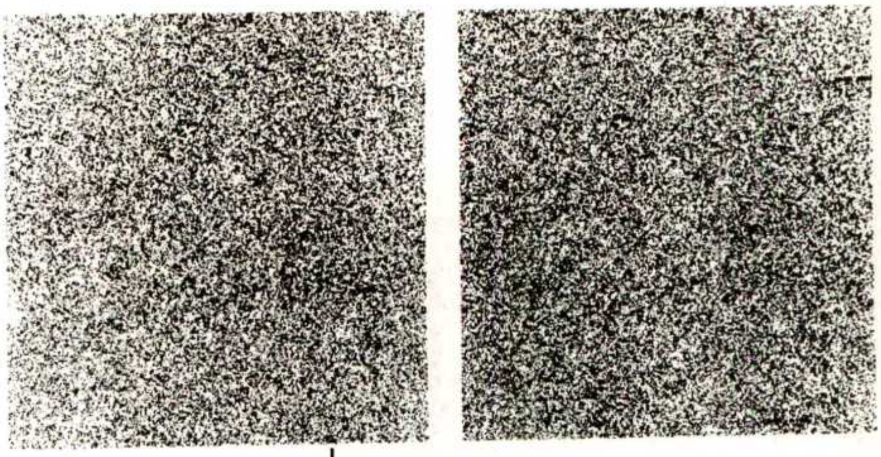

Fig. 1 Random-dot stereogram composed of 1,000 × 1,000 disparity elements portraying a cyclopean hyperbolic paraboloid with torus. If the reader has not seen random-dot stereograms before, he will notice the long latency before the stereoscopic figure emerges (about 1.5 min; average for 20 subjects). With six or seven exposures to the same pattern the perception time is progressively reduced to just 1–2 s. Once the figure has been seen, wide conjugate eye movements may be made without 'losing' the global percept. It would seem that although the learning *per se* is position specific, the solution to the global stereopsis 'problem' is invariant with respect to spatial location.

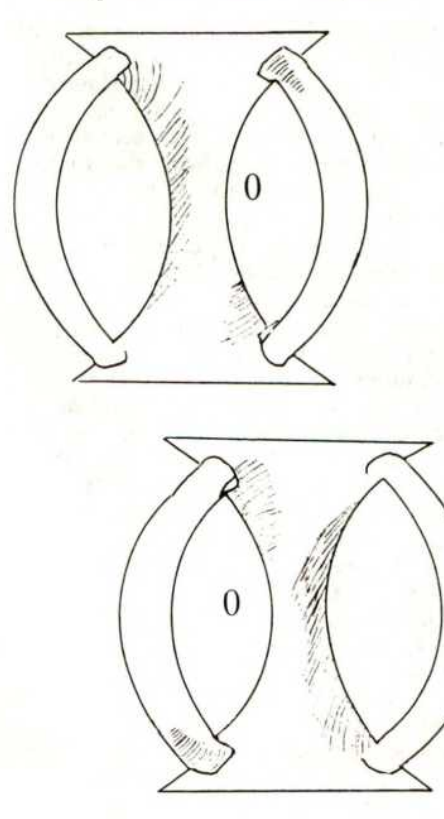
paradigm was used extending over several days. 'Long term' stereo learning was found to be position specific to the same degree as the short term effects reported above. The learning is not specific to the particular random sequence of dots used. Changing the random sequence without shifting the global figure resulted in complete transfer of learning.

The role of eye movements in stereo learning also remains to be elucidated. Testing an additional eight naive subjects, I found that as soon as they had become skilled, seven of them could see complex three-dimensional surfaces (for example, Fig. 1) in 150-ms flashes. When the stereogram was then shifted to a new position, these eight subjects showed the same basic relearning effect as the 13 subjects in Fig. 3. It seems likely, therefore, that at least some component of stereo learning occurs in the visual centres independent of eye movements. But this point needs to be confirmed using stabilised images.

Fig. 2 Sketch of the cyclopean figure which was shown to the observers, illustrates the way in which the figure is shifted in relation to the fixation spot.



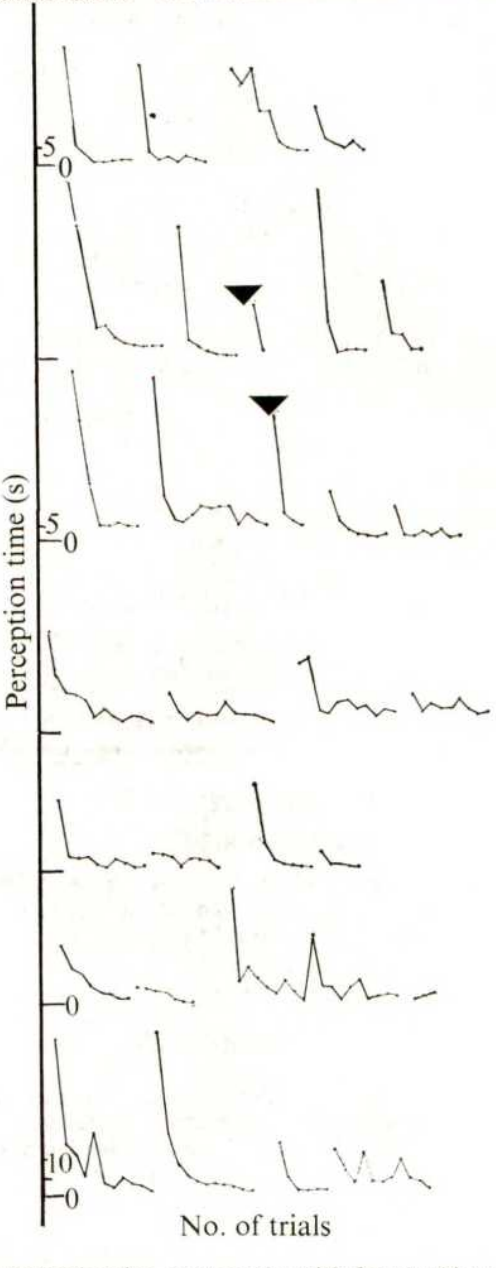


Fig. 3 Perception time on successive trials for 14 subjects. Each point refers to a single trial. On some trials the perception time was too long to be included in the graph; for these the line ending at the top of the plotting area points to the position of the data point. Data for each subject plotted to the same scale. The line connecting the dots is broken where the pattern was shifted between trials. Two of the subjects (*c* and *e*) were switched back again to the original position of the stereogram after they had reached an asymptote on the second position: ▼, point where this change was made. They apparently retained very little of the training they had acquired on the first position.

It is possible that what the observer initially learns is a strategy of vergence movements to bring disparate portions sequentially into register. As the observer becomes more skilled, overt eye movements are eliminated and the 'perception' of global stereopsis may simply involve a subliminal activation of the 'phase sequence' of sensory and motor elements that were originally driving the vergence system. This is equivalent to saying that vergence is replaced by 'cortical shifts' or that the Panum areas are permanently 'extended' by training. This line of reasoning is similar to that used by Hebb[6] to explain form perception.

Visual memory is generally invariant with respect to location in the visual field[7,8]; some authors have pointed out analogies between holograms and memory and suggested that the brain may store spatial Fourier transforms of visual inputs[9]. From my finding, however, that stereo learning is position specific, as well as from the observations of Wallach and Austin[10], it may not be too fanciful to suggest that at least some forms of visual memory are encoded and stored in specific brain areas in such a way as to become unavailable to neighbouring areas.

There is obviously considerable scope for further experiments in this field. Most conventional learning paradigms—such as massed compared with distributed practice, 'forgetting', relearning, and so on—could be fruitfully studied using Julesz patterns as stimuli. Such studies could provide novel insights into mechanisms underlying perceptual memory and learning.

Counter-intuitive property of effective population size

CONSIDER an organism with both autosomal and X-linked loci. The effective population sizes for an autosomal (N_{ea}) and an X-linked (N_{es}) locus can be shown[1] to be

$$N_{ea} = 4MF/(F+M) \qquad (1)$$

$$N_{es} = 4.5MF/(F+2M) \qquad (2)$$

where M and F are, respectively, the numbers of reproducing males and females in a random-mating population.

The ratio of the X-linked effective population size to that for autosomal loci is, from equations (1) and (2)

$$N_{es}/N_{ea} = 9(F+M)/8(F+2M) \qquad (3)$$

From (3), X-linked loci have only 75% of the effective population size that autosomal loci have when males and females are equally abundant, and the discrepancy increases when males outnumber females, as seems intuitively obvious. When there are seven females for every male, however, the two types of loci have the same effective population size; when the proportion of females is increased further, X-linked loci have the greater effective population size. The asymptotic values approached by the ratio N_{es}/N_{ea} are 9/8, as the number of females per male increases, and 9/16, as the number of males per female becomes infinitely large.

The biological significance of the above observation is hard to evaluate, but two points can be made. First, many insects, particularly parasitoids, have extremely female-biased sex ratios, and these species are mostly male haploids[2]. Second, it is now possible to test the influence of effective population size on genic diversity, in that preliminary evidence[3] indicates that male haploid and X-linked loci have fewer polymorphisms than autosomal loci. If this difference is general and effective population size differences are the major cause for it, then it should be still greater in male-biased male diploids, but in highly female-biased such species' X-linked loci should be more polymorphic than autosomal ones.

I thank the referee for suggesting inclusion of the asymptotic values.

Geography of photoperiodic response in diapausing mosquito

IN temperate latitudes, many arthropods rely on photoperiod to cue their seasonal development. Although the relationship between critical photoperiod and latitude is well illustrated, that between critical photoperiod and altitude remains obscure[1,2]. I wish to consider photoperiodic control of dormancy in the pitcher-plant mosquito, *Wyeomyia smithii*, and quantify the relative effects of altitude and latitude on the photoperiodic response of an organism.

W. smithii is found from the Gulf coast to Labrador and northern Manitoba[3–6] where it confines its breeding site to the water-filled leaves of a single species of plant, *Sarracenia purpurea*. The larvae overwinter in the pitchers in a state of developmental arrest. Short days evoke and maintain, while long days avert or terminate this diapause[7,8]. The photoperiod which promotes 50% development and initiates or maintains 50% diapause is known as the critical photoperiod[2,7,9,10]. In *W. smithii*, the critical photoperiod is the same for the initiation and termination of diapause among larvae reared in the laboratory and for the termination of diapause among larvae collected during early autumn[7]. I have collected larvae north of 38°N latitude only during the autumn (autumn larvae) and south of this latitude only during the winter (winter larvae). I packed the autumn larvae in ice on the day of capture and maintained them on ice until they reached the laboratory where I stored them in an ordinary refrigerator at 4±2 °C until the start of experiments. All experiments were begun within 45 d of capture. Since the winter larvae received unknown chilling in nature which might have affected the critical photoperiod[11,12], I reared them in the laboratory and determined the critical photoperiod for the initiation of diapause in the F_1 generation. Whether considering the maintenance of diapause among autumn larvae or the initiation of diapause among the F_1 of winter larvae, I exposed them to a range of LD 10 : 14 to LD 17 : 7 in 30-min increments at 25±1 °C. Rearing procedures and the criteria for diapause and development were the same as in previous studies[7,13].

I determined the critical photoperiod for 22 populations of *W. smithii* collected over a range of 19° latitude, 20° longitude and 1,200 m altitude. The critical photoperiods ranged from 12 to 16 h of light per day (Fig. 1) and were closely correlated with latitude ($t=14.26$; $P<0.001$) and altitude ($t=9.25$; $P<0.001$) but not longitude ($t=1.71$; $P>0.10$). Latitude accounted for 80.5% of the variation in critical photoperiod and altitude an additional 15.5%. Critical photoperiod may then be estimated from latitude and altitude by the least-squares regression equation

$$\text{critical photoperiod}=6.51+0.185 \text{ latitude}+0.00129 \text{ altitude}$$

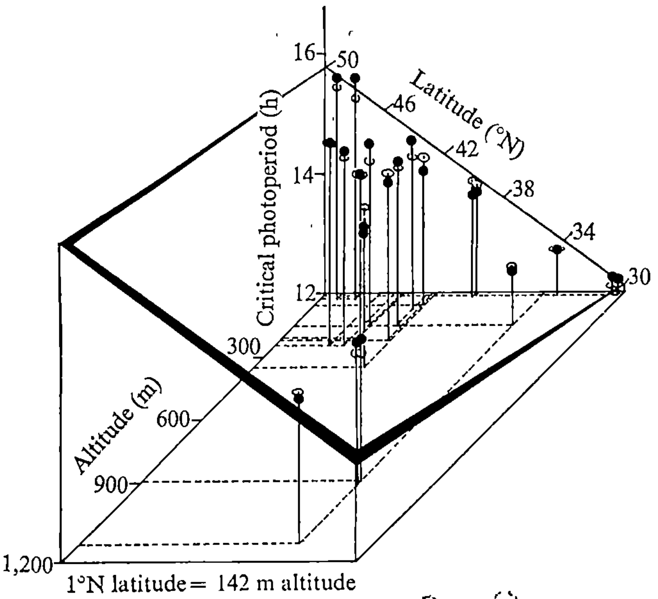
To correlate critical photoperiod with climatic variables, I modelled the growing season (mean number of freeze-free days) for 26 cities in the United States north of latitude 30°N and east of longitude 90°W (ref. 14). Although city temperatures are not the same as in bogs, they are presumably correlated[15]. I found that growing season was closely correlated ($r=0.97$) with latitude ($t=15.39$; $P<0.001$) and altitude ($t=4.59$; $P<0.001$) but not longitude ($t=0.42$; $P>0.60$). I then calculated the growing season for each locality in Fig 1 using its latitude and altitude and the least-squares regression equation relating growing season to these parameters

$$\text{growing season}=585.93-9.33 \text{ latitude}-0.094 \text{ altitude}$$

I found that growing season calculated in this manner was an excellent predictor of critical photoperiod in *W. smithii* (Fig. 2). This degree of correlation between an ecogeographic character and a specific climatic variable is unprecedented. In many other studies[16-20], the ecogeographic characters being examined are affected by a wide range of environmental influences which may be changing independently of geography. The photoperiodic response of *W. smithii* tracks climate so closely for several reasons. First, photoperiodism is a physiological adaptation concerned mainly with the timing of seasonal development; second, the low variation in microhabitat offered by the leaves of *Sarracenia purpurea* over a wide geographic range permits a more direct expression of this adaptation. Third, critical photoperiod in *W. smithii* is a continuous variable over the range considered, rather than a discontinuous variable as in some other insects[21,22].

To account for geographic differences in the timing of phenological events, including seeding and harvest dates of winter wheat and insect emergence, Hopkins proposed a bioclimatic law[23] equating a 1° increase in latitude with a rise in altitude of 122 m, or somewhat less than my estimate of 142 m per °N. My results are not grounds for modifying Hopkins' law and its prediction of phenological events, but rather point to the departure from this law by the photoperiodic cues which mediate seasonal development. The disparity between Hopkins' law and critical photoperiod in *W. smithii* relates to the observation that, for a given date between the spring and autumnal equinox, daylengths are longer in the north than in the south[24]. Consequently, insects on a southern mountain should use a shorter daylength to enter diapause on a given calender date than will those in a population further north which enters diapause on the same date. One would then have to go higher up the mountain than predicted from the bioclimatic law to find a locality where the mosquitoes are using the same critical photoperiod as the northern population. Hopkins' bioclimatic law in temperate and north-temperate latitudes may thus be expected to underestimate the effect of altitude on photoperiodism.

Fig. 1 Relationship between critical photoperiod, altitude and latitude. Circles on the regression plane indicate where the projections of the data points cross that plane. $r \doteq 0.98$; $P < 0.001$.



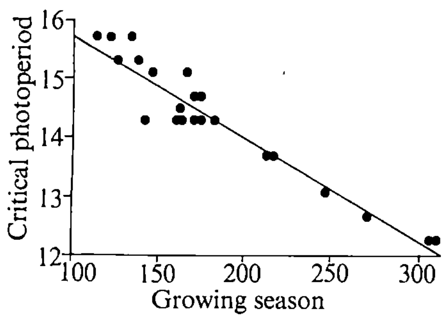


Fig. 2 Correlation of critical photoperiod with growing season. Freeze-free days for each locality were calculated from a least-squares regression equation relating number of freeze-free days of 26 cities in eastern North America to latitude and altitude. $r = 0.96$; $P < 0.001$.

The dispersal of young post-larval bivalve molluscs by byssus threads

New observations, both in the marine environment and in the laboratory, indicate that the byssus in young post-larval bivalves has a hitherto unsuspected function—that of dispersal. The method of transport is analogous to the gossamer flight of young spiders. In the laboratory, small scale currents will induce the secretion of what seems to be a single long thread which, by increasing the viscous drag exerted on the young bivalves, enables them to be carried along on relatively small currents. The threads, which stain readily in Alcian blue (a stain selective for acid mucopolysaccharides) are typically long compared with the length scale of the animal itself: for instance an *Abra* 1 mm long can produce a 2–4-μm diameter thread of length greater than 3 cm. This mechanism, which we term byssus drifting, is functional from the late pediveliger stage up to at least 2.5 mm size in some species, and it has been found to be present in the 20 species tested so far and listed in Table 1 (a functional byssus has not been reported previously[1] in post-larval bivalves of those genera marked with an asterisk).

The increase in drag produced by the byssus in the process of drifting was investigated experimentally in a simple apparatus which consisted essentially of a vertical glass tube enclosed at either end by fine-mesh netting and into which the animals could be introduced and confined. The upward flow of seawater through the tube was adjusted until a critical current speed, U, was obtained at which an animal could be suspended motionless relative to the tube. Where possible, three sets of readings of U were taken for each animal in each of the following states of activity: (1) live, inactive; that is immediately after the animal has been introduced into the tube and is still closed as a result of being handled, and therefore has not secreted threads into the water, (2) active; that is byssus drifting, and (3) dead (killed in 1% formalin in seawater).

While byssus drifting, an animal hangs from the thread with the ventral shell margins uppermost and held horizontally. The valves are generally only slightly open and the heel of the foot is brought close to the gape. Frequently an animal was observed to detach itself from its thread and fall freely through the tube. In some cases secretion of a new thread would check the descent or even produce upward motion. Sometimes the valves may be opened and shut rapidly several times in succession. At other times the foot is protruded and its anterior part may be wriggled about, or the animal may either swing from side to side (*Mytilus*) or perform what seemed to be digging movements (Tellinacea). The siphons are frequently protruded in the Tellinacea. Contrary to other observations[2], it was concluded from experimental observations on byssus drifting animals that the protrusion of the foot produces an insignificant increase in drag. Nelson[3] reported that post-larval *Mytilus* could remain pelagic by the secretion of gas into the mantle cavity. Gas bubbles have occasionally been seen in the mantle cavity of *Mytilus* during our experiments, but these are possibly caused by transferring the animals from seawater at a temperature of 9 °C to seawater of up to 20 °C in the apparatus.

It is usual[4] in hydrodynamics to express the effect of fluid drag on a moving body in terms of a dimensionless drag coefficient, C_D, defined as the ratio of the drag force per unit area to the quantity $\frac{1}{2}\rho U^2$, where ρ is the density of the fluid and U is its velocity relative to the body. By the nature of the terminal velocity measurements made in this study, the drag force on the body is simply equal to its weight in water. Assuming uniformity of shape within a given species, the drag coefficient for a body of volume, V, surface area, A, and density ρ_b can therefore be written as

$$C_D = (2g(\rho_b - \rho)V)/A\rho U^2 = kC_D^*$$

where k is a constant determined by the acceleration due to gravity, the relative density of the body, and some geometrical factor directly proportional to its ratio of volume to area. C_D^* is a modified drag parameter equal to a/U^2, where a is a typical linear dimension of the shell and the constant, k, takes a different value for each species.

Table 1 Species in which byssus drifting has been found to occur

Subclass Protobranchia	
Superfamily Nuculacea	*Nucula tenuis*
Subclass Lamellibranchia	
Superfamily Mytilacea	*Mytilus edulis, Modiolus* sp. *Musculus marmoratus*
Superfamily Anomiacea	*Heteranomia squamula*
Superfamily Cyamiacea	*Turtonia minuta*
Superfamily Erycinacea	*Montacuta ferruginosa, M. substriata*
Superfamily Cardiacea	*Cardium echinatum*
Superfamily Veneracea	*Venerupis pullastra*
Superfamily Mactracea	*Mactra corallina**, *Spisula** sp.
Superfamily Tellinacea	*Tellina tenuis**, *Gari fervensis**, *Abra alba**, *Donax vittatus**
Superfamily Solenacea	*Cultellus pellucidus, Ensis** sp.
Superfamily Saxicavacea	*Hiatella arctica, H. gallicana*
Superfamily Myacea	*Mya truncata, Corbula gibba*

Byssus drifting has been found to occur in all the 22 bivalve species tested so far.

*Those species or genera in which a functional byssus has not been reported previously.

Figure 1*a* and *b* shows values of the modified drag parameter C_D^*, plotted in the conventional manner as a function of the Reynolds number, Re ($=aU/\nu$, where ν is the kinematic viscosity of the fluid), for the species *Mytilus edulis* and *Abra alba*, respectively. Both graphs show that, in terms of the drag experienced by the bivalves, the dead and inactive samples behave in an almost identical manner, and the form of their behaviour is in excellent agreement with the classical experimental data[4,5] on the flow past a rigid body, in this Reynolds number range. Small individual departures from the classical curves can be ascribed to small amounts of debris attached to their shells.

Active animals, on the other hand, behave quite differently. This is illustrated by the large random departures from the

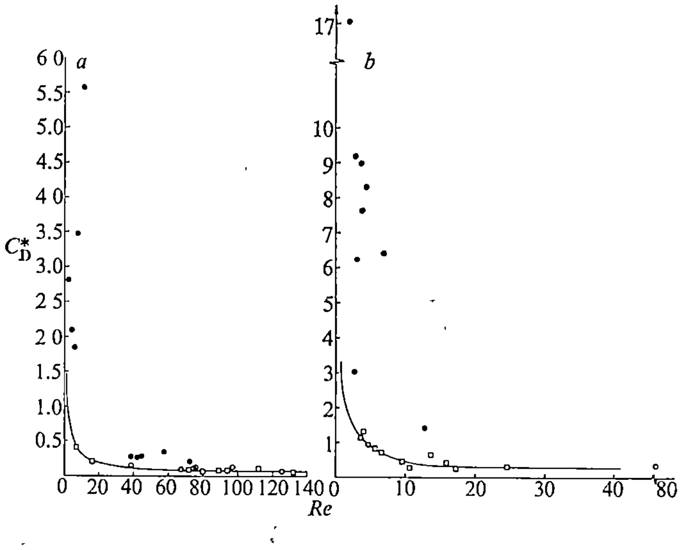

Fig. 1 Plot of modified drag coefficient, C_D^*, against Reynolds number, Re, for ●, live active; ○, live inactive; and □, dead samples of *Mytilus edulis* (*a*) and *Abra alba* (*b*). The solid curve represents a best fit to the data of the classical experimental results[4,5] on the flow past a sphere in this Reynolds number range.

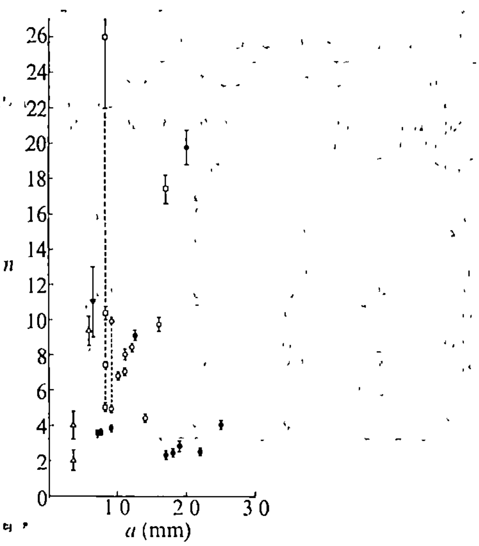

Fig. 2 Measured fractional increase in drag, *n*, plotted against shell length, *a*, for ●, *Mytilus edulis*; ○, *Abra alba*; □, *Gari*; △, *Montacuta*; and ▼, *Nucula*.

'dead' curves, indicating the presence of large drag forces which are not due to the shape of their shells alone but must be provided by some other mechanism. Figure 2 shows the relative increase in drag, *n*, defined as

$$n = (C_D^*)_{\text{active}}/(C_D^*)_{\text{dead}},$$

for active individuals of several species, plotted against shell length, *a*. It is seen that the drag increase is rarely less than a factor of three, while some adept 'drifters' acquire an increase of 20–30 times the value they experience when inactive. The large errors associated with some values of *n* are due to the relatively small number of observations in certain size ranges of these species. Hatched lines joining some points show the drag characteristics of the same animals can vary with time, corresponding to various stages of activity.

The experiments certainly indicate that byssus drifting constitutes an effective means of transport for young post-larval bivalves and that the upward components of ocean currents which are required to suspend active individuals are typically only 1 cm s^{-1}. The importance of this mechanism can hardly be doubted and the fact that it seems to be of widespread occurrence in bivalves supports that view. It is almost certainly the mechanism by which post-larval bivalves enter on a second pelagic or migratory phase reported for a few littoral bivalve species[2,6], the best documented case being that of *M. edulis*[2]. Preliminary field observations indicate that a prolongation of the larval pelagic phase by a post-larval "bysso-pelagic" phase may be a regular feature of the life history of several sublittoral bivalve species. *A. alba* up to 2 mm in length, and *Montacuta ferruginosa* and *M. substriata* up to 0.8 mm in length, together with post-larvae of several other species, have been taken in considerable numbers in plankton samples. At these sizes the ages of the above species may be from several months to over a year[7], indicating the possible duration of the "bysso-pelagic" phase. Further investigations into the occurrence and nature of byssus drifting are presently in progress.

Acknowledgements are due to the staff of the Dove Marine Laboratory for their advice and Dr D. J. Tritton is thanked for his helpful criticism of the drag data interpretation. Part of this work was carried out while one of the authors (J.B.S.) was in receipt of a British Council scholarship.

Nematocyst discharge and the effects of antibodies on feeding in hydra

WHILE attempting to isolate hydra morphogens by column chromatography of tissue homogenates, I decided that a bacteria-free culture would be advantageous. Having established that a final concentration of 100 μg ml^{-1} penicillin G plus 100 μg ml^{-1} streptomycin in the normal[1] culture medium M gave a 100-fold reduction in bacterial contamination in 24 h, I found that hydra could not feed in this solution; indeed, they seemed unaware of *Artemia* larvae bumping into them. On transferring the hydra to fresh medium without antibiotic they were immediately able to feed normally.

I then tested three aspects of normal feeding in hydra: the initial capture by discharge of nematocysts on contact; the subsequent contraction of the tentacles bringing the captured prey to the mouth and the opening of the mouth and engulfment of the prey. Nematocyst discharge can be stimulated by electric shock[2] mechanical plus chemical stimulation[3] or brief sonication. For example, a 0.1-s burst from a Dowe Soniprobe into 10 ml of medium M containing 100 hydra gives >80% discharge of nematocysts, as judged by counting stenotheles using a haemocytometer.

This mechanical discharge can be inhibited by first suspending the hydra in a medium of high osmotic pressure as indicated in Table 1. A 10-s sonication with the microtip at the no. 8 setting in 2 M sucrose gives only 5% discharge. Nuclei are also left intact in these conditions, in spite of rupture of all cell walls and homogenisation of cytoplasm[4]. These observations would seem to confirm the 'osmotic hypothesis' for the discharge of nematocysts[5] with one reservation: 2 M sucrose has an osmotic pressure equivalent to 1 M NaCl, yet even 2 M NaCl is not so efficient at inhibiting discharge. There is, therefore, the possibility of some additional influence in 2 M sucrose, possibly viscosity, aiding the osmotic effect.

Using a membrane filter with pore size 5 μm, it is possible to remove nematocysts from the homogenates that are produced and thus obtain a preparation that is relatively free from the nematocyst toxin that is a major component of many 'inhibitory' extracts[6]. The tentacle movement and mouth opening, collectively known as the "feeding response" can be stimulated by 5×10^{-4} M reduced glutathione in medium M (ref. 7). Table 2 shows the effects of various concentrations of the antibiotics on

Table 1 Percentage discharge of nemotocysts on sonication in a medium of high osmotic pressure

Solution	Sonication time and power setting	% Discharge
1 M Sucrose	5 s, no. 8	8.5

++, Excellent; +, good; ±, fair; –, poor.

the components of normal feeding in *Hydra littoralis* starved for 24 h. The figures given for the timing of tentacle waving and mouth opening are estimates based on the simultaneous observations of 10 hydra. The lack of precise data for individual animals makes an accurate statistical analysis impossible; the trends, however, are clear.

Together, penicillin G and streptomycin at 100 μg ml^{-1} reduce both the length of time that tentacles wave and the time the mouth is open. Mouth opening is also delayed compared with the control but the most important effect is on initial capture, indicating a total inhibition of nematocyst discharge. These effects are totally lost or much reduced at lower antibiotic concentrations.

On its own, penicillin G at 100 μg ml^{-1} delays and reduces the mouth opening time but has little or no effect on tentacle waving and nematocyst discharge. Streptomycin, on the other hand, at 100 μg ml^{-1} affects all the functions tested, in particular totally inhibiting nematocyst discharge. Again the effects are lost or much reduced when the antibiotics are diluted.

It should be noted that 5×10^{-6} M glutathione is apparently a suboptimal concentration for this particular clone of hydra, since Lenhoff[7] found a mean mouth opening time of 36 min commencing 0.7 min after application of reduced glutathione.

Streptomycin at 100 μg ml^{-1} has, however, no inhibitory effect on artificial mechanical nematocyst discharge by sonication. A temporary paralysis of the cnidocil trigger[6] is therefore indicated, but the exact mode of action is unknown. The effects on the feeding response suggest that the antibiotics may also interfere with cell to cell communication in hydra, either through the 'nerve net' or the direct electrical contacts that exist between cells[8]. The true significance of this effect is, however, in doubt since a rough χ^2 'goodness of fit' comparison between the most extreme results and the controls gives a chance probability of 0.1. Known inhibitors of the feeding response are structurally similar to glutathione, having the same peptide backbone and apparently acting by competition for a receptor site[7]. No more definite hypothesis can be advanced for the effect of streptomycin, but a warning note should be sounded with respect to the routine use of antibiotics in any experimental situation; there may be unforeseen modifications in cell surface recognition sites, sensory structures or intercellular communication equivalent to those described here.

Excitability of nerve-free hydra

THE simplest nervous systems known are those of coelenterate polyps, of which hydra is one. Nerve cells of the common freshwater hydra occur in a diffuse, two-dimensional nerve net dispersed among the epithelial cells of the outer, ectodermal layer[1–4]. There are also a few nerve cells in the inner, endodermal layer but these are scattered and do not seem to form a continuous net[5]. Nowhere in a hydra are there nerve cell concentrations or clusters of sufficient complexity to warrant being called ganglia. There have been many behavioural and electrophysiological investigations of hydra[6–9], but the function of the nervous system in the control of behaviour is still unclear. In other coelenterates epithelial cells have been shown to be capable of propagating behavioural signals[10,11]. Several conducting systems coupled with spontaneously active pacemakers have been identified in hydra, but it is not known which of these conducting systems, if any, are neuronal and which result from activity in non-neuronal, epithelial cells. We have investigated the behaviour of *Hydra attenuata* in effectively nerve-free animals and show that such behaviour as remains, is controlled by non-neuronal cells.

It is now possible to create hydra which are virtually free of nerve cells, by treating the animals with colchicine[12]. Colchicine causes the endodermal digestive cells to send processes through the mesoglea and engulf ectodermal nerve cells, interstitial cells and nematoblasts, and draw them into the endoderm where they are digested. After two successive treatments, the hydra consist almost solely of epithelial cells and endodermal gland cells, with only a few cells of the other types remaining. Most of these animals are totally nerve free. Because colchicine treatment removes both the nerve cells and their progenitors, the interstitial cells, these hydra and their buds subsequently remain nerve free. The colchicine-treated animals are somewhat smaller than untreated animals and have altered proportions, but possess all body parts and reproduce by budding. Lacking nematocysts, the treated animals cannot capture prey and are fed by forcing newly hatched *Artemia* through the mouth directly into the gut.

Experimental animals were maintained and studied in 'M' solution[13] supplemented with 50 μg ml^{-1} of the antibiotic rifampicin. The hydra were subjected to two 8-h treatments with 0.4% colchicine spaced two weeks apart[12]. They were then fed three times weekly for 3 months before the experiments.

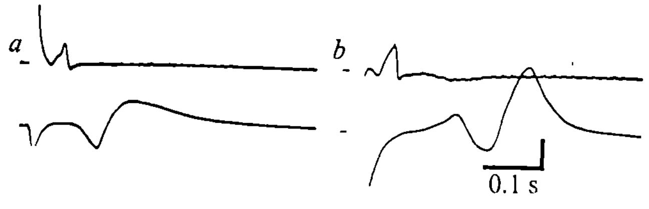

Fig. 1 CPs from a normal (*a*) and a nerve-free hydra (*b*). Positive potentials are upward deflections The animals were stimulated near the base; the upper traces were recorded from a basal disk electrode, the lower traces from an oral electrode. Latency values from the same two animals are plotted in Fig. 2. Vertical calibration: *a*, 5 mV; *b*, upper trace 2 mV, lower trace 5 mV.

Control hydra similar in size to the treated hydra were selected from a mass culture: some were kept in M solution and others in M solution containing rifampicin. All animals were starved for 48 h before the experiments.

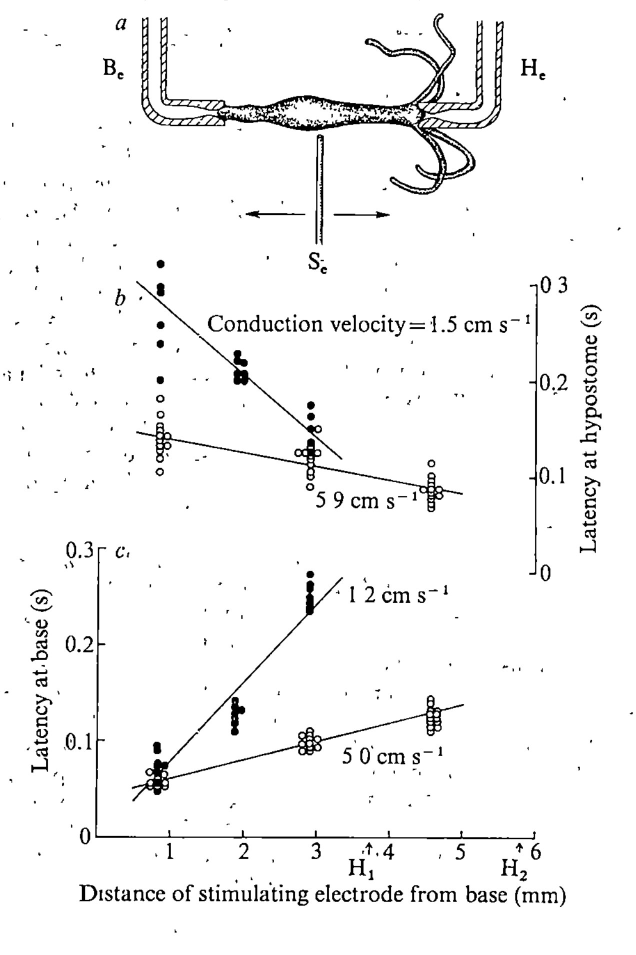
Electrophysiological studies have previously identified three classes of spontaneous electrical potentials in normal hydra[9]: (1) contraction pulses (CPs), generated by the ectodermal cell layer and associated with symmetrical, longitudinal contraction of the body column; (2) rhythmic potentials (RPs), generated by the endodermal cell layer and associated with contraction of endodermal circular muscles leading to column elongation; and (3) tentacle contraction pulses (TCPs), produced by the tentacles and associated with tentacle contraction. In normal hydra, these potentials occur somewhat sporadically with a mean frequency of the order of 1 per several minutes. Colchicine-treated animals show virtually no spontaneous behaviour, and not a single spontaneous electrical response was recorded in a total of 10 h of recording[14] from five treated animals. The behavioural inertness of colchicine-treated animals is particularly apparent in a time-lapse film, exposed at one frame per 30 s, of a dish containing a normal and a treated animal. In the film (which compresses 33 h of activity into 5 min) the normal animal contracts, elongates and sways from side to side, continuously, whereas the treated animal is motionless except for slight rippling contractions and occasional discharging of gut fluid through the mouth. Passano[15] suggested that a major function of nerve cells in primitive organisms is to initiate spontaneous activity. The absence of spontaneity in colchicine-treated hydra is thus consistent with this view.

Colchicine-treated animals are relatively unresponsive to external stimuli. Bright light, mild mechanical agitation, and *Artemia* extract all fail to elicit the electrical potentials or behaviour they do in the normal animal[9] Strong mechanical stimulation, such as pinching with forceps, or electrical stimulation of the column, does however, initiate propagated CPs and column contraction. The CPs of colchicine-treated hydra are of somewhat longer duration than those of normal animals (Fig. 1). The conduction velocity of the CPs was determined by recording them from the basal and oral ends of a hydra while the animal was stimulated at various positions along the column. As a stimulating electrode is moved from the base towards the mouth of an animal, the delay between an applied shock and the appearance of the recorded CP peak increases at the basal electrode and decreases at the oral one. The ratio of change in distance to change in latency gives the conduction velocity[7] (Fig. 2). Conduction velocity determinations were made from four colchicine-treated hydra, four untreated animals which had been transferred to culture solution containing antibiotic, and four animals grown and tested in normal culture solution. The colchicine-treated animals were the same used to investigate spontaneous activity; one of the latter was too small for conduction velocity measurements. For each animal the column was stimulated sequentially at three points: near the base, near the middle of the column, and near the oral electrode. Usually 10 sets of stimuli were given to each animal. The measured conduction velocity was different in the basal and oral directions, but the direction of preferred conduction varied from animal to animal. Basal and oral conduction velocities were averaged to give a single value for each animal. The CP conduction velocities of normal animals (5.7 cm s^{-1}, s.e. = 0.4) and antibiotic-treated controls (5.2 cm s^{-1}, s.e. = 0.2) were not significantly different, indicating that the rifampicin did not affect this parameter. These conduction velocities are not significantly different from that earlier reported for *H. littoralis* (5.2 cm s^{-1}, s.e. = 0.3; ref. 7). The CP conduction velocity in colchicine-treated animals (1.8 cm s^{-1}, s.e. = 0.2) was significantly lower than that of untreated animals.

One possible explanation for the reduced conduction velocity in colchicine-treated animals would be that the treatment directly alters the excitability of epithelial cells. In preliminary experiments we have found that the conduction velocity in the column returns to near normal after nerve-free animals are repopulated with interstitial (and thus nerve) cells from a temporary implant of normal tissue[16]. This indicates that colchicine does not have long term effects on the epithelial cells and that the depressed conduction velocity is related directly to the absence of nerve cells.

The effectiveness of the colchicine treatment in rendering the animals nerve free was verified by counting cells in macerated preparations of these animals[17]. When present, nerve cells are readily detected by this method. In normal animals approximately 5% of the column cells are nerve cells. Samples, each containing ~ 1,000 cells, were selected from the top, middle and bottom of the column of each treated hydra. The three samples together constituted about half of all the cells in the hydra. No nerve cells were found in four of the five treated animals. In the remaining animal, three nerve cells

Fig. 2 The latency between a stimulus to the column and the appearance of the positive peak of the evoked CP at the basal (*c*) and oral (*b*) electrodes. ●, A nerve-free hydra (H_1); ○, a normal hydra (H_2) H_1 and H_2 indicate the total length of each animal. The sketch in *a* illustrates the electrode placement; B_e and H_e are the basal and hypostomal recording electrodes, and S_e is the moveable stimulating electrode.



were found in samples containing a total of 2,749 non-neuronal cells. All the hydra had about five "big interstitial cells"[17] per 1,000 epithelial cells. Thus, four of the animals were apparently free of nerves and the fifth certainly contained too few nerve cells to form a continuous nerve net.

From these results, we conclude that: (1) nerve cells are necessary for normal spontaneous behaviour in hydra; (2) epithelial cells of hydra are excitable, and can conduct electrical signals which elicit column contraction; and (3) conduction velocity in the column is reduced in the absence of nerve cells. These experiments provide the first direct demonstration of non-neuronal conduction in hydra.

Directional hearing in crickets

CRICKETS have auditory organs at the proximal ends of the fore-tibiae; the binaural sensory input enables orientation to a sound source and in response to sound, crickets turn towards the more intensely stimulated of their two ears[1]. Airborne vibrations activate the auditory tympana of the ears, and are communicated to sensory scolopidia attached to the outer surface of the leg trachea, which forms an air space behind the tympanum[2,3]. For directionally-sensitive hearing, the responses of the two ears should differ when the direction of incident sound forms an angle with the insect's body axis. Directional hearing in crickets has previously been attributed to shielding of the contralateral ear by the insect's body[4]. We believe that shielding is insufficient to account for observed directionality, and propose an alternative theory which predicts the directional sensitivity of the cricket auditory system measured physiologically

We examined two species of cricket, *Teleogryllus commodus* and a smaller undescribed species we designate WB2 (specimens of which are lodged with the Australian National Insect Collection, Canberra). In anechoic conditions[5], we recorded auditory sensory thresholds to the sound frequency of the species song from primary fibres in the leg nerve, and from interneurones in the cervical connective. The directional sensitivity measured at each level in the sensory pathway is similar, and we found no influence of contralateral input on directionality. In normal preparations, crickets were mounted, ventral side up, on a thin vertical support which projected into a uniform sound field radiated horizontally. The prothoracic legs were held with the femora horizontal and perpendicular to the body axis, and the tibiae projecting vertically. Wings and other legs were removed. In other preparations, the cricket was mounted on its side with one foreleg extended vertically and the other held close to the body and covered with vaseline. In the latter preparations, sound was directed on to one ear only, and the orientation of this ear to the horizontal was near normal, although inverted.

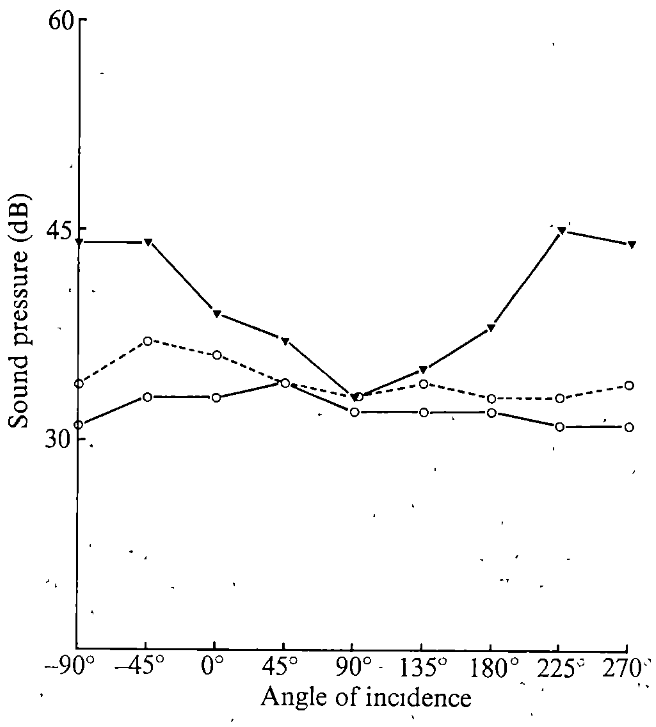

Fig. 1 Auditory thresholds obtained from the cervical connective in species WB2 in response to 4.5-kHz stimuli presented at different angles of incidence. ▼, Intact preparation, note the directional sensitivity; ○, single ear preparations; ——, individual ear in a free sound field; – –, individual ear asymmetrically shielded with a wax block. The single ear preparations have no directional sensitivity.

When rotated through 360° in the sound field, normal preparations showed auditory thresholds which differed by 10 to 25 dB for ipsilateral and contralateral incidence of sound. When one ear only was stimulated from different directions, no directional sensitivity was observed. Further, when a wax block approximating in size and shape to the head and prothorax of the cricket was placed next to the single ear, in the position normally occupied by the body, the preparation remained non-directional (Fig. 1). These results indicate that the auditory system is directional only when both ears are stimulated simultaneously, that the individual ear is non-directional; and that shielding of the contralateral ear by the insect's body does not account for the directional response.

In normal preparations, the directional sensitivity is abolished in two ways: (1) by blocking the trachea in either foreleg or in the prothorax and (2) by covering the tympanum of the opposite ear with vaseline. Independently, Zhantiev *et al.*[6] have demonstrated that directionality of hearing in *Gryllus bimaculatus* is decreased when the contralateral foreleg is removed and the leg trachea blocked. In crickets, therefore, the prothoracic leg tracheal system normally conducts sound from one ear to the other, and the directional response is the result of the interaction of the external and internal sound pressures at each tympanum. If sound is prevented from entering and traversing the internal tracheal pathway in any way, the auditory system is non-directional.

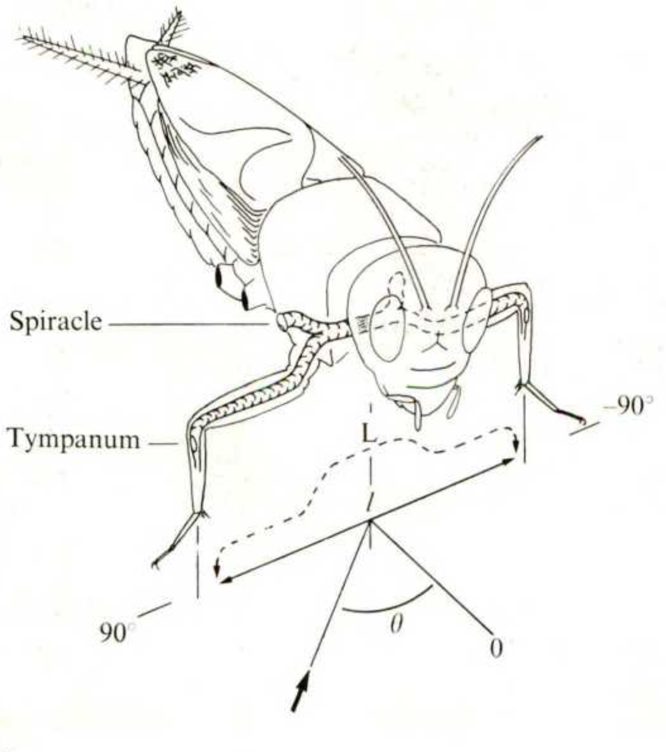
The elements of the prothoracic tracheal system on which directional hearing depends are illustrated in Fig. 2. Simple acoustical considerations explain the basis of the directional sensitivity. When a plane sound wave is incident at an angle to the body axis, a sound pressure of unit amplitude acting on the outside of the ipsilateral tympanum may be described by $\cos(\omega t)$. The net pressure acting at the ipsilateral tympanum is the difference between the external pressure and the internal pressure transmitted along the trachea from the opposite ear. The phase angle between the external and internal pressures results from the extra distance traversed by sound reaching the inside of the tympanum, namely, the effective distance between the ears, which is a function of the angle of incidence, and the length of the internal tracheal pathway. If it is assumed that there are no other phase changes or amplitude losses, then, at the tympanum

$$P_{(\text{net})} = \cos(\omega t) - \cos(\omega t + \frac{l}{\lambda} 2\pi \sin\theta + \frac{L}{\lambda} 2\pi) \qquad (1)$$

where l is the external distance between the ears, L is the length of the tracheal pathway, θ is the angle of incidence of sound and λ is the wavelength of sound. In the species we have studied, $l+L$ is nearly half the wavelength of the species' song. (In *T. commodus*, $l+L = 38$ mm, $\lambda/2 = 43$ mm; in species WB2, $l+L = 30$ mm, $\lambda/2 = 38$ mm.) Thus when $\sin\theta = 1$, the phase angle between the external and internal sound pressures at the tympanum approaches π, and the amplitude of $P_{(\text{net})}$ is a maximum. Conversely, when $\sin\theta = -1$, the phase angle between external and internal sound pressures approaches zero, and the amplitude of $P_{(\text{net})}$ is a minimum.

Using equation (1) with the appropriate anatomical and song frequency values, we have calculated the relative amplitude of the net sound pressure at the tympanum for values of θ and expressed it in dB. For each species, this calculated net sound pressure at the ear for different directions of sound corresponds to the experimental directional sensitivity (Fig. 3).

Fig. 2 Drawing of a cricket showing the apposed leg tracheae which form a sound pathway between the two tibial auditory organs. Sound reaches the exterior and interior of the tympanic membrane along paths of different length. When sound is incident at an angle θ to the body axis, the path to the interior of the ipsilateral tympanum through the tracheae exceeds that to the exterior of the tympanum by the extra distance of the contralateral ear from the source $l \sin\theta$, plus L (the length of the tracheal pathway). Therefore, the net sound pressure at the tympanum is the resultant of the exterior and interior sound pressures, which differ in phase by $2\pi/\lambda\ (l \sin\theta + L)$, where λ is the wavelength of incident sound.



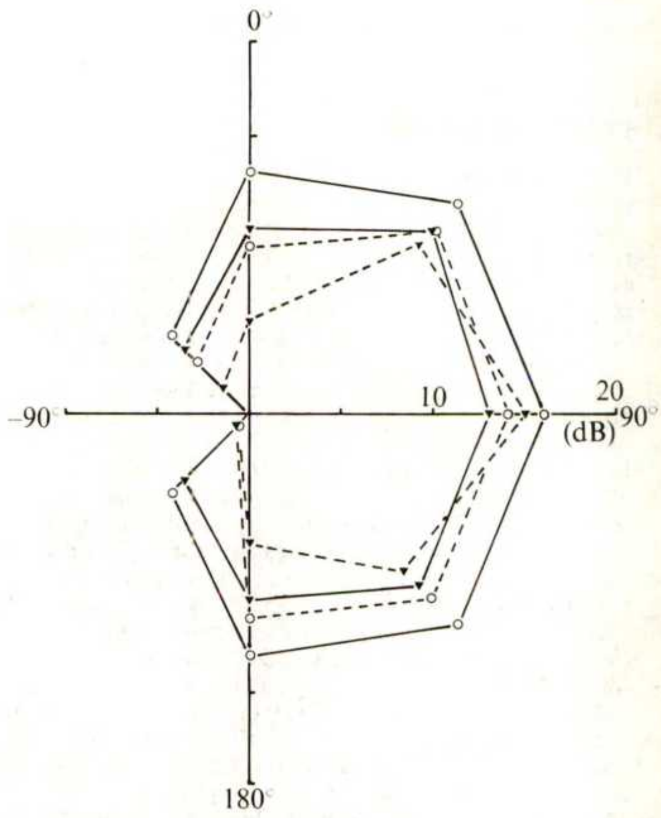


Fig. 3 Predicted net sound pressure at the auditory tympana (——) for values of θ compared with measured hearing sensitivity (– –) for *T. commodus* (▼) and species WB2 (○) on polar coordinates.

Transmission of sound along the tracheal pathway is limited with respect to frequency according to the resonance characteristics of the tube. The directional sensitivity of normal preparations applies only to a narrow frequency band near the tuned frequency of the ear, and which corresponds to the frequency of the species' song.

This account of the basis of directional hearing in crickets is consistent with the inability of unilaterally deafened crickets to locate a sound source in phonotaxis trials[1], and with the specificity shown by female crickets in their orientation to signals having different carrier frequencies[7]. The mechanism illustrates the importance of the leg trachea as an integral part of the auditory system. In tettigoniids also, the leg trachea has a crucial, but fundamentally different role in hearing[5,8]. The cricket derives the directional sensitivity of its ears from the fact that the tracheae of the forelegs are interconnected acoustically at the midline.

We thank Dr E. Ball, Dr C. E. Hill and Professor G. A. Horridge for their help in the preparation of the manuscript.

Effect of phloridzin and phloroglucinol on apple shoots

PHENOLIC compounds and their glycosides are widespread in plants. They have uncertain metabolic roles, although they are regarded as metabolic by-products conferring resistance to pathogens[1,2]. Phloridzin, the 2′-glucoside of phloretic acid, for example, is unique to species of *Malus* and is the major phenolic compound of commercial apple trees (*Malus pumila* Mill), representing 3–7% of the dry weight of leaves as well as occurring in bark and roots[3]. It is not involved in resistance to apple scab as formerly supposed[4], but affects the metabolism of many organisms. It inhibits growth of wheat coleoptiles[5] and tomato roots[6] but more than doubles photosynthetic rates in *Elodea*[7,8]. In animals it inhibits the utilisation of carbohydrates[9], and one of the degradation products[4,10] of phloridzin, phloroglucinol, acts synergistically with auxin to promote growth of oat mesocotyls[11]. There have been indications that phloridzin, and phloroglucinol, promote the expansion of apple leaves[12] and the rooting of apple shoots[13], respectively. This suggests that phloridzin may have important effects on *Malus*. I have now shown that phloridzin promotes the growth of cultured apple shoots. The effect is pronounced and has practical application.

Tips (1–2 cm) of shoots (2–5 cm) of M.7 or M.26 (virus-free) apple rootstocks were cultured as described previously[14] in sterile conditions in test tubes (15 × 2.5 cm), each containing 10 ml culture medium. Shoot tips were kept at 25 °C and received 16 h light daily from Crompton white tubes giving 14 W m^{-2} at the surface of each culture tube.

Phloridzin and phloroglucinol (10^{-3} M) were added to a basic medium (medium 1)—Quoirin's medium B (ref. 15) with the vitamins and glycine replaced by the vitamins used by Wetmore and Sorokin[16]. For one test with phloridzin, indol-3-yl acetic acid (IAA) was omitted and for others with phloroglucinol, medium 2 was used—as medium 1 but with only 0.5 mg l^{-1} benzyl amino purine (BA), thiamine hydrochloride (0.4 mg l^{-1}) and inositol (100 mg l^{-1}) in place of the vitamins, and with indol-3-yl butyric acid (1 mg l^{-1}) as ammonium salt (IBA) in place of IAA. All constituents of the media were sterilised by autoclaving at 103 kN m^{-2} for 5 min, except for phloridzin, phloroglucinol, and IBA which were passed through Millipore filters (0.45 μm diameter).

Table 1 and Fig. 1 summarise the results and show that the two phenolic compounds markedly stimulated shoot growth. With medium 1 minus IAA, each tip produced a single shoot, and phloridzin increased internode extension, leaf production and expansion. With medium 1 each tip produced between one and three shoots, and phloridzin and phloroglucinol promoted internode extension and increased the number of shoots per tip to between three and six. The shoots originated from terminal and lateral meristems and not *de novo* from callus at the base of cultures (Fig. 1).

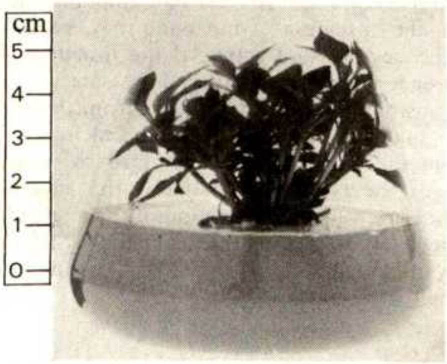

Fig. 1 Effect of phloridzin on M.7 shoots. *a*, Inoculum; *b*, after 5 weeks on medium 1; *c*, after 5 weeks on medium 1 plus 10^{-3} M phloridzin.

Fifteen cultures of M.26 that had produced two shoots each during 4 weeks on medium 1, were transferred singly to 35-ml volumes of medium 2 in 100-ml flasks. This procedure was repeated with medium 2 plus 10^{-3} M phloroglucinol, and in this case 15 cultures were also transferred to 125-ml volumes of medium in 250-ml flasks. After 5 weeks, each culture with 35 or 125-ml medium plus phloroglucinol had produced between 8 and 14 or 20 and 38 shoots, respectively, 2–5 cm long (Fig. 2). With unsupplemented medium 2, however, there were only 3–5 shoots per culture, all less than 2 cm long.

Fig. 2 Effect of phloroglucinol on M.26 shoots. M.26 shoot culture on medium 2 + 10^{-3} M phloroglucinol 5 weeks after initiation from a culture with two shoots.

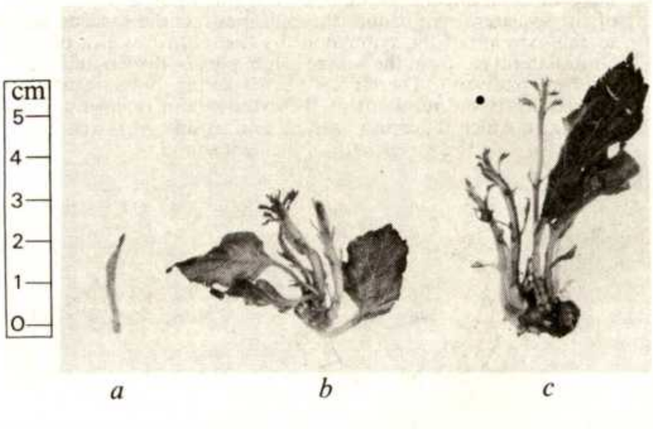

Table 1 Effect of 10^{-3} M phloridzin (PZ) and phloroglucinol (PG) on apple shoots

Shoots	Medium	No. of replicates	Mean growth values*				
			Fresh weight (mg)	No. of shoots per culture	Shoot length (mm)	No. of leaves + primordia	Leaf area† (cm^2)
M.7	1 −IAA	15	152	1.0	17	13	1.78
	1−IAA + PZ	13	257¶	1.0	24§	17‡	2.73¶
M.7	1 + PZ	20	755	2.4	21	14	—
		17	1108¶	3.7¶	29‡	14	—
M.26	1 + PZ	12	715	2.0	17	17	—
		12	1120¶	3.3‡	24‡	16	—
M.7	1 + PG	10	359	1.0	32	19	—
		6	783¶	3.0¶	44¶	20	—

*Culture period 5 weeks except with medium 1 −IAA, where it was 3 weeks.
† Of oldest leaf.
Significantly greater than without PZ or PG (P = ‡ 0.05; §0.01; ¶0.001).

No roots developed in any of the tests described so far, but 100 shoots excised from cultures grown with medium 2 plus phloroglucinol all rooted within 5 weeks when transferred to fresh medium of the same composition but without BA.

These results suggest that phloridzin, possibly through the production of phloroglucinol, is involved in the growth of apple trees. From a practical point of view, the effect on the development of apple shoots has potential for improved propagation of apple trees *in vitro*[18]. Methods described recently[17] gave much less shoot growth and rooting than described here with phenolic compounds.

I thank Mr D. O'Farrell for technical assistance.

Malate-switch hypothesis to explain the action of stomata

DURING the past ten years major advances have been made in our understanding of the mechanics of stomata. A most important discovery has been that potassium enters the guard cells in sufficient quantities to account for the decreases in osmotic potential which occur on stomatal opening[1]. Association of potassium with stomatal movements has now been reported for at least 22 species[2]. There is doubt, however, about the nature of the anions which accompany K^+. Chloride has been found to balance about 40% of the K^+ in *Zea mays*[3] and considerably less in *Commelina communis*[4]. Malate could be the balancing anion as it has been found to accumulate in the guard cells on stomatal opening[5] although it is not clear whether it is synthesised in the guard cells or is transported there from the surrounding cells. Clearly an understanding of the mechanism of the ion transport in and out of the guard cells is necessary as a first step to the unravelling of the stomatal mechanism. An hypothesis is proposed here which attempts to explain the transport aspect of stomatal function. It is based mainly on data obtained from studies with the monocotyledon *C. communis* but should be applicable to other species.

Stomata of *C. communis* have a complex structure with a number of subsidiary cells (Fig. 1). K^+ and Cl^- concentrations in each type of cell have been determined for stomata in both the open and closed states[4,6]. There seemed to be considerable transport of K^+ and Cl^- between the cells during opening and closure but Cl^- never accounted for more than 27% of the K^+. Table 1 shows data for K, Cl and malate concentrations in the lower epidermis of *C. communis* leaves with open and closed stomata. They show that the total amounts of these ions do not change with stomatal aperture and assuming a valence of 1.5 for malate it approximately balances the K^+ not accounted for by Cl^-. It seems reasonable to assume, therefore, that as the malate concentration in the leaf epidermis does not change, malate is not synthesised or broken down to any marked extent but moves with potassium from cell to cell during stomatal activity.

Table 1 Levels of malic acid, K^+ and Cl^- (mol m^{-3}) obtained from water extracts of the lower epidermis of the leaf of *Commelina communis*

	Malic acid	K^+	Cl^-
Stomata open	64.0	147.3	49.2
Stomata closed	61.3	139.9	48.0

Figures are means of five determinations.

The vacuolar *p*H of each of the cells of the stomatal complex of *C. communis* changes with stomatal movements, The *p*H of the guard cell for example, rises from 5.1 to 5.7 when stomata open[7]. Knowing the concentrations of K^+ and Cl^- (refs 4 and 6) and the *p*H, it is possible to write down the approximate concentrations of mono- and divalent malate in each cell for open and closed stomata (Tables 2 and 3). The data in Tables 2 and 3 are rounded off to make the figures for open and closed stomata symmetrical. The most significant point is that the concentrations of monovalent malate varies little between the cells both when the stoma is open and when it is closed. On the other hand, there is a steep gradient in the concentrations of divalent malate across the stomatal complex. The gradient is reversed when the stomata open or close.

It is proposed that K^+ moves from cell to cell with the monovalent malate but that the divalent form of malate is unable to move and is locked in the cell. Cram[8] has evidence that malate is taken into barley root cells as the singly ionised form rather than as doubly ionised or unionised molecules. It is suggested that stomatal closure brought about by factors such as darkness, high ambient CO_2 and abscisic acid occurs because these factors cause the *p*H of the guard cells to drop from 5.8 to 5.1. The majority of the malate will switch from the divalent to the monovalent form and a gradient of monovalent malate will develop across the stomatal complex (Table 3). Monovalent malate will thus move across the stomatal complex and eventually reach the epidermal cell whose *p*H will rise, locking the malate in its vacuole as the divalent form. Equilibrium will be reached when the gradient of monovalent malate is zero and the situation of Table 2 will prevail with the stomata closed.

Stomatal opening would be brought about in the reverse manner. It is proposed that the factors which usually bring about opening such as light, low CO_2, high temperature and circadian rhythms all work by bringing about a rise in the *p*H of the guard cells. Malate would switch from being predominantly monovalent to being mainly divalent. A gradient in monovalent malate would be set up and K malate would flow into the guard cells (Table 2). On entering the guard cell the malate would be switched to the divalent form and locked in the cell. The osmotic potential of the guard cell would fall, the turgor pressure rise and the stoma would open. The gradient of monovalent malate would again become zero and a new equilibrium would be attained (Table 3).

It is proposed that the energy for stomatal opening and

Fig. 1 Diagram to show the arrangement of the cells in the stomatal complex of *Commelina communis.*

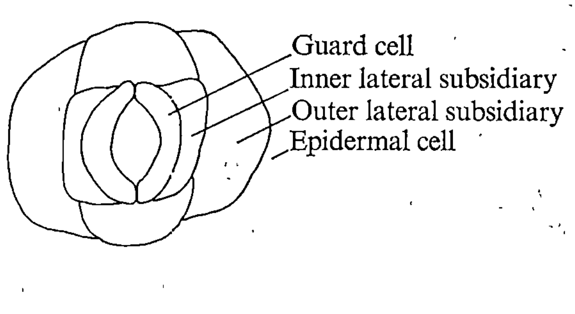

Table 2 *p*H and concentrations of di- and monovalent malate (mol m^{-3}) in the various cells of the stomatal complex of *C. communis* when the stomata are closed and also about to open

Stomata closed	GC	ILS	OLS	EPID
*p*H	5.1	5.5	5.7	5.8
Monovalent malate	32	50	45	60
Divalent malate	9	25	53	120
Pre-opening	(*p*H 5.8)			
Malate⁻	10	50	45	60
Malate²⁻	20	25	53	120

GC, Guard cell; ILS, inner lateral subsidiary; OLS, outer lateral subsidiary; EPID, epidermal cell.

closing would be expended in bringing about the change in *p*H of the guard cell from the *p*K value of malic acid of 5.1 to 5.8 and back again. It is assumed that all the environmental factors which cause stomatal opening and closure work by changing the *p*H of the guard cell and so operating the malate switch. This would explain why a number of factors can influence stomata by acting independently and also by seeming to act together. For example, before dawn endogenous rhythm could cause a partial rise in guard-cell *p*H which would be completed by a reduction in ambient CO_2 at the onset of photosynthesis at dawn. This would explain how stomata anticipate dawn by partially opening before the light period. It is not the purpose of this paper to suggest how environmental factors cause the change in guard cell *p*H.

Table 3 *p*H and concentrations of di- and monovalent malate (mol m^{-3}) in the various cells of the stomatal complex of *C. communis* with the stomata open and also about to close

Stomata open	GC	ILS	OLS	EPID
*p*H	5.8	5.7	5.5	5.1
Malate⁻	60	60	50	32
Malate²⁻	120	70	25	9
Pre-closing	(*p*H 5 1)			
Malate⁻	192	60	50	32
Malate²⁻	53	73	25	9

It follows from this hypothesis that: (1) Opening and closing of stomata should always be preceded by a *p*H change in the guard cells. (2) The important ion is not K^+ but malate and this would explain why other monovalent cations are effective in bringing about stomatal opening[9,10].

Although malate is considered to be the important ion in *C. communis* because of its ability to switch its valence, it is possible that other organic acids may provide the switch anion in some other species. There are, however, few organic acids which have *p*K values at the *p*H normally found in plant cells.

The mechanism of transport of the ions between the cells of the stomatal complex is not crucial to the validity of the hypothesis but the gradients envisaged suggest that diffusion could be the most important factor. In this case the active transport found between the cells[4,6] would be secondarily active. Primary active transport between the cells cannot, however, be ruled out at the present time.

Plant uptake and leaching of dimethylnitrosamine

THE occurrence of carcinogenic nitrosamines is of considerable interest because they have been found in foods consumed by humans[1] and they can be produced, at least *in vitro*, from agricultural chemicals[2,3]. Furthermore, the widespread occurrence of potential precursors of nitrosamines—secondary or tertiary amines and inorganic nitrogen compounds that are readily converted to nitrite by microorganisms—led to studies demonstrating that the carcinogens can be formed in soil samples and aquatic environments[4,5]. A hazardous chemical in soil is not of toxicological significance, however, unless it is volatilised or enters the human food chain by being assimilated by food crops or leached through soil into ground waters ultimately used for drinking. We report here that dimethylnitrosamine (DMNA) can be assimilated by the roots of lettuce and spinach, is translocated to the tops and that it also moves readily through soil.

Lettuce was grown from seed in quartz sand or Williamson silt loam contained in clay pots and incubated at 16 °C in a growth chamber in which the daylength was 16 h. The plants were watered daily with Hoagland's inorganic nutrient solution[6] at one-quarter strength; the leaves were not wetted during the watering. Spinach was grown from seed in the same nutrient solution, the liquid being aerated constantly and replaced weekly. The spinach plants were maintained at 20 °C under Growlux fluorescent lights timed to provide a 16-h day. After two months, the various pots received either 0.57 µCi of ^{14}C-DMNA plus the unlabelled nitroso compound to a final concentration of 100 µg ml^{-1}, or 0 057 µCi of ^{14}C-DMNA plus unlabelled nitrosamine to a final concentration of 10 µg ml^{-1}. The total amounts of DMNA added were 2.50 and 0.25 mg for the high and low levels of exposure, respectively. After 2 d, the aerial portions of these plants, as well as of plants not exposed to the nitrosamine, were harvested and washed, and 100-g portions homogenised in 150 ml of 6.0 N NaOH. The homogenised slurry was refluxed for 30 min, filtered through glasswool, and steam-distilled, half of the volume being collected as distillate. The distillate was extracted three times with volumes of methylene chloride one-third that of the distillate, and the extract was dried with Na_2SO_4 and concentrated to 2 ml by evaporation in a Kuderma–Danish evaporative concentrator operating at 60 °C. Half of the extract was added to 10 ml of a scintillation cocktail containing 5 g PPO, 0.1 g POPOP, and 1 l of toluene, and the radioactivity was counted on a Beckman model LC-100C liquid scintillation system. A second experiment with lettuce growing in sand was conducted similarly, but the plants were harvested at 4, 9 and 15 d.

The results show that both spinach and lettuce can absorb radioactivity from the growth medium (Table 1), the amount assimilated being proportional to the amount of ^{14}C-DMNA added to the pots. The absorbed ^{14}C disappeared with time, in agreement with results on nitrosamine uptake by *Lepidium sativum*[7]. The percentage of radioactivity taken up by lettuce grown in soil was slightly higher than that of plants grown in sand. The quantity of DMNA taken up per unit weight of plant material was, however, severalfold greater for the soil-grown plants, possibly because of the lower yield obtained when the lettuce was grown in the silt loam. It has been reported that cereals can absorb nitrosamines[8], and the present findings not only extend previous observations, but pertain to two major vegetable crops.

To confirm the identity of the labelled product, 2-month-old lettuce plants were exposed for 2 d to 5.7 µCi of ^{14}C-DMNA in 25 ml of nutrient solution made to 500 µg ml^{-1}

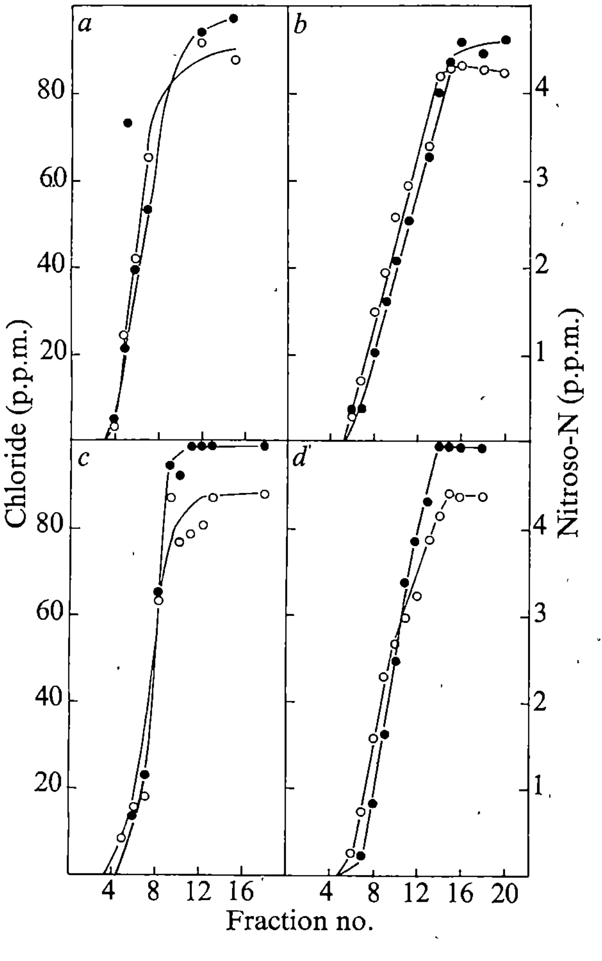
Table 1 Uptake of dimethylnitrosamine by spinach and lettuce

Plant	Growth medium	^{14}C-DMNA supplied (μCi)	Length of exposure (d)	DMNA taken up* (μg per g dry wt)	DMNA taken up by plant* (%)
Lettuce	Sand	0.057	2	1.38	3.20
		0.57	2	14.38	3.25
Lettuce	Soil	0.57	2	106.0	5.06
Spinach	Water	0.057	2	0.54	0.38
		0.57	2	5.60	0.27
Lettuce	Sand	0.57	4	7.04	1.56
			9	1.40	0.21
			15	0.07	0.02

*Each figure represents the average of four replicates.

with the unlabelled nitrosamine. Compounds containing the radioactivity were extracted and concentrated, and then 0.5 ml of the methylene chloride extract was placed on each of two silica gel thin-layer plates (Eastman chromatogram sheets), only one of which was exposed to ultraviolet radiation (240 nm) for 15 min before development. After development in hexane–diethyl ether–methylene chloride (4 : 3 : 2), the chromatograms were counted on a strip chart recorder (Actigraph III, Nuclear Chicago), and the location of the radioactivity was compared with that on chromatograms of authentic ^{14}C-DMNA. The radioactivity on the non-irradiated chromatogram had the same R_f value (0.34) as ^{14}C-DMNA, and the radioactivity on the ultraviolet-irradiated chromatogram had the same R_f value (0.03) as ^{14}C-dimethylamine, which is formed by the photolytic cleavage of DMNA. The yield of dimethylamine was essentially stoichiometric. As a further confirmation of identity, the extract was analysed by gas chromatography using a Varian Aerograph series 1700 gas chromatograph equipped with a flame ionisation detector and a 1.84 m×3.2 mm stainless steel column packed with 10% Carbowax 20M on Chromosorb W-HMDS. The column was maintained at 80 °C for 5 min and then programmed to 110 °C at a rate of 2 °C min^{-1}. The retention times of the unknown and authentic DMNA (512 s) were identical.

Fig. 1 Leaching of chloride (●) and dimethylnitrosamine (○) through columns of four soils. *a*, Deerfield; *b*, Scarboro; *c*, Lima; *d*, Williamson.



To determine whether DMNA can leach through soil, columns of Williamson silt loam (*p*H 5.8, 1.9% organic matter), Lima loam (*p*H 7.8, 3.8% organic matter), Deerfield sand (*p*H 5.1, 2.5% organic matter), and Scarboro sand (*p*H 5.6, 14.8% organic matter) were prepared using 100–200 g of air-dry soil that had been passed through a 2-mm sieve. The columns were moistened with distilled water to bring the soil to field capacity, and a solution containing 100 μg ml^{-1} of chloride and DMNA (5 μg nitroso nitrogen ml^{-1}) was allowed to pass through the column. Equal fractions (10 ml) were collected, and the fractions analysed for chloride and DMNA content using the methods of Bergmann and Sanik[9] and Daiber and Preussmann[10], respectively. Nitrite, which gives a positive reaction in the method of DMNA analysis, was determined in all samples by the procedure of Montgomery and Dymock[11], and corrections were made for the small amounts present in the first few fractions. The results in Fig. 1 demonstrate that DMNA is not retained by the soils but moves as readily as chloride. Because the soils were open to the atmosphere, some of the added DMNA may have been lost through volatilisation.

The earlier findings that nitrosamines can be formed and are persistent in samples of soil[4,5,12] and our observation that DMNA can potentially move from soil into food crops and downwards into groundwater suggest that a hazard may exist from a previously unrecognised source of exposure. Investigations on nitrosamine uptake by edible crops and movement through soil are also important in light of the report that the *N*-nitroso derivative of at least one pesticide has been found in a municipal water supply (D. H. Fine, personal communication). Further research is required to determine whether such a possible hazard is in fact a reality.

This investigation was supported in part by a NIH Fellowship from the NIEHS.

Non-enzymatic photochemical reduction of nitrate in rice seedlings

LIGHT plays an important role in nitrate assimilation in leaves by providing the reductants and by stimulating the synthesis of nitrate and nitrite reductases[1-3]. Activity of nitrate reductase is considered to be the rate-limiting step in nitrate assimilation and in the production of grains and grain proteins in crop plants[4,5]. It has been known for some time, however, that the ultraviolet radiation in sunlight photochemically reduces nitrate in aqueous solution to nitrite[6,7]. Stoy[8,9] reported that ultraviolet light had a much stronger effect on nitrate assimilation in wheat leaves than light of longer wavelengths. We have observed, in experimental conditions, significant accumulation of nitrite in rice leaves exposed to sunlight, even when nitrate reductase activity was negligible, so we have investigated non-enzymatic photochemical reduction of nitrate in leaves.

The absorption spectrum of 0.2 M KNO_3 measured in a Gilford spectrophotometer showed a trough at 260 nm ($E = 0.3$) and a sharp peak at 302 nm ($E = 1.04$). Negligible absorption was observed at wavelengths 340 nm and above. On the other hand, 0.2 M $NaNO_2$ revealed a broad absorption band ($E = 1.25$–1.75) in the whole range of wavelengths from 260 to 325 nm, after which it showed a decline, with negligible absorption at 400 nm and above.

When 10 mM KNO_3 solution was exposed to bright sunlight of intensity from 7,000 to 10,000 foot candles (70–108 klx), about 10 to 20 nmol NO_2^- ml^{-1} h^{-1} was produced. This could be compared with the amount of nitrite produced *in vitro* by an active preparation of nitrate reductase from rice leaves, incubated with 0.34 mM NADH and 10 mM KNO_3, which was found to be 20–30 nmol NO_2^- ml^{-1} h^{-1}. When 10 mM $NaNO_2$ was irradiated with sunlight, negligible loss of nitrite was observed.

That the ultraviolet component of solar radiation was responsible for the reduction of nitrate was easily confirmed by using filters, which absorbed that part. Negligible quantities of nitrite were formed when nitrate solution was treated with such filtered sunlight. Exposure of nitrate to ultraviolet light from a mercury lamp was as effective for reduction as direct sunlight.

To detect non-enzymatic accumulation of nitrite in leaves exposed to sunlight, it was necessary to eliminate, or diminish considerably, the activities of both nitrate and nitrite reductases. In order to achieve this, rice seedlings were grown in complete darkness. It is known that synthesis of the two enzymes is retarded in etiolated plants[2,3]. When these leaves are exposed to sunlight, however, the enzymes are likely to be synthesised as the chloroplasts develop and to prevent this, nitrate was added in the presence of sodium tungstate and chloramphenicol. Tungstate blocks the *in vivo* synthesis of an active nitrate reductase, by forming the enzymatically inactive tungsten analogue by replacement of molybdenum in the enzyme molecule[10]. Chloramphenicol, an inhibitor of protein synthesis on 70S ribosomes, inhibits the formation of nitrite reductase, which requires protein synthesis on chloroplastic ribosomes, without affecting the synthesis of nitrate reductase, which takes place on 80S ribosomes in the cytoplasm[3,11]. Thus, by a combination of tungstate and chloramphenicol treatments, we hoped to diminish the activities of nitrate reductase and nitrite reductase considerably.

Results show that in normal seedlings grown in sunlight with nitrate (Table 1; treatment 1), the activities of the two enzymes were quite high. Free nitrite was not detected in the leaves because of its rapid reduction to ammonia in healthy seedlings. The seedlings in which the activities of the two enzymes were blocked (treatment 3) progressively accumulated nitrite for up to 4 h in leaves exposed to sunlight. The same result was brought about by ultraviolet light from a mercury lamp; but detached leaves kept in the dark did not accumulate nitrite. When the seedlings were treated with chloramphenicol (treat-

Table 1 Effect of sunlight on the accumulation of nitrite in leaves of rice seedlings

Conditions of growth of seedlings: Treatment number	Light regime	Additions to nutrient solution	Period of exposure of detached leaves to sunlight (h)	Nitrate reductase (μmol NO_2^- per 20 min per g tissue) *In vitro*	*In vivo*	Nitrite reductase (μmol NO_2^- reduced per 20 min per g tissue)	Nitrate (μmol per g tissue)	Nitrite (μmol per g tissue)

Seedlings of rice (*Oryza sativa*), variety Taichung Native-1 were raised in well washed quartz sand with Hoagland solution lacking nitrate as described earlier[3]. Seedlings grown in sunlight in treatments 1 and 2 were exposed during the day (10 h) and kept in dark during the night. In treatment 1, 15 mM KNO_3 was added on the 14th day In treatment 2, 15 mM KNO_3 and 3 mg ml^{-1} chloramphenicol were added on day 14 and seedlings kept in the dark for 2 d In treatment 3, on day 14, 15 mM KNO_3 with 5 mM sodium tungstate and 3 mg ml^{-1} chloramphenicol were added to the nutrient solution and also sprayed on the etiolated plants and seedlings kept in the dark for 2 more days. Leaves from 15-d-old seedlings from the three treatments were detached from plants and immersed in 15 mM KNO_3 solution so that the bottom 1 cm dipped into the solution and the remaining portion was exposed to sunlight. The nitrate solution was kept in flasks covered with a black paper, so it was not exposed to sunlight and photochemical reduction of nitrate in the flasks was avoided The protruding leaves alone were exposed to light for different intervals as indicated in the table. At the end of this period, leaf extracts were prepared and *in vitro* activities of nitrate reductase and nitrite reductase were assayed as described previously, using NADH and reduced methyl viologen as electron donors, respectively[3]. *In vivo* nitrate reductase activity in the leaf disks was assayed by the method of Jaworski[12]. Nitrite content in the leaf extracts as well as in the enzyme assays, was determined by the standard Greiss–Ilosvay colorimetric method Nitrate content in suitably diluted leaf extracts was determined after its quantitative enzymic reduction to nitrite by an active dialysed nitrate reductase obtained from rice leaves.

ment 2), the activity of nitrite reductase was negligible, whereas nitrate reductase was synthesised during a 4-h exposure of green detached leaves to sunlight. In these conditions, large quantities of nitrite accumulated. The amount of nitrite accumulated *in situ* was about three times that formed by the assumed photochemical reduction observed in treatment 3.

Activity *in vivo* of nitrate reductase in leaf disks was less than 10% of the *in vitro* activity in leaf extracts, assayed in the presence of excess NADH. Similar results indicating a comparatively low *in vivo* activity of nitrate reductase have been reported[13,14]. Moreover, it is uncertain whether either the *in vivo* or *in vitro* assay is a true reflection of the *in situ* nitrate assimilation. The estimated input of reduced nitrogen based on *in vivo* enzyme assay is known to exceed substantially the actual accumulation of reduced nitrogen by the plant *in situ*[5]. Our results show that photochemical reduction of nitrate could be as large as 30% of the *in situ* reduction.

In plants exposed to very bright sunlight, as in tropical countries, photochemical reduction of nitrate could thus be significant. Activity of nitrate reductase alone may not, therefore, be a factor limiting the rate of nitrate assimilation.

Immunopathology of schistosomiasis in athymic mice

EOSINOPHILIA—tissue eosinophil infiltrates—granuloma and IgE formation are associated with helminth infections. Eosinophils phagocytose antigen–antibody complexes, neutralise histamine and serotonin, mediate inflammatory reactions and modify delayed hypersensitivity[1]. The tissue-invasive stage of some parasitic infections provides suitable antigen and stimulates the production of IgE, which in turn induce eosinophilotaxis. We have investigated the need of T-cell participation in the eosinophil response, IgE formation and granuloma formation in schistosomiasis in congenitally athymic mice which have profound deficiency in T-cell dependent immune response. We looked in particular at eggs as they are important in the pathogenesis of schistosomiasis. They are trapped in tissues and induce chronic granulomatous inflammation with numerous eosinophils. Warren *et al.*[2–6] reported that egg granuloma is a cell-mediated hypersensitivity reaction and it is significantly altered in immunosuppressed mice.

Sixteen homozygous athymic nude (*nu*/*nu* mice with an outbred Swiss mouse background and 16 normal heterozygous (*nu*/+) littermates 9 weeks old were housed in specific pathogen-free conditions (mouse hepatitis virus). They were infected through tail immersion with 35–40 *Schistosoma mansoni* (Puerto Rico strain) cercariae freshly released from the intermediate snail host, *Biomphalaria glabrata*. This level of infection results in a chronic murine hepatosplenic disease which closely resembles, pathophysiologically, human chronic schistosomiasis[7]. Animals were killed 52, 58 and 66 d after infection. Although *nu*/+ mice had ruffled hair coat and hunched back, *nu*/*nu* mice showed no remarkable signs of illness. The hepatosplenomegaly and enlargement of mesentery lymph node associated with schistosomiasis was significantly more severe in *nu*/+ mice. Microscopic examination of the liver showed that *S. mansoni* eggs were trapped in the small intrahepatic blood vessels and granuloma was formed around them. In the immune-intact normal mice, the egg granuloma was a circumscribed lesion consisting of predominately eosinophils, macrophages, lymphocytes, epithelioid cells, granulation tissue and sometimes giant cells. Reparative fibrosis was distinct. The white necrotic hepatic lesions in athymic mice were smaller than those in control mice. The sizes of egg granulomas, determined by measuring two diameters at right angles to each other with an ocular micrometer 52, 58 and 66 d after infection, are presented in Table 1. The mean sizes of granulomas in athymic mice were significantly smaller than those in heterozygous mice at $P<0.001$ as calculated by Student's *t* test. Granulomas decreased in size during the course of infection. No tissue eosinophils were found in the egg granuloma in the athymic mice, whereas neutrophils, macrophages, lymphocytes, epithelioid cells and pigments were usually present. We did not see giant cells in granulomas. Occasionally only a few or no inflammatory cells were found around the eggs. Granulation tissue or collagen formation was observed in some egg granuloma lesions, although they were not as well established as those

Fig. 1 The lymphocyte transformation of splenic cells of athymic (*nu*/*nu*) and heterozygous (*nu*/+) mice 52 d after infection with 35–40 *S. mansoni* cercariae. The blastogenic activities stimulated with 20 μg of PHA, 40 μg of LPS and 12 μg of adult *S. mansoni* antigen, are expressed as the stimulation index by comparing the thymidine uptake by infected splenic cells with the thymidine uptake by control (unsensitised) splenic cells. The spleen cell suspension (2×10^6) was added to each well of microtrays and cultured in triplicate The soluble adult antigen was prepared by homogenised lyophilised worms in RPMI 1640 medium, centrifuged at 2,500 r p.m. for 30 min. The supernatant was sterilised by passing through a 0.45-μm filter and used as antigen. After 72 h of incubation at 37 °C, 2 μCi of ^{3}H-thymidine were introduced to each well; incubated for another 16 h, cells were collected, extracted and counted in a scintillation counter.

in normal mice. Small granulomas with few eosinophils were observed occasionally in the intestinal wall of the athymic mice.

Blood eosinophilia was studied in seven athymic and 10 normal mice before and after infection at weekly intervals. Tail blood smears were made at about 1400 and were stained by the Jenner–Giemsa method. A total of 300 leukocytes was examined per slide. Circulating eosinophils were observed in infected athymic mice (2–4%) although their levels were significantly lower ($P<0.001$) than those in infected heterozygotes (10–12%) after 7 weeks infection. Evidently the eosinophilpoeisis in athymic mice was not impaired. The role and specific function of eosinophils in the granuloma has not been established. According to Walls *et al.*[8] the destruction of liver tissue by eggs should stimulate the local eosinophil response. This apparently is not true in infected nude mice. The migration of tissue eosinophils to the affected sites seems to be dependent on T cells or other thymus factors which are absent in athymic mice. Eosinophils are known to ingest antibody–antigen complex. The complex may not be formed in nude mice because of the lack of the functional T cell required to produce anti-parasitic antibodies.

The lymphocyte responsiveness of athymic mice and heterozygotes to specific adult *S. mansoni* antigens and to nonspecific mitogens, phytohaemagglutinin (PHA) and *Salmonella typhimurium* lipopolysaccharide (LPS) was determined by measuring the incorporation of ^{3}H-thymidine into DNA. The blastogenesis of spleen cells of infected and non-infected athymic mice and heterozygotes is shown in Fig. 1. The B cells of both non-infected and infected nude mice, as well as the non-infected heterozygotes responded strongly to LPS, while the B-cell function of infected *nu*/+ mice was greatly depressed. T cells of non-infected and infected *nu*/+ mice reacted vigorously to PHA stimulation in contrast to those of nude mice. In the response to adult *S mansoni* antigen, infected *nu*/+ mice reacted strongly, whereas the nude mice (infected and non-infected) and control *nu*/+ mice spleen cells were not stimulated by the specific antigen. This evidence indicates that the lymphocyte responsiveness to *S. mansoni* is dependent on T cells or thymus factor.

Table 2 Titre of reaginic antibodies in sera of *nu*/*nu* and *nu*/+ mice infected with 100 *S. mansoni* cercariae determined by the PCA reactivity in rats or nude mice

	Time after infection							
	Day 49		Day 53		Day 58		Day 72	
Genotype	IgE	IgG$_1$	IgE	IgG$_1$	IgE	IgG$_1$	IgE	IgG$_1$
nu/+	40	40	10	20	40	30	10	40
nu/*nu*	0	0	0	0	0	0	0	0

The presence of IgE in pooled sera was measured by the PCA test in rats (adult male Sprague–Dawley) with a latent period of 24 h and in female nude mice with 72 h of sensitisation. The IgG$_1$ antibody was determined by PCA reactions in nude mice with a latency of 3 h. A sample of 0.05 ml of diluted sera was injected intradermally into each skin site. The antigens for intravenous challenge were soluble crude extracts from adult *S. mansoni* worms or eggs and were adjusted to 0.8 mg of protein per ml of solution. The volume was 1 ml per rat and 0.2 ml per mouse in mixing with equal amounts of 1% potamine sky blue dye solution. The size and bluing intensity of PCA reactions on the underside of skin were read 20–30 min after antigen challenge through the tail vein. The highest dilution of sera giving a reaction, 5 mm greater than normal serum control in at least half of PCA recipients, was regarded as the titre.

The relationship between functional T cells and reaginic antibodies (IgE and IgG$_1$) was studied in nude and *nu*/+ mice infected with 100 *S mansoni* cercariae. We found that T-cell deficient nude mice were unable to produce detectable levels of IgE and IgG$_1$ antibodies whereas the *nu*/+ mice produce both long term skin-sensitising IgE antibody and short term skin-sensitising IgG$_1$ antibody as early as 49 d after infection (Table 2). Both IgE and IgG$_1$ persisted in the blood for more than 10 weeks after infection. Evidently, the IgE and IgG$_1$ formation in response to *S. mansoni* antigens may require the participation of T cells. We have not observed significant quantitative differences in levels of both IgE and IgG$_1$ antibodies in *nu*/+ mice responding to soluble adult or egg antigen. Mota *et al.*[9] were unable to detect reaginic antibody in ICR mice infected with 150 *S mansoni* cercariae by passive cutaneous anaphylaxis (PCA) in mice. Our finding, however, confirms the recent report[10] that both IgE and IgG$_1$ were produced in CBA/J mice with chronic schistosomiasis. The lack of reaginic antibodies in nude mice may contribute to the absence of the local tissue eosinophil reaction[1].

Buchanan *et al.*[11] failed to induce egg granulomas in the liver and intestines of experimentally T-cell-depleted mice. Our study, however, has demonstrated that congenitally athymic mice can form granulomas around *S. mansoni* eggs. The lymphocytes in granulomas of athymic mice might be B-lymphocyte-related cells that respond to certain T-cell independent antigens. Therefore the egg granulomas may be mediated partly by B cells, if not solely by T cells This remains to be studied. We did not see giant cells in the granulomas of athymic mice, although it is not uncommon in normal mice The observation suggests the association of giant cell formation with thymus factor[12].

Growth of *Mycobacterium leprae* and *M. marinum* in congenitally athymic (nude) mice

THE failure to grow the leprosy bacillus, *Mycobacterium leprae*, *in vitro* means that there is a requirement for a highly susceptible experimental animal model. The only animal confirmed so far as naturally highly susceptible is the nine-banded armadillo, of which at least some specimens develop, after inoculation, a disseminated disease which resembles human lepromatous leprosy[1]. The inoculation of *M. leprae* into the footpads of mice results in a localised, self-limiting infection, with a maximum bacillary yield of about $10^{6\cdot5}$ organisms per footpad[2]. Suppression of the immune response of the mouse, by thymectomy and irradiation, results in enhancement of the footpad infection, and dissemination of *M. leprae* bacilli to internal organs and peripheral tissue such as ears, nose and tail[3]. This ability to enhance infection by nonspecific depression of T-cell function suggests that the congenitally athymic, or nude, mouse might provide a suitable, naturally susceptible host for *M. leprae*. In spite of the severe impairment of the cellular immune response of nude mice[4–7], the only report of the growth of *M. leprae* in such mice concluded that there was no significant increase in bacillary proliferation, and no tendency to promote a generalised infection[8]. This conclusion was based, however, on observations made only 6 months after inoculation—an interval that is almost certainly too short for detection of significant enhancement or dissemination.

To investigate further the growth of *M. leprae* in nude mice, we established a small breeding colony based on the mating of a closed, but not inbred group of mice. Heterozygous females (nu/+) were mated with homozygous males (nu/nu) to give a progeny half homozygous and half heterozygous. The homozygous mice were used as experimental (nude) mice, and the heterozygous, phenotypically normal littermates were used as controls.

In a preliminary experiment, *Mycobacterium marinum* was used as the infecting agent. Infection of mice with *M. marinum* and *M. leprae* is analogous[9]; growth of both organisms reaches a maximum of 10^6–10^7 bacilli per footpad, followed by killing of the organisms. But, the fact that *M. marinum* grows much more rapidly than *M. leprae* and is cultivable *in vitro* makes it a convenient model for the study of the *M. leprae* infection.

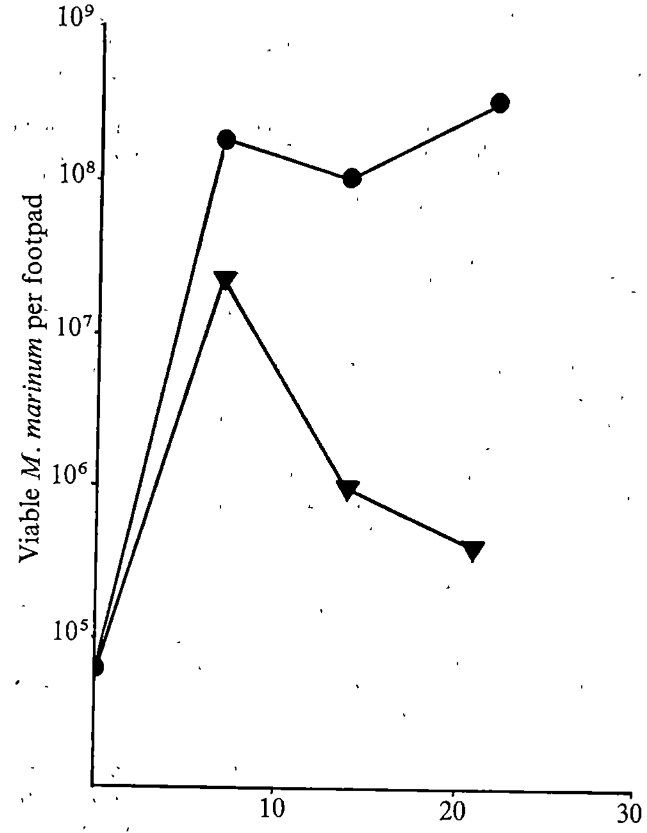

Fig. 1 Growth of *M. marinum* in the footpads of nude mice (●) and control mice (▼). Each sample represents the viable count of bacilli from the pooled tissue of three mice. Footpads were removed and homogenised in Middlebrook–Dubos medium, and viable counts made by the method of Miles and Misra[13].

Mice were inoculated with *M. marinum* in the left hind footpad and bacillary growth was monitored as shown in Fig. 1. *M. marinum* grew to a peak of $10^{7\cdot2}$ viable bacilli per footpad by 7 d in control mice, and this was followed by a rapid decline in viable numbers, falling to $10^{5\cdot4}$ at 21 d. In the nude mouse group, the number of organisms had reached $10^{8\cdot2}$ per footpad by 7 d, and although this was followed by a plateau, there was no decline in viable numbers.

At the same time that footpads were collected, liver, lungs, spleen and the contralateral footpads were also removed and examined for the presence of viable bacilli (Table 1). Viable organisms were detectable in the internal organs of nude mice at all collections, whereas at no stage of the infection were viable organisms recoverable from the internal organs of control mice.

To study the growth of *M. leprae* in nude mice, 30 nude and

21	4.0×10^5	—	—	—	—

Each sample represents the viable count of bacilli from the pooled tissue of three mice. Tissue was removed and homogenised in Middlebrook–Dubos medium, and viable counts were made by the method of Miles and Misra[13]. — Represents $< 10^3$ viable *M. marinum* per organ.

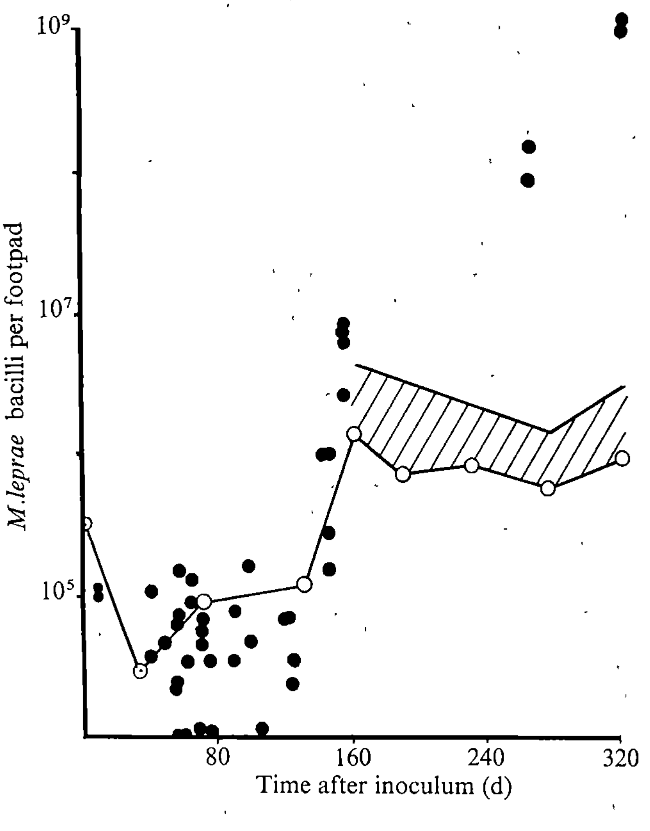
60 control mice were inoculated into both hind footpads, with bacilli from a biopsy specimen from an untreated lepromatous leprosy patient. The results are shown in Fig. 2. Because of the poor survival of nude mice, they were not killed for collection, but footpads were removed and bacillary counts were made at their natural death. Collection of *M. leprae* from mouse tissue, and counting of acid-fast bacilli were carried out as described before[10]. There was no evidence of an increase in bacillary numbers in any of the mice during the first 4 months after inoculation, but while growth in the control group reached a maximum at about 10^6 bacilli per footpad, counts in nude mice continued to rise. Enhancement of bacillary growth in the two longest surviving nude mice, collected at 266 and 322 d, was highly significant ($P \ll 0.01$), and was accompanied by clearly visible swelling of the footpads.

The longest surviving nude mouse was examined for the presence of acid-fast bacilli in ears, nose, testes, tail, forepaws, liver and spleen (Fig. 3). A few bacilli were detectable in the testes, nose, tail and forepaws, though in the testes, tail and forepaws, the numbers were only just above the level of detection and represent only one or two bacilli observed by the counting technique. Significant levels of bacilli were present in liver and spleen, however, with $10^{5.6}$ and $10^{5.3}$, respectively. The liver and spleen are also heavily infected with leprosy bacilli in the highly susceptible nine-banded armadillo[11]. No acid-fast bacilli were recoverable from the internal organs or peripheral tissue, other than the inoculation site, in control mice.

Confirmation of the identity of the *M. leprae* bacilli collected from nude mice was made by removal of acid fastness by pretreatment with pyridine[12], and by subinoculation into the footpads of normal mice—bacillary growth reached a maximum of 10^6 120 d after inoculation, conforming to the classical growth pattern of *M. leprae*.

Thus, in contrast to the findings of Prabhakaran *et al.*, whose observations were made over only 6 months, we found that inoculation of *M. leprae* into the footpads of nude mice resulted in a very significantly enhanced infection compared with immunologically normal mice; and the recovery of significant numbers of bacilli from the spleen and liver of the longest surviving nude mouse certainly suggests a tendency to promote a systemic *M. leprae* infection. If the problems of survival can be overcome, the nude mouse could prove to be of considerable value as a model for the study of lepromatous leprosy and as a means of detecting a small number of viable organisms against a large background of dead bacilli in the tissues of patients undergoing therapy.

Fig. 2 Growth of *M. leprae* in the footpads of nude mice. Each point on the control curve (⊙) represents the mean value of twelve mouse footpad counts, and the shaded area is the 95% upper confidence limit of the control group during the plateau phase. Nude mouse values (●) are the bacillary counts of individual footpads removed at autopsy.



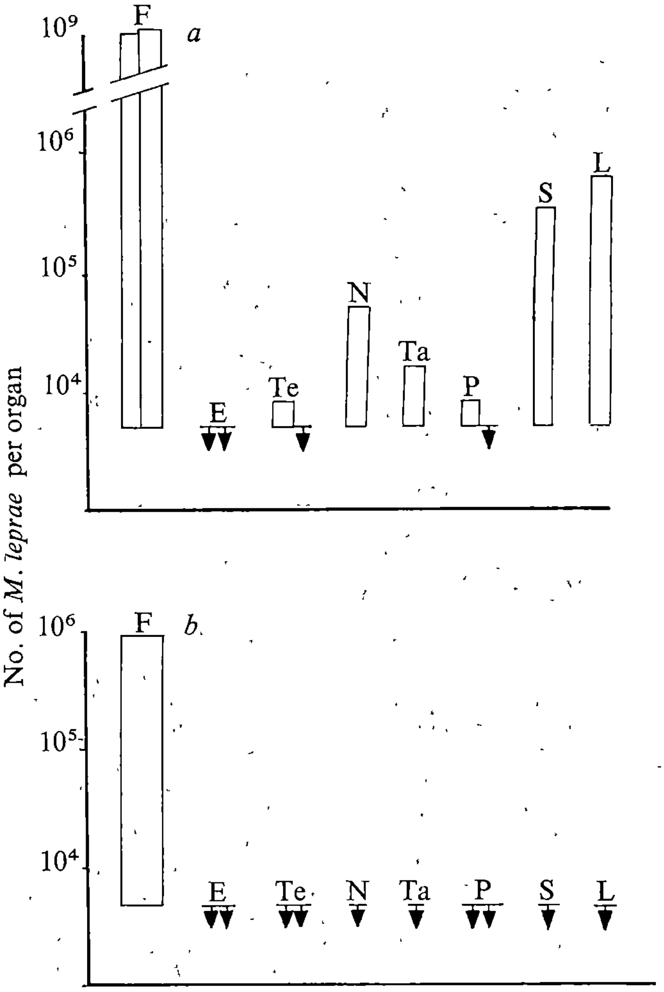


Fig. 3 The recovery of *M. leprae* from the internal organs and peripheral tissue of the longest surviving nude mouse, and from control mice (mean value of six mice), following footpad inoculation. All mice were sampled 322 days after inoculation. F: footpads; E: ears; Te: testes; N: nose; Ta: tail; P: forepaws; S: spleen; L: liver.

Control of lymphokine secretion by prostaglandins

SEVERAL lines of evidence exist implicating prostaglandins (PGs) as mediators in inflammation[1]. In type IV hypersensitivity (delayed hypersensitivity, cellular immunity) reactions, although there is evidence of PG involvement[2,3] lymphokines, the products of antigen-activated thymus-dependent lymphocytes, have received greater attention as potential mediators[4,5]. It has been reported that PGE$_1$ is a potent inhibitor of lymphocyte activation *in vitro*[6] and we have observed that guinea pig peritoneal exudate macrophages produce substantial amounts of E-type PG (ref. 7). It is well established that macrophages are capable of modifying lymphocyte activation[8,9], and that there is close association between these two cell types in reactions of cellular immunity *in vitro*[10] and *in vivo*[11]. We have now shown that production of E-type PGs by macrophages modifies the secretion of lymphokines by lymphocytes in response to antigen and that this may serve to provide a negative feedback mechanism for regulating the extent and duration of reactions of cellular immunity.

The *in vitro* test that shows the best quantitative correlation with delayed hypersensitivity reactions in the guinea pig is macrophage migration inhibition[4] and so we have used this test both for measurement of the reactivity of sensitised lymphocytes to antigen and for the direct measurement of lymphokine activity. Antigen-induced cell migration inhibition of sensitised cells was reduced by PGE$_1$ (0.1–1.0 μg ml^{-1}), although the inhibition of cell migration by preformed lymphokine was not affected by PGs of the E series (Table 1), suggesting that lymphokine formation rather than lymphokine action on target cells was inhibited by PGE compounds. Neither PGF$_{2\alpha}$ nor PGA$_1$, at these concentrations, influenced antigen-induced cell migration inhibition (Table 1). On the other hand, indomethacin (0.1 μg ml^{-1}), a potent prostaglandin synthase inhibitor[1], enhanced antigen-induced inhibition, but had no effect on lymphokine-induced inhibition (Table 1), implying that there is sufficient endogenous PG biosynthesis in these cultures to modify the response to antigen. These observations support the proposition that endogenous E-type PGs act by reducing the lymphokine secretion by antigen-activated lymphocytes, rather than by modifying the action of lymphokines on target cells.

Accordingly, we have measured lymphokine production by lymph node lymphocytes in response to specific antigen, in the presence and absence of E-type PGs and indomethacin. PGE$_1$ (0.1–1.0 μg ml^{-1}) and PGE$_2$ (0.1–1.0 μg ml^{-1}) produced dose-related inhibition of antigen-induced lymphokine secretion, measured in terms of migration inhibitory activity (Table 2). These results are in agreement with the direct effects of PGE compounds on antigen-induced migration inhibition. We have obtained similar results to those shown in Tables 1 and 2 for mitogenic lymphokine, in that antigen-induced stimulation of DNA synthesis in lymph node lymphocytes was inhibited by PGE$_1$ and PGE$_2$ (0.1 and 1.0 μg ml^{-1}) and that this action of E-type PGs was accompanied by reduced production of mitogenic lymphokine.

Table 2 Effect of prostaglandins E$_1$ and E$_2$ and indomethacin on lymphokine formation measured by guinea pig cell migration inhibition

Treatment (μg ml^{-1}) Inducing antigen	Drug	Response (% ± s.e.m.) PGE$_1$	PGE$_2$	Indomethacin
–	–	100±2.2	100±2.2	100±2.3

1,000	1.0	81.7±4.9	81.6±4.3	ND

Lymphocytes were obtained from the teased lymph nodes of BGG-sensitised animals. They were placed in culture tubes at 1×10^7 cells ml^{-1} in Eagle's MEM supplemented with 5% pooled normal guinea pig serum. BGG (1 mg ml^{-1}) with or without E-type PGs were added to test cultures and after 24 h incubation at 37 °C, culture supernatants were partially purified and tested for migration inhibitory activity. Results were expressed as percentage response of control ± s.e.m. Supernatants without added antigen or drugs were taken as controls.

–	100	1.0	76.5±4.1	73.1±2.8	ND	ND	ND

Cell migration inhibition was carried out as described previously[17]. Guinea pig peritoneal exudate cells in Eagle's MEM with 10% foetal calf serum were cultured at 4×10^6 cells per capillary tube in chambers with or without antigen, lymphokine or drugs. Cell migration was recorded after 40 h as area (mm^2) and then expressed as percentage inhibition of control (that is, with no addition) ± s.e.m. Purified protein derivative of tuberculin (PPD) was used as antigen (Ag) with tuberculin-sensitised animals (0.1 ml BCG intraperitoneally 4 weeks before use) and preformed lymphokine (LK) was generated from bovine gamma globulin (BGG) sensitive lymph node lymphocytes in culture with 1.0 mg ml^{-1} BGG. Lymphokine preparations were partially purified by ammonium sulphate precipitation as described previously[17].

Indomethacin (0.1 μg ml^{-1}) had only a slight enhancing effect on lymphokine secretion by lymph node lymphocytes (Table 2), whereas it clearly augmented antigen-induced inhibition of cell migration—a system which utilises mixed cell populations (that is, macrophages and polymorphonuclear (PMN) leukocytes, in addition to lymphocytes) (Table 1). These observations confirmed that the action of PGE was at the level of lymphokine secretion by lymphocytes, but implied that the source of endogenous E-type PGs was unlikely to be the lymphocytes themselves.

As a result of these findings, we have examined PG production by inflammatory cell populations (lymphocytes, macrophages and PMN leukocytes) during short term culture. Macrophage-rich cell populations (60–80% macrophages, 10–30% PMN leukocytes, 10% lymphocytes) produced substantial amounts of PGE-like activity (mean±s.e. = 11.6±2.1 ng PGE$_2$ per 10^6 cells per 24 h) whereas PMN leukocytes (80–90% leukocytes, 10–20% monocytes) and lymph node lymphocytes (>90% lymphocytes) were much less active in this respect (0.45±0.03 ng and 1.7±0.11 ng PGE$_2$ per 10^6

Table 3 *In vitro* prostaglandin production by guinea pig inflammatory cell populations stimulated by lymphokine or specific antigen

Antigen ($\mu g\ ml^{-1}$)	PGE_2 (ng per 10^6 cells per 24 h)	Lymphokine ($\mu g\ ml^{-1}$)	PGE_2 (ng per 10^6 cells per 24 h)

1.0	11.58±0.83	100.0	11.58±1.43
10.0	20.38±1.41	500.0	23.87±1.89
100.0	26.00±0.98		

*Mean ± s.e.m.

Sterile Falcon culture tubes containing 5×10^5 washed, macrophage-rich peritoneal exudate cells and increasing doses of specific antigen (PPD) or lymphokine were incubated at 37 °C for 24 h and the supernatants removed and stored at −20 °C before assay for PG activity by radioimmunoassay using sheep anti-PGE_2-BSA. Anti-PGE_2 antiserum cross reacted with PGE_2 (100%); PGE_1 (55%); $PGF_{2\alpha}$ (1.5%); 15-keto PGE_2 (1.2%); PGA_2 (0.6%); PGB_2 (0.2%).

cells per 24 h, respectively). Macrophage populations (>90% macrophages) enriched by selection of glass-adherent cells show a similar PG-synthesising capacity to that of unseparated exudate cell populations, further implying that the macrophage is the major cell type responsible for PG production.

Prostaglandin-like activity was mainly E-type, as detected by radioimmunoassay, had the properties of an acidic lipid on extraction into ethyl acetate and cochromatographed with authentic PGE_2 on thin-layer chromatography. The biological activity of the material on rat stomach strip, human Fallopian tube and ADP-induced platelet aggregation suggested that the bulk of the activity resembled PGE_2 rather than PGE_1, a conclusion consistent with the high proportion of arachidonic acid (the PG_2 precursor) in macrophage membrane phospholipids[12]. A dose-related increase in PGE production was induced by specific antigen using sensitised cells and by preformed lymphokine using non-sensitised cells (Table 3), thus satisfying an obligatory requirement of the negative feedback hypothesis. Furthermore, indomethacin at a concentration which completely inhibited PGE production (0.1 $\mu g\ ml^{-1}$) increased the formation of macrophage migration inhibitory lymphokine by antigen-stimulated peritoneal exudate cells from 19.7±2.1% inhibition (untreated cells) to 29.53±2.6% inhibition (treated cells), confirming that the level of PGE production is sufficient to modify lymphokine generation *in vitro*.

We have established here that E-type PGs inhibit lymphocyte activation and the secretion of lymphokines and that such preparations stimulate E-type PG production by macrophages. This is consistent with the proposition that E-type PG production in response to lymphokine stimulation provides a negative feedback mechanism for regulation of the cellular immune response. Inhibition of mediator secretion by PGs in allergic reactions is not restricted to type IV hypersensitivity reactions. Thus, PGE_1 and PGE_2 are both effective inhibitors of histamine secretion by human basophils in type I hypersensitivity[13] and antigen-induced SRS-A production by lung fragments[14]. Consistent with this phenomenon is the observation that low doses of indomethacin enhance SRS-A release from passively sensitised human lung[15]. In these situations, in contrast to the type IV response, the cellular origin of PG production has not been clearly established. In type III allergic reactions, although PGE_1 can inhibit the release of lysosomal enzymes from PMN leukocytes[16], the capacity of such cells to produce PGE seems to be insufficient for this effect to be of physiological relevance. The inability of therapeutic doses of non-steroidal anti-inflammatory drugs to affect markedly types I, III and IV hypersensitivity reactions *in vivo* implies that other control systems also operate in physiological, as opposed to pathological, circumstances.

The self-limiting mechanism that we propose for type IV reactions has the virtue of relating lymphokine, lysosomal enzyme and PG release to a common basis. This relationship may have interesting consequences, both for aetiology and pathogenesis in chronic inflammatory diseases[16], and in the design of anti-inflammatory drugs, by highlighting potential loci of action that have hitherto received little attention.

Phorbol esters stimulate DNA synthesis and ornithine decarboxylase activity in mouse epidermal cell cultures

TUMOUR-PROMOTING agents have been defined by their ability to promote tumour formation on carcinogen-initiated mouse skin. The most potent of these agents are the diesters of phorbol which are the active components of croton oil, the classic promoting substance. Phorbol esters can be chemically modified in a number of positions to form molecules with a wide range of promoter potency[1]. Such modifications have been useful in determining structure–function relationships[2]. A good correlation exists between the ability of phorbol esters to promote epidermal tumours and their ability to stimulate epidermal macromolecular synthesis *in vivo*[3,4]. In particular, all tumour promoters stimulate synthesis of epidermal DNA, although not all chemicals which induce hyperplasia are promoters[1]. Recently O'Brien *et al.*[5] suggested that the degree of induction of ornithine decarboxylase (ODC) activity in mouse skin after application of promoting and non-promoting compounds correlates well with their promoting potency. Evidence from our laboratory indicates that brief exposure to the potent phorbol ester 12-*O*-tetradecanoyl-phorbol-13-acetate (TPA), stimulates DNA synthesis and

ODC activity in mouse epidermal cell cultures (S.H.Y., T.B., E.P., D. Michael, K. Elgjo and H.H., to be published, and U.L. and S.H.Y., to be published). Using such a culture system, we have examined a series of phorbol esters to test the correlation of promoter potency *in vivo* with the stimulation of DNA synthesis and ODC activity *in vitro*.

Mouse epidermal cells were isolated and cultured as previously reported[6,7]. Phorbol esters were dissolved in DMSO as stock solutions of 1 mg ml^{-1} or 0.1 mg ml^{-1} and stored at −70 °C. Experimental media were prepared immediately before use In most experiments cells were exposed to the promoter for 1 h (except for phorbol which was kept continuously in medium), starting 20–24 h after plating. After removal of the promoter, cells were washed with phosphate-buffered saline and reincubated in complete medium (CM)[7], which was changed daily for the assay of DNA synthesis.

The dose–response curve for stimulation of DNA synthesis in cells treated with the relatively strong promoter 12-*O*-hexadecanoylphorbol-13-acetate (HPA) is shown in Fig. 1*a*. At all doses tested there was an initial inhibition of DNA synthesis at 24 h after the 1-h pulse treatment, followed by a return to near-normal or elevated levels by 2 d. The highest dose (1 μg ml^{-1}) tested gave the largest initial inhibition. By day 3 after treatment, effective doses produced a dose-dependent stimulation with a maximum usually occurring on day 4. Cells responded to doses as low as 0.05 μg ml^{-1} (8×10^{-8} M). Exposure to more than 0.5 μg ml^{-1} seemed to reduce the ultimate stimulation, perhaps because of increased initial toxicity. These results, however, were collected from experiments carried out on separate cell isolates (solid lines and dashed lines), making absolute dose–response comparisons across experiments difficult to interpret accurately. Similar studies using TPA as promoter[14] demonstrated a dose-dependent stimulation of DNA synthesis at doses between 10^{-5} and 10^{-9} M.

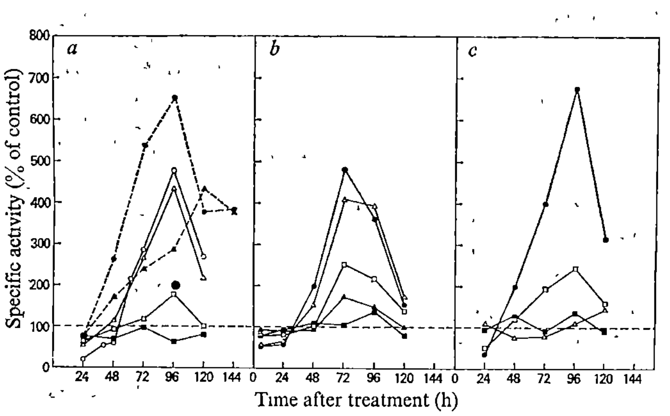

Fig. 1 Promoter-stimulated DNA synthesis. Epidermal cells were seeded at 7.5×10^6 cells per dish into 100-mm culture dishes. Twenty-four hours after plating, cultures were exposed to medium containing phorbol esters or vehicle (DMSO 0.1%) for 1 h, washed, reset with growth medium and changed daily. Concentration of the phorbol esters are given in μg per ml of culture medium. In the case of phorbol treatment (*c*), the experimental medium remained continuously, with a fresh solution prepared daily. At indicated intervals after treatment, dishes were pulsed with 1 μCi ml^{-1} methyl-^{3}H-thymidine (6 Ci mmol^{-1}, Schwarz–Mann, Orangeburg, New York) for 1 h. Labelled cells were washed three times with cold phosphate-buffered saline containing 0.1% unlabelled thymidine, scraped from the dishes, centrifuged and the pellets frozen. Pellets were washed three times with 0.2 N PCA and hydrolysed in 0.5 N PCA at 90 °C for 20 min. The DNA content of each hydrolysate was determined by the diphenylamine reaction[10] and radioactivity by counting an aliquot in Hydromix (Yorktown Research, New Hyde Park, New York) in a Beckman LS 250 scintillation counter. Results are expressed as the specific activity (c.p.m. per μg DNA) of the treated groups relative to the DMSO control. All data represent the average of at least duplicate dishes. The variation in control values for each point within experiments was less than 20%. *a*, Data collected on different primary cell isolates represented by – – –, HPA 0.5 (●) and 0.05 (▲) μg ml^{-1}; ——, HPA 1.0 (○), 0.1 (△), 0.01 (□) and 0.001 (■) μg ml^{-1}. The time course and maximum stimulation of DNA synthesis varies somewhat for different primary cell populations. *b*: ●, TPA 0.1 μg ml^{-1}; △, PDBe 1.0; ▲, PDBe 0.1; □, PDBu 1.0; ■, PDBu 0.1. *c*: ●, TPA 0.1 μg ml^{-1}; □, MeTPA 1.0; ■, MeTPA 0.1; △, phorbol 1.0.

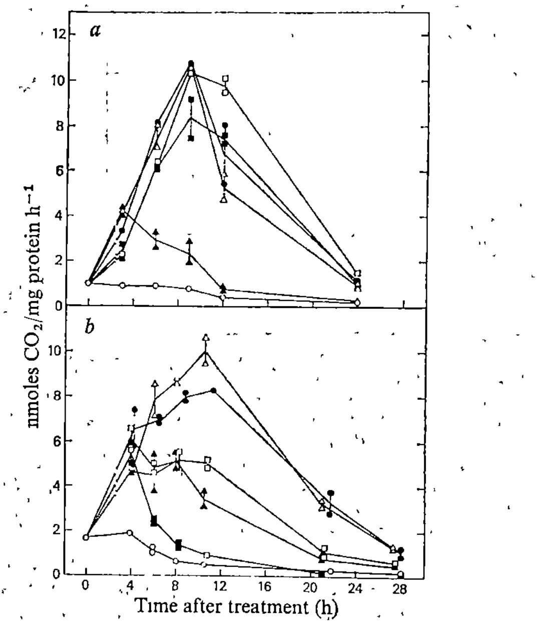

Fig. 2 Epidermal ornithine decarboxylase activity after 1-h treatment with phorbol esters. Cells were plated at 3×10^6 cells per 60-mm culture dish and treated at 21 h (*a*) and 23 h (*b*). *a*: ●, TPA 0 1 μg ml^{-1}; □, HPA 1.0; ■, HPA 0.1; △, PDBu 1.0; ▲, PDBu 0.1, ○, DMSO. *b*: ●, TPA 0.1 μg ml^{-1}; □, MeTPA 1.0; ■, MeTPA 0.1; △, PDBe 1.0; ▲, PDBe 0.1; ○, phorbol 1.0. At indicated times after the start of the treatment, duplicate dishes were washed with PBS and stored frozen until assayed. Cells were scraped from dishes and suspended in 300 μl PBS. ODC was measured on 50-μl aliquots of the cell lysate in a final volume of 100 μl containing 0.25 μmol dithiothreitol, 0.1 μmol EDTA, 0.01 μmol pyridoxal phosphate, 5.0 μmol sodium phosphate, *p*H 7.2 and 0.1 μCi L-1-^{14}C-ornithine (2.3 mCi mmol^{-1}, diluted from DL-1-^{14}C-ornithine HCl, New England Nuclear, Boston, Massachusetts, 54 mCi mmol^{-1}, with non-radioactive L-ornithine). The incubation was carried our for 1 h at 37 °C in 17 × 100-mm Falcon culture tubes capped with serum stoppers equipped with polypropylene centre wells (Kontes Glass Co., Vineland, New Jersey) containing a filter paper wick. The reaction was stopped with 0.2 ml 2 N perchloric acid and $^{14}CO_2$ was trapped by 0.2 ml NCS (Amersham/Searle Corp., Arlington Heights, Illinois) in the centre well during an additional 1-h incubation. The centre well and its content was counted in 10 ml Spectrafluor (Amersham/Searle) in toluene. Counts were corrected for blanks that contained all components except the cell lysate. Protein was measured on 50-μl aliquots of the cell lysate by the method of Lowry as detailed by Layne[11]. Each point on the graph represents the average of duplicate determinations of specific enzyme activity on cells from a single culture dish (variation <10%). In *b* the DMSO control and phorbol-treated culture values are superimposed.

When the less potent tumour-promoting phorbol esters, phorbol dibenzoate (PDBe) and phorbol dibutyrate (PDBu), are compared with TPA for ability to stimulate DNA synthesis (Fig. 1*b*), one finds that at approximately equimolar doses, PDBe and PDBu are much less effective than TPA At 0.1 μg ml^{-1} PDBu induces no stimulation, whereas PDBe stimulates only slightly. At doses 10 times higher than TPA, the stimulation with PDBe is equivalent to TPA, whereas that with PDBu is less than half of that found with TPA. Phorbol itself, a non-promoter for mouse skin, failed to stimuate even at a dose of 1 μg ml^{-1} (Fig. 1*c*). But 4-*O*-tetradecanoylphorbol-13-acetate (MeTPA), also reported to be a non-promoter for skin carcinogenesis[8], induced an initial inhibition followed by a twofold stimulation of DNA

Table 1 Correlation between potency of phorbol esters for promoting skin tumours and their ability to stimulate DNA synthesis and induce ODC activity in epidermal cells *in vitro*

Phorbol ester	Molecular weight	Tumour-promoting potency (1/TD$_{50}$)*	Maximum stimulation of DNA synthesis *in vitro*† 0.1 μg ml^{-1}	1 μg ml^{-1}	Maximum induction of ODC *in vitro*† 0.1 μg ml^{-1}	1.0 μg ml^{-1}

*TD$_{50}$ = total dose (μmol) of promoter required to produce papillomas on 50% of CD-1 mice previously initiated with 51 μg 7,12-dimethylbenz(*a*)anthracene. Data for TPA, HPA, PDBe, PDA and phorbol derived from ref. 12; data for PDBu derived from ref. 13; data for MeTPA from ref. 8 and mouse strain was not identified.

†Maximum stimulation did not always occur at same time after treatment.

‡DNA synthesis after HPA and TPA was not studied simultaneously in the same cell prepartions. Since variations in absolute responses occur in different cell preparations (see Fig. 1*b* and *c*), direct comparisons between HPA and TPA cannot confidently be made. Based on experience with a number of separate experiments, TPA induces 20–30% more stimulation than HPA at approximately equimolar doses.

§Data available only for 20% tumour incidence in CD-1 mice (see ref. 9).

¶Phorbol-13,20-diacetate calculated from data reported in ref. 14 and unpublished work of S.H.Y., T.B., E.P., D. Michael, K. Elgjo and H.H.

Tumour-promoting potency was assigned as indicated from appropriate literature citation. Capacity to stimulate DNA synthesis and induce ODC activity was measured using data in Figs 1 and 2, or as otherwise noted. Comparisons were made only with data from experiments performed on the same primary cell isolate. For both indices the maximum level of stimulation induced by TPA after subtraction of vehicle control levels, was assigned a value of 1.00. Other compounds are presented as the ratio of their net values (maximum stimulation minus vehicle control) to that of TPA. Repeated experiments indicate that the absolute ratios presented would vary from experiment to experiment, but the relative rankings would be constant.

synthesis at a dose of 1 μg ml^{-1} (Fig. 1*c*). At 0.1 μg ml^{-1} it was ineffective. This compound has also been reported to inhibit replicative and repair DNA synthesis in human fibroblast cultures at doses greater than 1 μg ml^{-1} (ref. 8).

Induction of ornithine decarboxylase activity has been proposed as a marker for promoter activity *in vivo*[5] and *in vitro* (our unpublished work). The results in Fig. 2 demonstrate the relative effectiveness with which a series of phorbol esters induce ODC in epidermal cells *in vitro*. At a dose of 0.1 μg ml^{-1}, TPA induces a 5–10-fold rise in activity within 6–12 h of exposure, with a return to near-normal values by 24–28 h. The time course and maximum level of stimulated enzyme activity varies somewhat for different primary cell populations. As seen for stimulation of DNA synthesis, HPA (1 μg ml^{-1} and 0.1 μg ml^{-1}), PDBu (1 μg ml^{-1}) and PDBe (1 μg ml^{-1}) induced a similar rise in ODC activity, whereas PDBu (0.1 μg ml^{-1}), PDBe (0.1 μg ml^{-1}) and MeTPA (1 μg ml^{-1}) were less effective as inducers. Phorbol (1 μg ml^{-1}), phorbol-13,20-diacetate (1 μg ml^{-1}, not shown) and the DMSO vehicle were completely ineffective in inducing ODC. The lower dose of MeTPA (0.1 μg ml^{-1}) caused a transient early rise in activity which returned to control values by 8 h. The accelerated kinetics of induction and decay seen with 0.1 μg ml^{-1} MeTPA and PDBu were at doses which failed to stimulate DNA synthesis; the significance of this observation remains to be determined.

These results indicate that there is a good correlation between the potency of phorbol esters for promoting skin tumours *in vivo* and their ability to stimulate DNA synthesis and induce ODC activity in epidermal cells *in vitro* (Table 1). The molecular weights of all compounds other than HPA and MeTPA are lower than that of TPA. Therefore the molar concentrations at which they were tested exceeded the TPA concentration. Only HPA seems to approach the effectiveness of TPA in stimulating both DNA synthesis and ODC activity at the same molar concentration. For MeTPA, results *in vitro* suggest that it has biological activity and should be retested as a promoter *in vivo*, preferably on mice sensitive to formation of skin tumours[9], before it is accepted as a negative control for TPA. Although promoter and non-promoter compounds outside the phorbol family must be tested before more general conclusions are reached, mouse epidermal cell cultures seem to be a useful system for identifying and appraising potential promoting agents. Additionally, the similarity between *in vivo* and *in vitro* results indicates that this model should be useful for investigating the cellular mechanisms of promoter action and for studying two-stage carcinogenesis *in vitro*.

Intracellular messenger role of cyclic GMP in exocrine pancreas

THE response of cells to hormones and neurotransmitters is mediated by chemical regulators, of which calcium, adenosine cyclic 3′,5′-monophosphate (cyclic AMP) and guanosine cyclic 3′,5′-monophosphate (cyclic GMP) are considered to be of primary importance. The endogenous occurrence of

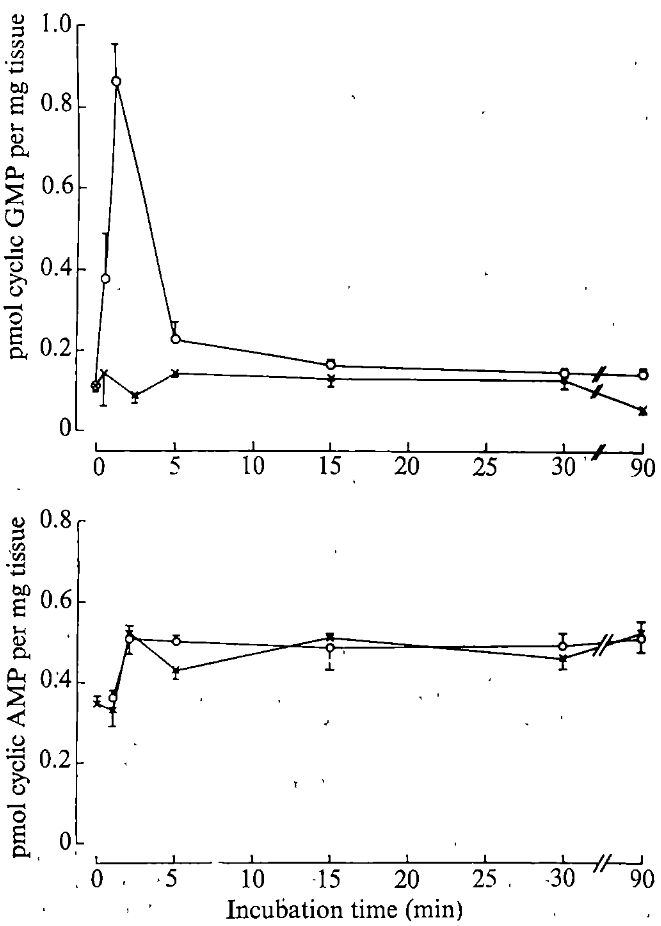

Fig. 1 Time course of cyclic GMP and cyclic AMP levels in isolated guinea pig pancreatic slices produced by CCK (1 U ml^{-1}; GIH preparation). Pooled pancreatic slices were initially incubated for 15 min. Three or four slices of total weight between 80–110 mg were then incubated in individual Erhlenmeyer flasks containing 2 ml of Krebs–Ringer bicarbonate buffer with 0.5% bovine serum albumin. Each flask was gassed with 95% O_2–5% CO_2. After preincubation for 15 min, CCK was added to the flask. On completion of incubation the slices were removed and frozen in an aluminium clamp precooled in liquid nitrogen. The frozen tissue was dropped into 0.5 ml of 6 mM theophylline at 100 °C and boiled for 10 min. The denatured tissue slices were homogenised fully. The homogenate was stored overnight at −20 °C, after addition of 0.5 ml of acid ethanol (1% HCl in absolute ethanol). The samples were centrifuged at 1,500g for 5 min and the supernatants were decanted. Each precipitate was washed with 0.5 ml of acid alcohol and, after respinning, the corresponding supernatants were pooled. The extracts were taken to dryness at 50 °C and the dried residue was resuspended in 0.5 ml of 50 mM Tris-HCl buffer, pH 7.4. Samples of 50 µl were used for measuring cyclic GMP and cyclic AMP. Cyclic AMP was measured by a binding protein method[6,7]. Cyclic GMP values were determined using a rabbit antiserum (HO/2/75) raised to succinylated cyclic GMP conjugated to human serum albumin[8]. A sample of 100 µl of antiserum diluted 1:1,000 in Tris buffer (50 mM, pH 7.4), 50 µl of tritiated cyclic GMP, specific activity 21 Ci mmol^{-1}, containing 3 nCi of ^{3}H-cyclic GMP, and 50 µl of cyclic GMP standards (0–3 pmol), or unknown samples, were incubated at 4 °C for 12 h. Free and antibody-bound ^{3}H-cyclic GMP were separated by filtration through a 0.45-µm Millipore filter. Filters were then extracted in a toluene–methoxyethanol-based scintillant, and the antibody-bound ^{3}H-cyclic GMP was measured in a liquid scintillation spectrometer. Cyclic AMP in a concentration of 1 pmol ml^{-1} showed a cross reaction in the assay of less than 0.2%, and other cyclic nucleotides less than 0.01%. Nucleotides, and nucleotide monophosphates, diphosphates and triphosphates, showed virtually no cross reaction up to a concentration of 10^4 pmol ml^{-1}. Dilutions of pancreatic cyclic GMP showed parallelism with dilutions of standard cyclic GMP. As a further check that the immunoreactive material was identical with cyclic GMP, control pancreatic slices and slices stimulated with acetylcholine were extracted using the standard trichloroacetic acid procedure. The extracts were then divided and one portion of each was treated with 50 µl of beef heart cyclic nucleotide phosphodiesterase (Sigma), at a concentration of 1 mg ml^{-1}, for 60 min at 37 °C and then boiled for 4 min. Standard cyclic GMP was treated similarly. The immunoreactive cyclic GMP in the control and stimulated samples were destroyed to the same extent as the standard cyclic GMP. Each experimental point represents the mean of three incubations. The tissue cyclic nucleotide content of each incubation sample was measured in triplicate The cyclic nucleotide values are calculated as pmol of cyclic nucleotide per mg wet weight pancreatic tissue. The vertical bars indicate 1 s.e.m. a, Cyclic GMP levels; b, cyclic GMP levels; × control; ○, CCK (1 U ml^{-1}).

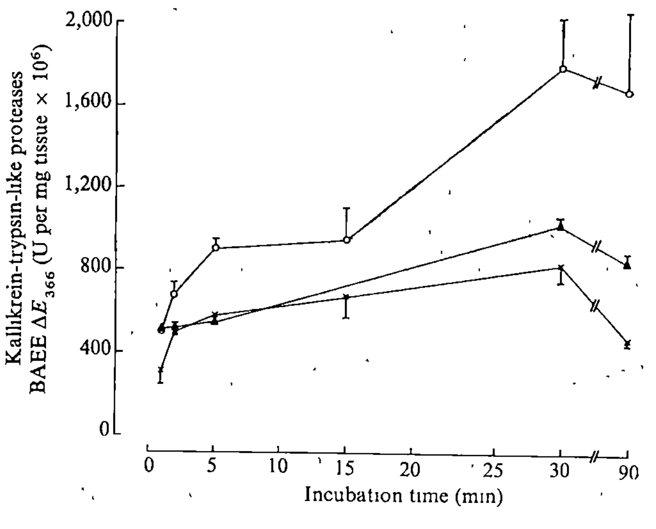
cyclic GMP was discovered more than 10 yr ago, but until recently its formation has been reported chiefly in association with the activation of cholinergic muscarinic receptors[1,2]. The description in the pancreas of a cyclic GMP-dependent protein kinase[3], a cyclic GMP phosphodiesterase[4], and the ability *in vivo* of cholecystokinin to increase cyclic GMP levels[5], suggested a physiological role for cyclic GMP in the mediation of hormone action. We report here experiments on isolated guinea pig pancreatic slices, in which the hormone cholecystokinin (CCK) and the neurotransmitter acetylcholine (ACh) both produced a marked, transient increase in the tissue level of cyclic GMP, which preceded the release of secretory enzymes. Exposure of the isolated pancreatic slices to the hormone secretin evoked a more prolonged increase in cyclic AMP, without any significant effect on cyclic GMP.

CCK (GIH Research Unit, Karolinska Institute), highly purified CCK (given by Professor Viktor Mutt), and the synthetic C-terminal octapeptide of CCK (given by Dr Miguel Ondetti, Squibb Institute), all produced within seconds a rapid increase in cyclic GMP that reached peak values at 2 min and fell rapidly to near the control level by 5 min (Fig. 1). The increase in cyclic GMP preceded any significant acceleration in the release of zymogens (Fig. 2). ACh evoked a pattern of increase in cyclic GMP that was similar to that obtained with CCK with regard to time course and relationship to onset of enzyme release. The increase in cyclic GMP triggered by ACh (10^{-7}–10^{-3} M) and CCK (5×10^{-8}–1×10^{-7} M) was dose related. Atropine abolished the ACh-mediated zymogen release and increase

Fig. 2 Stimulation of enzyme secretion from isolated guinea pig pancreatic slices by CCK. Tissue was incubated as described for Fig. 1. The esterase activity of the kallikrein-trypsin-like proteases released into the medium was determined by hydrolysis of the synthetic substrate, benzoyl-l-arginine-ethyl ester (BAEE), after activation of the proenzymes by enterokinase. A sample 0.5 ml of enzyme solution was incubated with 0.1 ml enterokinase (50 µg) for 10 min at 37 °C before assay. The accumulated proenzyme activity is expressed as BAEE ΔE_{386} U per mg wet weight tissue, with 1 U equivalent to an absorbance change recorded as absorbance units per min per ml of enzyme solution × 10^6. Vertical bars indicate 1 s.e.m. ×, Control; ○, CCK (GIH, 1 U ml^{-1}); ▲, secretin (GIH, 1 U ml^{-1}).

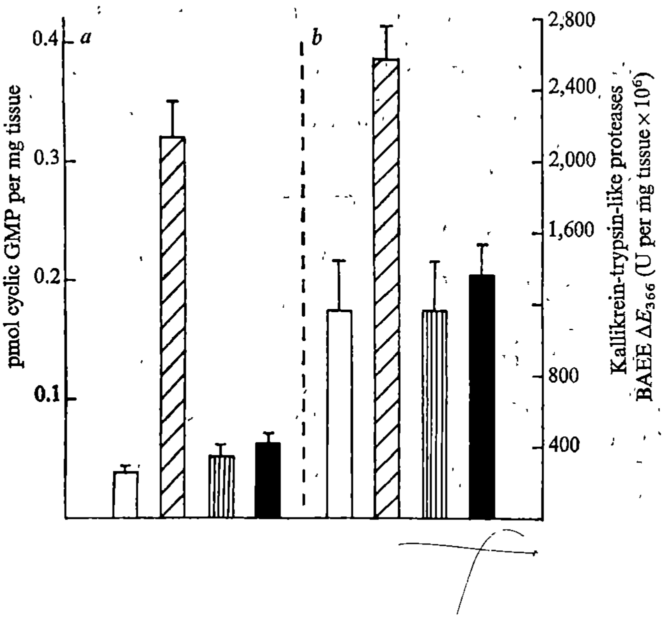


in the tissue level of cyclic GMP (Fig. 3), but did not affect the CCK response. Both ACh and CCK failed to alter significantly the basal cyclic AMP values in actively secreting pancreatic slices. In the presence of the phosphodiesterase inhibitors, theophylline (3 mM) and 3-isobutyl-1-methylxanthine (IBMX, 0.5 mM), basal levels of cyclic AMP were increased about fivefold, but no further increase was observed with CCK. In contrast, the basal levels of cyclic GMP were increased to a lesser extent (about twofold) by theophylline and IBMX and the increase in cyclic GMP caused by CCK was potentiated. In three separate experiments, the synthetic analogue 8-bromo cyclic GMP (1 mM) increased enzyme secretion over control values by 27.5% ($P<0.025$) in pancreatic slices incubated for 30 min.

Secretin, in the presence of trasylol (260 U ml^{-1}), produced a rapid increase in cyclic AMP that reached a maximum at 1 min but remained elevated for at least 30 min and returned to basal values at 90 min (Fig. 4). Secretin did not significantly alter cyclic GMP levels, even in the presence of theophylline (3 mM) and trasylol (260 U ml^{-1}).

Enzyme secretion from pancreatic exocrine acinar cells is stimulated by CCK and the vagus nerve (ACh). Activation by CCK and ACh of specific receptors on the plasma membrane of acinar cells results in a rapid, marked, but transient increase in cyclic GMP. This may trigger the intracellular mobilisation of ionised calcium, which is considered to initiate the release of zymogens from acinar cells. Alternatively, it is possible that the increase in cyclic GMP results from, rather than precedes, the changes in intracellular calcium. The difference in the time courses of cyclic GMP and the accumulated enzyme secretion may be explained by the fact that the transient increase in cyclic GMP, through activation of a cyclic GMP-dependent protein kinase[3], may trigger intracellular release of ionised calcium which then stimulates the enzyme secretion; this response once initiated may be maintained by regenerative release of calcium or by some other molecular mechanism. The secretion of electrolytes and water that accompanies enzyme release is primarily controlled by the hormone secretin. The interaction of secretin with cell receptors activates adenylate cyclase[10], resulting in increased formation of cyclic AMP. The sequential molecular events through which cyclic nucleotides stimulate enzyme and electrolyte secretion are still obscure. Our results strongly suggest that in the exocrine pancreas each of the two major physiological functions is modulated by a specific cyclic nucleotide, enzyme secretion by cyclic GMP, and fluid and ion secretion by cyclic AMP. Dysfunction of the molecular mechanisms involved in the turnover of the two messengers may be of considerable importance in the aetiology of pancreatic disease.

Fig. 3 Histogram of the effect of atropine on the increase in cyclic GMP and enzyme secretion evoked by acetylcholine. Isolated pancreatic slices were incubated in Ehrlenmeyer flasks as described in Fig. 1. Atropine (10^{-6} M) was added to the appropriate Krebs–Ringer buffer solution at the beginning of the 15 min of preincubation. Open columns, control; diagonally hatched columns, acetylcholine (10^{-6} M); vertically hatched columns, atropine (10^{-6} M); closed columns, atropine (10^{-6} M) + acetylcholine (10^{-6} M). The vertical bars represent 1 s.e.m. *a*, Cyclic GMP content of pancreatic slices after 1 min of incubation with drug, expressed as pmol per mg wet weight tissue. *b*, Accumulated release of kallikrein-trypsin zymogens after 30 min into the incubation medium, expressed as BAEE ΔE_{366} units per mg wet weight of tissue, 1 U being equivalent to an absorbance change recorded as absorbance units per min per ml of enzyme solution × 10^6.



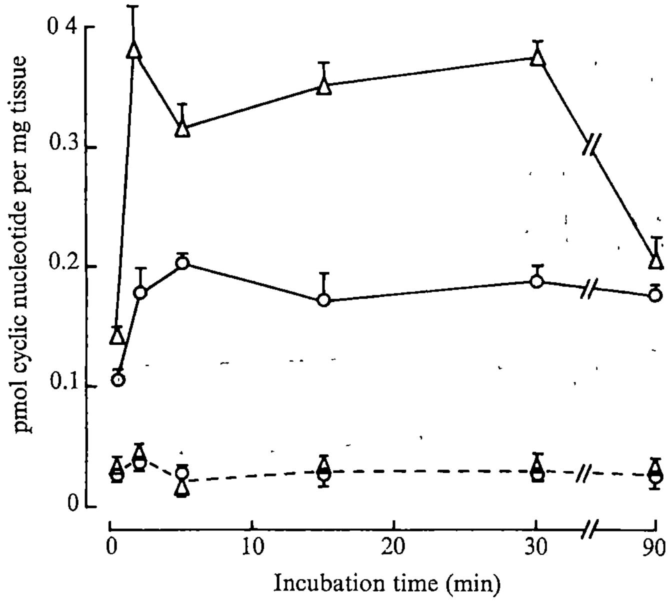


Fig. 4 Time course of cyclic AMP and cyclic GMP formation in guinea pig pancreatic slices after addition of secretin. Tissue incubation and cyclic nucleotide measurement were as described in Fig. 1, except that the Krebs–Ringer buffer solution contained trasylol (260 U ml^{-1}). Levels of cyclic nucleotides are expressed as pmol per mg wet weight. The vertical bars represent 1 s.e.m. ○, Control; △, secretin (1 U ml^{-1}); ——, cyclic AMP; - - -, cyclic GMP.

Role of oestrogen receptor in androgen-induced sexual differentiation of the brain

THE sexual differentiation of gonadotropin secretion[1] and female sexual behaviour[2] occurs in the rat hypothalamus[5] during the early postnatal period and is produced by testicular androgen in the male, although it may be mimicked in the female by administration of oestrogen or androgen[3]. The mechanism of this neural differentiation probably involves the aromatisation of testicular androgen to oestrogen in the hypothalamus[4], followed by a complex series of biochemical events contingent on the binding of this oestrogen to a receptor and the translocation of the steroid–receptor complex to the nucleus. Cytosol oestrogen receptors[6–8] and aromatising enzymes[4] have been demonstrated in the neonatal brain; aromatising enzymes are localised to the differentiating areas[4] whereas oestrogen receptors are found throughout the forebrain[6,7]. In the study reported here, we have measured the nuclear oestrogen receptor in the neonatal brain using a nuclear exchange assay[9] and have found that its distribution is consistent with the postulated role of the oestrogen receptor in the sexual differentiation of the brain.

Two regions of the 4-d-old brain were used, one containing the ventral half (HYP) and the other the dorsal half (CORT) of all brain between two coronal cuts, one immediately rostral to the optic chiasma and the other immediately caudal to the mammillary bodies.

Figure 1 shows the exchange of ^{3}H-oestradiol in purified nuclei prepared from the HYP region of neonatal males. Saturable, diethylstilboestrol (DES)-suppressible, exchanged ^{3}H-oestradiol was found in nuclei from the neonatal male HYP region with a K_d of 3.4×10^{-10} M, a value typical of oestrogen receptors[13] and close to the K_d for oestradiol of the cytosol oestrogen receptor from neonatal rat brain[6].

Table 1 shows that 2.4×10^9 sites per mg of DNA were found in the neonatal HYP region, but none in the male CORT region or either region of the female brain. To test the hypothesis that the steroid responsible for the nuclear translocation of the oestrogen receptor in the male hypothalamus was secreted by the testis, nuclear sites were assayed in male rats 24 h after castration on day 3. No sites were detectable in either brain region of these animals. We then measured nuclear oestrogen receptor in females injected systemically with 50 μg of testosterone. This gave an identical distribution of nuclear receptor to that seen in the neonatal male but with about three times the number of sites found in the male HYP region (Table 1).

Thus nuclear oestrogen receptor sites appear solely in the HYP region under the influence of the testis or exogenous testosterone and this is consistent with their organising effect on the neonatal hypothalamus being exerted through the oestrogen receptor. These findings substantiate our previous study in which nuclear binding was measured after injection of radioactive steroid[14]. The low affinity of testosterone for the neonatal brain oestrogen receptor[6] and various studies on aromatisation in the neonatal brain[4,15] suggest that obligatory aromatisation precedes the binding of testosterone to the oestrogen receptor.

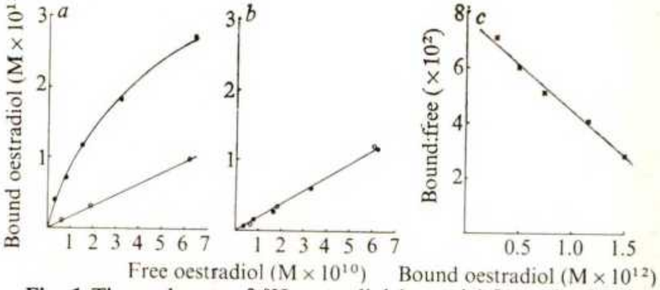

Fig. 1 The exchange of ^{3}H-oestradiol in nuclei from the HYP region (*a*) and CORT region (*b*) of 4-d-old male rats. Purified nuclei were prepared by the method of Plapinger and McEwen[12] and samples (about 200 μg of DNA), suspended in 0.4 ml buffer (1 mM phosphate, 0.32 M sucrose, 3 mM $MgCl_2$, *p*H 6.5) were incubated with various concentrations of ^{3}H-oestradiol (95 Ci mmol^{-1}) for 1 h at 37 °C as described by Anderson *et al.*[9]. A separate series of tubes was incubated in the presence of a 200-fold molar excess of DES for the determination of nonspecifically bound ^{3}H-oestradiol. After incubation, the nuclei were washed four times by sedimentation (800*g* for 10 min) and resuspension for 25 min at 0°–2 °C in 1 ml of fresh buffer. Radioactivity in the washed nuclei was measured, with an efficiency of 50%, after overnight extraction into 10 ml of scintillant (PPO 4 g l^{-1}; POPOP, 0.1 g l^{-1} in toluene). Specific binding was determined by subtraction of nonspecifically bound ^{3}H-oestradiol (○) from total bound ^{3}H-oestradiol (●) and plotted according to Scatchard[10] (*c*, male HYP region only), to give the dissociation constant (K_d) and number of specific binding sites (N_s). Samples of nuclei were analysed for DNA by the method of Burton[11].

After intracerebral injection of 0.27 μg of DES, nuclear oestrogen receptor was found in similar amounts in the HYP and CORT regions of both male and female brain (Table 1). The number of sites was four to five times that in the male HYP region and we find this is the maximum number of sites obtainable by intracerebral injection of DES. The distribution of nuclear oestrogen receptor after intracerebral injection of DES is identical to that of the cytosol receptor in the untreated animal, that is, it is found throughout the forebrain[6,7]. This is in marked contrast to the distribution of nuclear receptor after testosterone injection which mirrors the localisation of the aromatase enzymes, that is, nuclear receptor is found only in the HYP region. Thus there seems to be no inherent difference between the HYP and CORT receptors except in their proximity to aromatising enzymes. Cortical receptors are translocated to the nucleus when exposed to oestrogen and so may be important in some undefined aspect of brain development occurring when oestrogen levels are high, for example, prenatally or around day 10 of life in the female[16].

It is probable, from the lack of nuclear oestrogen receptor in the CORT region of the untreated male and both regions of

Table 1 Distribution and dissociation constant of nuclear-bound oestrogen receptor in purified nuclei from brain of untreated and steroid-injected 4-d-old rats

*Undetectable.

the untreated female and castrate male, that no receptor has been translocated by circulating oestrogen. This is consistent with there being very little oestrogen circulating in the 4-d animal[16], and any oestrogen present being sequestered by low affinity binding proteins of the blood and brain[17]. We believe that measurement of the nuclear receptor is likely to show where a steroid is acting, in contrast to the measurement of the cytosol receptor which merely shows where a steroid has the potential to act. In addition, we show that target tissue metabolism of a steroid may restrict nuclear translocation to a subset within a population of receptors, thereby restricting the action of the steroid to a few cells of a target organ though many may contain the receptor; this may be of relevance to other steroid sensitive tissues.

In conclusion, the distribution of the nuclear oestrogen receptor contrasts markedly with that of the cytosol receptor in the neonatal brain and is entirely consistent with the postulated roles of the oestrogen receptor and aromatisation in the androgen-induced sexual differentiation of the brain.

2-Amino-4-phosphonobutyric acid as a glutamate antagonist on locust muscle

THE characterisation of glutamate receptors in nerve and muscle membranes requires compounds which interact specifically with these receptors. In the vertebrate central nervous system various substances are reported to act as agonists or antagonists of glutamate (reviewed in refs 1 and 2). At the locust and crustacean nerve–muscle junctions, where the receptors are readily accessible for biochemical and pharmacological characterisation, comparatively few compounds activate the glutamate-sensitive receptors or antagonise the excitatory action of glutamate[3–9] and so such substances are needed. We report here that the glutamate analogue, DL-2-amino-4-phosphonobuytyric acid (DL-APB) (Fig. 1), inhibits the binding of glutamate to 'receptor-like' hydrophobic proteolipids isolated from locust muscle[10,11] and antagonises the excitatory action of glutamate applied iontophoretically to receptors present in the locust muscle membrane. The shape and charge distribution of DL-APB are appropriate for interaction with glutamate receptors[2,7,12].

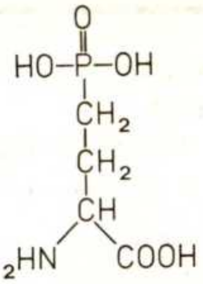

Fig. 1 2-Amino-4-phosphonobutyric acid.

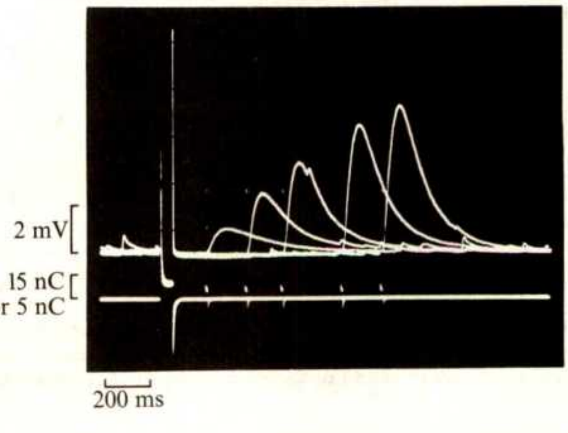
Proteolipids were extracted from approximately 2 g of the total intrathoracic muscle of locusts (*Schistocerca gregaria*)[10]. U-^{14}C-L-glutamate (Amersham) was added to the proteolipid preparations which were then incubated at room temperature for 20 min before chromatography on a column (20×2 cm) of Sephadex LH 20 equilibrated with chloroform[10]. The effect of DL-APB (Calbiochem) on the binding of glutamate was measured by preincubating the proteolipid with DL-APB for 1 h before addition of U-^{14}C-glutamate[11]. Electrophysiological experiments were made on the extensor tibiae muscle, where junctional glutamate receptors are accessible to drugs applied iontophoretically[13]. Double and multi-barrel micropipettes of high resistance (200–300 MΩ)[13,14], with braking currents of 4×10^{8}–6×10^{-9} A were used to apply L-glutamate (Na salt, 0.1 M, *p*H 8) and DL-APB (Na salt, 0.1 M, *p*H 7) to glutamate receptors in the muscle membrane. In some experiments drugs were applied from two separate micropipettes, to exclude the possibility that interaction between barrels of the micropipette was affecting the observations.

Experiments on isolated proteolipids were made over a range of glutamate concentrations from 3.7×10^{-6} M to 1.0×10^{-4} M. Glutamate binding to the proteolipid was obtained by measuring the amount of glutamate associated with the peak of proteolipid eluted with chloroform[10,11]. Saturation of binding occurred between 6.6×10^{-5} and 1.0×10^{-4} M when 7.25 nmol glutamate per mg proteolipid were bound. The dissociation constant, K_d, of the binding site was 8×10^{-6} M. The effect of DL-APB on the binding of glutamate to the proteolipid was measured over a range of glutamate concentrations (3.7×10^{-6}–3.8×10^{-5} M) and over a range of DL-APB concentrations (1.0×10^{-5}–5.1×10^{-5} M). Lineweaver–Burke and Dixon plots revealed that DL-APB behaves as a competitive inhibitor of glutamate binding with an apparent dissociation constant, K_d, of 6.6×10^{-5} M.

The iontophoretic application of glutamate to junctional glutamate receptors resulted in a rapid and transient depolarisation with a slower time course than the excitatory junction potential produced by nerve stimulation. The iontophoretic application of DL-APB from the adjacent barrel to junctional glutamate receptors produced no detect-

Fig. 2 Time course of the inhibitory action of DL-APB on the junctional response to glutamate. The drugs are applied iontophoretically to junctional glutamate receptors from adjacent barrels of a twin-barrelled micropipette. Five superimposed traces are shown and on each, a single pulse of DL-APB precedes a smaller pulse of glutamate. As the interval between the DL-APB pulse and the glutamate pulse is increased, the junctional response to glutamate increases, that is, the inhibitory action of DL-APB decreases. The current passing through each barrel of the micropipette is monitored on the lower trace. 15 nC calibration refers to DL-APB which is the first pulse on the lower trace.



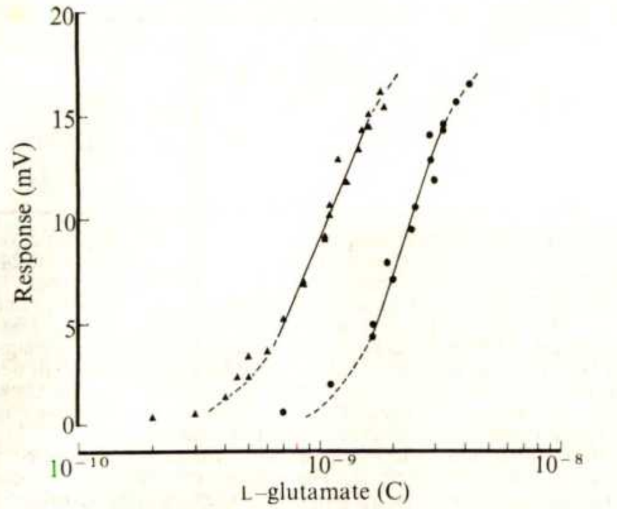


Fig. 3 Log dose–response curves illustrating the effect of locally applied glutamate alone (▲) and in the presence of DL-APB (●). The drugs were applied iontophoretically to junctional glutamate receptors from adjacent barrels of a twin-barrelled micropipette. In the right-hand curve, pulses of glutamate were applied in the presence of a constant pulse of DL-APB. Ordinate, amplitude of the junctional depolarising response to glutamate; abscissa, logarithmic scale of current (in C) passing through the glutamate barrel of the micropipette.

able response. When a pulse of DL-APB was applied to the junction during a steady glutamate application, however, the glutamate depolarisation was rapidly reduced and then recovered to the original depolarised level.

In most experiments a single pulse (40 ms) of DL-APB was followed by a single pulse (10 ms) of glutamate. Sufficient time was then allowed for complete recovery of receptors before again applying a single pulse of each drug. This precaution eliminated possible desensitisation effects. When glutamate application followed DL-APB application by a sufficiently short interval, the response to glutamate was absent or greatly diminished (Fig. 2). To study the time course of action of DL-APB the interval between single pulses of the two drugs was varied. The time constant of decay of DL-APB action (~400–500 ms) is approximately one third that of (+)-tubocurarine action at the frog endplate[16]. The difference in time constants may represent a difference in the dissociation rate of the drug receptor complexes or in the speed of diffusion of the drugs away from the receptors.

The degree of interaction between glutamate and DL-APB varied depending on the dose of the two drugs (measured in nC), so for a constant dose of DL-APB the inhibition of the response to glutamate became less as the glutamate dose was increased. This may not necessarily represent competition between the agonist and the antagonist, because the time constant of dissociation of DL-APB from receptors is much longer than the rapid rise of the glutamate depolarisation, during which time dissociation would need to occur. In addition, larger doses of glutamate can be expected to reach more distant receptors[15,17,18] which may be less affected by DL-APB.

To determine whether these two drugs were interacting in a competitive or non-competitive manner, dose–response curves were obtained for glutamate both in the presence and absence of a constant DL-APB pulse (Fig. 3). Problems arose from rapid decay of DL-APB action and the need to have a constant amount of inhibitor present over a larger area than was reached by glutamate. These were overcome by applying a short glutamate pulse (10 ms) at a fixed time during a much longer DL-APB pulse (500 ms). The dose–response curves for glutamate in the presence of DL-APB showed a parallel shift to the right, consistent with the concept of a competitive antagonism between the DL-APB and glutamate molecules, for the glutamate receptor, although the possibility of a postsynaptic action of the DL-APB molecule at a level other than the glutamate receptor, cannot be discounted.

The junctional response to iontophoretically applied glutamate was not markedly inhibited by the application of DL-APB (5×10^{-4} M) in the bathing medium. Similarly miniature excitatory junctional potentials, which result from spontaneous release of transmitter packets, were unaltered. The apparent difference in effectiveness when DL-APB is applied iontophoretically may well reflect a difference in the concentration of drug reaching the receptors. Previous studies, however, have also shown that relatively high concentrations of substances, which specifically block the postsynaptic action of glutamate, may be required to produce antagonism of glutamate[3,4].

Both the biochemical and electrophysiological findings support the suggestion that DL-APB acts as a glutamate antagonist at the insect myoneural junction. It is hoped that the drug will prove to be a useful tool in the investigation of the nature and mode of action of the postsynaptic glutamate receptor.

S.G.C.-C. held a Royal Society European Science Exchange Programme Fellowship and thanks Professor S. Thesleff for his hospitality and encouragement. R.W.J. is in receipt of an SRC/CAPS award in conjunction with Shell Research Limited.

Susceptibility of teratocarcinoma cells to adenovirus type 2

As mouse embryos develop they become susceptible to infection by the small DNA oncogenic viruses, simian virus 40 and polyoma[1,2]. Recently, the mouse teratocarcinoma, an alternative model system for the study of early development[3,4], was used in an approach to understanding how differentiation affects host–virus interaction (ref. 5 and M.B. and F.K., unpublished). Several differential teratocarcinoma lines were shown to be fully permissive to polyoma virus and could be transformed by SV40, therefore reacting to viral infection like most commonly used mouse cells. In contrast, the multipotential embryonal carcinoma cells were resistant to both viruses and the block seems to lie early in the lytic cycle, after penetration of the virus, but before synthesis of the viral T antigen. Adenoviruses have much in common with the papovaviruses but are larger and more complex. We therefore examined the susceptibility of teratocarcinoma cells to these viruses. Here we report that both embryonal carcinoma cells and cells from a differentiated teratocarcinoma line are susceptible to adenovirus type 2.

The two teratocarcinoma cell lines used in this study have been derived from the transplantable mouse teratocarcinoma OTT 60-50-970 isolated by Stevens[6]. PCC3 (clone A/1) is a primitive embryonal carcinoma line which undergoes differentiation when injected into mice as well as *in vitro*[7,8]. PCD3 was derived from embryoid bodies which were allowed to differentiate *in vitro*: it has a stable fibroblast morphology in culture and is non-tumorigenic (H. Jakob, personal communication). HeLa cells were used as a susceptible control. Following infection of PCC3 and PCD3 cells by adenovirus type 2, we screened the cells for production of viral antigens and infectious viral particles, as described in Table 1.

In brief, adenovirus antigens were detected by indirect immunofluorescence on cells seeded on glass coverslips, 20 h and 36 h after infection. The specific reagents were hamster anti-T antigen antiserum and rabbit multivalent capsid antiserum. Normal non-immune sera were used as controls. The indicator was fluorescein-conjugated anti-γ globulins (Institut Pasteur).

Virus titres were determined by the formation of foci on layers of HeLa cells[9]. These foci were stained by indirect immunofluorescence, with the use of anti-capsid serum as the specific reagent.

The results are summarised in Table 1. Synthesis of adenovirus-specific T antigen and of late capsid proteins was found to occur in both the primitive PCC3 and the differentiated PCD3 cells. The fluorescence pattern of the T antigen is characteristic of adenovirus, as shown in Fig. 1. Both types of cell produced infectious virus, although at a titre 50–100 times lower than HeLa cells.

Fig. 1 T-antigen immunofluorescence (indirect test) in Ad2-infected (*a*) multipotential PCC3/A/1 cells, and (*b*) differentiated PCD3 cells (see legend Table 1).

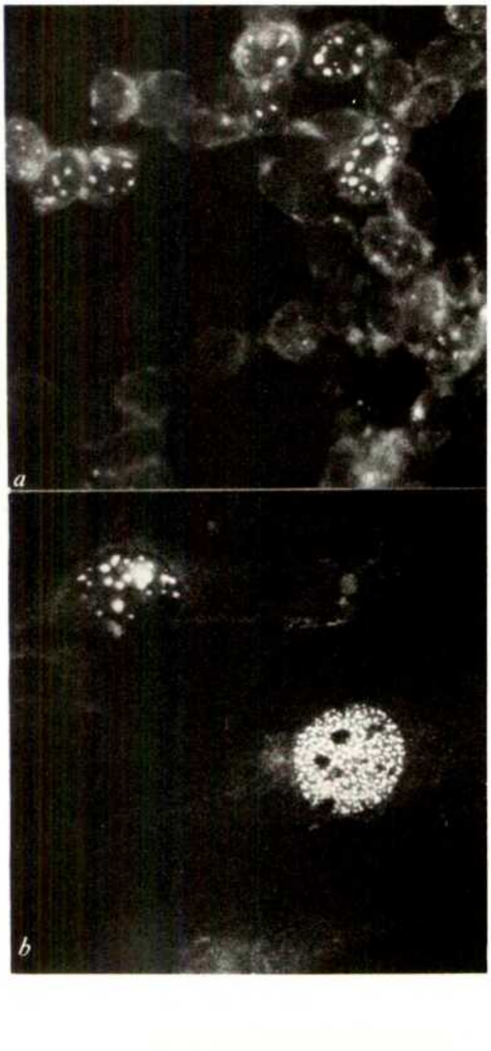

Table 1 Ad 2 antigens and virus production in HeLa cells and in two teratocarcinoma cell lines

Cells	T antigen*	Capsid antigen‡	FFU ml^{-1}†
HeLa	50	100	1.0 10^8
PCC3/A/1	40	16	1.7 10^6
PCD3	38	53	0.9 10^6

For detection of viral antigens, cells were seeded on glass coverslips (2×10^5 cells per 35-mm plastic Petri dish) and grown for 24 h at 37 °C in Dulbecco's modified Eagle's medium containing 10% foetal calf serum and in an atmosphere containing 12% CO_2. Cells were infected with adenovirus type 2 (a gift from Pierre Boulanger, INSERM, Lille) at an input multiplicity of 10 plaque-forming units per cell. Virus was adsorbed for 1 h at 37 °C. Cells were then covered with medium containing 2% foetal calf serum. Coverslips were removed 20 h and 36 h after infection, washed three times in phosphate-buffered saline and fixed in methanol–acetone (3 : 7) at −20 °C for 5 min. Adenovirus-specific proteins were detected by indirect immunofluorescence. The specific reagents were hamster anti-T-antigen antiserum (a gift from Pierre Boulanger, originally from Dr R. V. Gilden) and rabbit multivalent capsid antiserum (Pierre Boulanger). The indicator was fluorescein-conjugated anti-γ globulins (Institut Pasteur). *% cells positive 20 h after infection; †% cells positive 36 h after infection. Virus production was determined by fluorescent focus assay on HeLa cells[9]. Cells were grown and infected in the conditions described above on 60-mm dishes. Cells and overlying medium were collected 48 h after infection and frozen and thawed 3 times. HeLa cells grown on coverslips were infected with convenient dilutions of the cell extracts. They were fixed 48 h after infection and stained by indirect immuno-fluorescence using rabbit multivalent capsid antiserum, as the specific reagent. ‡Virus yield expressed as fluorescent focus units (FFU).

These results show clearly that adenovirus type 2 can infect the primitive teratocarcinoma cells as efficiently as it can the differentiated cells. In contrast, the primitive cells are resistant to both polyoma virus and SV40: less than 1 in 10^4 cells was T-antigen and V-antigen positive after polyoma infection and no T-antigen positive cell could be detected after SV40 infection (M. Boccara and F. Kelly, unpublished). The diversity in response to the viruses is interesting in view of both similarities and differences exhibited by papovaviruses and adenoviruses. All three viruses replicate exclusively in the nuclei of the permissive cells and the viral genome is integrated into the host chromosome during the lytic cycle[10]. Adenoviruses, however, contain seven times as much DNA and are also more complex. In particular, at least two early genes of adenovirus are necessary for replication of the viral DNA[11], whereas early mutants of SV40 and polyoma fall into only one complementation group. It is also interesting to note that adenovirus recombines far more efficiently than does SV40 or polyoma.

Because very little is known about the early events which take place in the nucleus before initiation of viral transcription and the appearance of the T antigen, one can only speculate on the basis for the different response of the primitive stem cells to papovaviruses and adenoviruses. The hypothesis we favour is that one or several cellular functions required early in the lytic cycle of SV40 and polyoma, possibly recombination between host and viral genomes, is missing in these cells. A function, carried or coded by the more complex adenoviruses could obviate this deficiency. Experiments are in progress to test whether coinfection by adenovirus will help SV40 or polyoma to infect primitive teratocarcinoma cells. We are also attempting to obtain clones of primitive cells containing a fragment of the adenoviral genome, which may be useful as a marker during their differentiation.

Is the scrapie agent a virus ?

THE nature of the scrapie agent has been obscure for many years. It is not known whether it is a virus in a strict sense, some replicating agent which is devoid of nucleic acid[1,2], or a transmissible self-replicating cellular membrane[3,4]. In previous experiments with the Chandler strain of the scrapie agent, numerous 14-nm virus-like particles were isolated[5] from infected mouse brains using repeated fluorocarbon extraction procedures which have been used for the isolation of Aleutian disease virus from infected mink tissues[6,7]. The present experiments were designed; first, to determine if similar 14-nm virus-like particles could be isolated from hamster brains infected with scrapie agent; and second, to determine if the 14-nm virus-like particles induce scrapie in mice and hamsters.

Hamster brains (39 g) infected with the scrapie agent were obtained from Dr R. F. Marsh[8] of the University of Wisconsin. The hamster brain suspensions were extracted repeatedly with fluorocarbon as described previously[5]. The final scrapie extracts from the 39 g of hamster scrapie brains were resuspended in 1.5 ml of 0.05 M Tris-HCl, *p*H 7.4. A CsCl density gradient ultracentrifugation was performed with these hamster scrapie extracts at 25 °C at 243,000*g* for 72 h. In the same run, three other preparations (mouse scrapie brain extracts, normal mouse brain extracts and normal hamster brain extracts) were also ultracentrifuged. Mouse scrapie brain extracts and normal mouse brain extracts were used as prepared previously[5]. Normal hamster brain extracts were prepared from the same strain of 10-week-old hamsters (LVG: LAK strain) (purchased from Lakeview Farms, Newfield, New Jersey). From 68 g of normal hamster brains, 1.7 ml of normal hamster brain extract was prepared. After the CsCl gradient ultracentrifugation, only one band was visible with the normal mouse brain and normal hamster brain extracts. This band was located in the region of buoyant density of 1.29–1.30 g cm^{-3} in the CsCl (fraction 5). With the mouse and hamster scrapie extracts, however, one band was observed at the same place and another in the region of buoyant density of 1.33–1.34 g cm^{-3} (fraction 6). Numerous virus-like particles, measuring about 14–15 nm in diameter as seen previously[5] were observed in the second band of both hamster and mouse scrapie extracts. The structure and size of these particles from these two scrapie extracts from mice and hamsters are identical. No virus-like particles were observed in the first band (density 1.29–1.30 g cm^{-3}) of any of the four different preparations, nor in the regions of buoyant density of 1.33–1.34 g cm^{-3} of normal hamster or mouse brain extracts. The CsCl gradient was collected in 10 fractions from the top of the tube using Pasteur pipettes. Particles with the structure of membranes were not detected in the fractions from the four different extracts.

Comparative titres of infectivity of the different stages of fluorocarbon extractions and the CsCl gradient fractions of mouse scrapie extracts were determined in mice. Groups of six to ten Swiss albino mice were inoculated intracerebrally with 0.03 ml in serial tenfold dilutions of the various scrapie preparations. Each experiment of mouse scrapie infectivity was terminated 47 weeks after inoculation and brains and spinal cords removed from those mice which developed scrapie symptoms. Scrapie was diagnosed by the astrocyte response in these tissues using the Cajal's gold sublimate method as described by Hadlow[9]. The infective dose (ID_{50}) defined as that dilution of material which induced scrapie in 50% of the inoculated animals, was calculated by the method of Reed and Muench[10].

The results of titration of mouse scrapie preparations are shown in Table 1. Scrapie infectivity was markedly reduced by the repeated fluorocarbon extraction procedures and CsCl gradient ultracentrifugation. In the CsCl gradient of mouse scrapie extracts, maximum infectivity was detected in the pooled fractions 6–8 which yielded 14-nm virus-like particles. In this group of mice, scrapie symptoms were first observed 23 weeks after inoculation, whereas in those mice inoculated with mouse scrapie brain suspension, scrapie symptoms were first observed at 17–18 weeks after infection. The astrocyte response was always detected in mice which developed scrapie symptoms.

Infectivity of hamster scrapie brain (195 ml), final hamster scrapie extracts (1.5 ml) and of the pool of fractions 6–7 (1.5 ml) of the CsCl gradient of hamster scrapie extracts which yielded the 14-nm virus-like particles, was titrated in hamsters by inoculation with 0.05 ml intracerebrally. The infectivity titres of these three inocula were ID_{50} $10^{8.7}$, $10^{5.5}$ and $10^{3.5}$ per 0.05 ml respectively during the observation period of 39 weeks. The diagnosis of scrapie in hamsters was also confirmed by astrocyte response. In hamsters, scrapie symptoms were first observed 10 weeks after infection with hamster scrapie brain suspension and after 12 weeks with the other two preparations. The infectivity titre of hamster scrapie extracts is being determined more precisely using fractions 1–5 collected from the top of the CsCl gradient, and fractions 6–10 through a hole in the bottom of the tube.

Previous studies[5] showed that the final mouse scrapie extract from 132 g of brain contained 8.8 mg of protein in a total volume of 10 ml. Therefore, the fluorocarbon stage in the purification of virus-like particles leads to the removal of about 99.99% or "4 logs" of brain tissues. In the present experiments 5.8 $\log_{10}ID_{50}$ units of mouse infectivity and 5.2 $\log_{10}ID_{50}$ units of hamster infectivity were lost during fluorocarbon treatment, and exposure to CsCl caused further decreases in the infective titre. This marked reduction of scrapie infectivity is consistent with the observations of others[11] that the scrapie agent is inactivated by various lypophilic solvents and by CsCl. The density of the 14-nm particles and the maximum infectivity found in fractions 6–8, is however, consistent with the report of Gibbs[12] in which maximum scrapie infectivity was observed at densities between 1.32 and 1.37 g cm^{-3} in a CsCl gradient.

In view of the findings that identical 14-nm virus-like particles were isolated from the brains of two different animal species (mouse and hamster) obtained from two different laboratories, scrapie infectivity was detected in the fractions yielding these 14-nm particles, and as these virus-like particles form a homogenous band is a CsCl gradient, I suggest that the 14-nm particles are likely to be the causative agent of scrapie.

I thank W. J. Hadlow for providing mouse scrapie brains

Table 1 Infectivity of mouse scrapie brain extracts

Preparations		Amount (ml)	Titres of scrapie infectivity $\log_{10}ID_{50}$ per 0.03 ml	Total titres ($\log_{10}ID_{50}$)
Scrapie mouse brains suspension		790	7.0	11.4
↓				
Freon 113 extraction				
↓				
10,000*g* 30 min supernatant		660	4.9	9.2
↓				
100,000*g* 5 h supernatant		660	2.0	6.3
↓				
100,000*g* 5 h pellets		100	Not done	—
↓				
Freon 113 extraction				
↓				
10,000*g* 30 min supernatant		100	3.8	7.3
↓				
100,000*g* 10 h supernatant		100	1.4	4.9
↓				
100,000*g* 10 h pellets (mouse scrapie extracts)		10	3.1	5.6
CsCl fractions*	Electron microscopy	Total amount		
1–4 pool	No virus	10†	$\leqslant 0.5$	$\leqslant 3.0$
5	No virus	10	$\leqslant 0.58$‡	$\leqslant 3.08$
6–8 pool	Numerous 14-nm virus-like particles and some ferritins	10	2.5	5.0
9–10 pool	Ferritins	10	$\leqslant 0.5$	$\leqslant 3.0$

* Fractions were collected from top of the table. Two bands were visible: in fraction 5 (density 1.29–1.30 g cm^{-3}) and in fraction 6 (density 1.33–1.34 g cm^{-3}).

† Only 1 ml of the total amount of 10 ml mouse scrapie extract was centrifuged on CsCl. The CsCl fractions were diluted with 0.85% saline, concentrated by centrifugation at 300,000*g* for 5 h and the pellets were suspended in 1 ml of saline.

‡ Scrapie was diagnosed in one of 7 inoculated at 10^{-1} dilution at 35 weeks. No mice showed scrapie symptoms at 10^{-1} or higher dilutions in the fractions 1–4 and 9–10 pools.

Rifampicin-resistant RNA polymerase and NAD transferase activities in coliphage N4 virions

SEVERAL animal viruses carry within the infectious particle a number of enzymatic activities[1,2]. Prominent among these are the RNA synthetases of orthomixo, paramixo, rhabdo- and diplornaviruses[3–6], the DNA-dependent RNA polymerase of poxviruses[7] and the reverse transcriptases of oncornaviruses[8,9], all of which play important roles in the virus life cycle. Exclusion of vital enzymes from the virion of all complex bacterial viruses seems, on the other hand, to have been the result of the evolutionary trend followed by these agents. A notable exception to this rule seems to be represented by coliphage N4 (ref. 10). It has been reported that transcription of N4 early genes[11,12] and incorporation of ^{32}P-orthophosphate into several host proteins[13] occur in *Escherichia coli* cells treated before infection with rifampicin and chloramphenicol. A possible explanation for these findings was that N4 injects into the cell the relevant enzymes along with its DNA. We report here the detection of a rifampicin-resistant RNA polymerase and a nicotinamide adenine dinucleotide (NAD) transferase in purified N4 particles.

To demonstrate the existence of virion-associated enzymes several procedures were successfully developed for the rupture of the virus protein coat[14] since preliminary experiments failed to show any activity in intact phage preparations. Disruption of isopycnically purified N4 (ref. 10) by three cycles of freezing in liquid nitrogen and thawing at 37 °C was finally adopted for the sake of simplicity. These NA cryolysates were briefly sonicated and the DNA precipitated with streptomycin. Residual intact virions, ghosts and DNA were removed by centrifugation, and the clear extracts, after dialysis, served as the source of enzyme.

Table 1 shows that incorporation of ^{3}H-UTP into RNA was mediated by these N4 preparations in a modified RNA polymerase assay[15]. Like the RNA polymerase of *E. coli*, N4 enzyme requires all four ribonucleotide triphosphates, Mg^{2+} and a DNA template for optimal activity. The acid-insoluble product is totally susceptible to RNase digestion, and it is not synthesised in the presence of actinomycin D. On the other hand, N4 enzyme is inhibited by low concentrations of monovalent ions and by phosphates, and shows a stringent template specificity in that only homologous phage DNA acts as an efficient primer. Furthermore, the functioning of N4 polymerase is highly resistant to the antibiotic rifampicin at concentrations that inhibit *E. coli* RNA polymerase[16,17].

As an indication of the fidelity of transcription by the phage enzyme, RNA synthesised *in vitro* from N4 DNA hybridised with high efficiency (43%) to denatured N4 DNA

Table 1 Characteristics of N4 virion-associated RNA polymerase activity

	Activity (%)
Complete system	100
Omit ATP, or CTP, or GTP	1
Omit Mg^{2+}	8
Omit N4 DNA	2
Add calf thymus DNA (50 μg ml^{-1})	18
Add *E.coli* DNA (200 μg ml^{-1})	7
Add 0.15 M KCl	21
Add 0.05 M K phosphate, *p*H 7.0	19
Add RNase (10 μg ml^{-1})	1
Add actinomycin D (10 μg ml^{-1})	1
Add rifampicin (5 μg ml^{-1})	96

Isopycnically purified N4 preparations were obtained as described previously[30]. After three cycles of freezing in liquid nitrogen and thawing at 37 °C the viscous lysates were sonicated for 30 s in a Branson apparatus at an output of 50 W. Removal of DNA was effected by adding streptomycin to a final concentration of 6%. After 15 min at 4 °C, precipitated DNA, ghosts and residual intact phage particles were sedimented by spinning at 40,000 r.p.m. for 90 min in the 50 rotor of an L3-50 Spinco ultracentrifuge. After thorough dialysis against 0.01 M Tris-HCl buffer, *p*H 7.2, containing 0.001 M $MgCl_2$, the clear extract was used as the source of enzyme.

Complete system for the assay of N4 polymerase activity contained 10 μmol Tris-HCl (*p*H 7.9), 2.5 μmol $MgCl_2$, 25 nmol dithiothreitol, 25 nmol EDTA, 125 μg bovine serum albumin, 2 pmol N4 DNA, 37.5 nmol each of the four ribonucleoside triphosphates of which UTP was labelled with ^3H (Amersham, England; specific activity 5×10^3–2×10^4 c.p.m. $nmol^{-1}$) and 30 μl N4 cryolysate in a final volume of 250 μl. After incubation at 37 °C for 15 min, the reaction was terminated by the addition of 3 ml ice-cold 5% TCA containing 10^{-2} M sodium pyrophosphate. The acid-insoluble RNA product was collected on Whatman GF/C filters, washed and counted as reported previously[30]. For the complete system 100% activity was 5,200 c.p.m.

(Table 2). In addition, unlabelled RNA synthesised by N4-infected Hfr 3300 cells either untreated or pretreated with rifampicin and chloramphenicol[11,12] competed (greater than 90% inhibition) with labelled RNA produced *in vitro*. These data indicate that the RNA species synthesised *in vitro* by N4 virion polymerase are not qualitatively different from those produced during *in vivo* infection.

Phosphorylation of proteins is catalysed by phage-coded products through at least two mechanisms involving either protein kinases that transfer phosphate from ATP to seryl groups of acceptor molecules[18], or NAD transferases that modify target polypeptides by the simultaneous addition of adenosine and phosphorus[19–21]. None of these enzymes has been shown to be virion associated.

N4 particles do not carry a protein kinase since ^{32}P was not transferred to proteins in reaction mixtures containing γ-^{32}P-ATP (not shown). On the other hand, N4 cryolysates were active in transferring radioactivity from ^{14}C-NAD into acid-precipitable linkage with various acceptor proteins (Table 3). Among those proteins tested, lysozyme was the best acceptor. Dithiothreitol markedly stimulated ^{14}C-NAD incorporation possibly implying an activation of the enzyme by thiol compounds[21].

The label bound to the reaction product resisted heat treatment in mild acidic and alkaline conditions, and digestion with DNase. After treatment with Pronase and snake venom phosphodiesterase ^{14}C-radioactivity was converted to an acid-soluble form (not shown). These results suggest that N4 enzyme may be similar to the ADP–ribosyl transferase activities that have been established for diphtheria toxin[21,22], *Pseudomonas aeruginosa* PA toxin[23] and T4 'alteration' factor[20].

In a preliminary effort to characterise the molecular nature of N4 enzymes, $^{35}SO_4$-labelled isopycnically purified virions were disrupted, treated with DNase, and clarified from ghosts and residual intact particles by centrifugation; the supernatant containing both enzymatic activities was electrophoresed in sodium dodecyl sulphate (SDS)–polyacrylamide slab gels[24]. In the autoradiogram shown in Fig. 1 two radioactive bands with approximate molecular weight of 65,000 are visible. Whether these polypeptides can be considered dissociated subunits of one or both N4 enzymes or merely represent internal proteins, remains to be established.

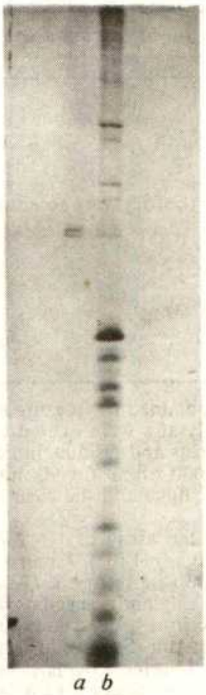

Fig. 1 Identification of polypeptides present in N4 virion cryolysates. Isopycnically purified $^{35}SO_4$-labelled N4 particles[30], disrupted by three cycles of freezing and thawing, were treated with DNase (5 μg ml^{-1}) for 15 min at 37 °C. Ghosts and residual intact virions were removed by spinning as specified in Table 1. Samples of intact radioactive particles (25 μl, 50,000 c.p.m.) and enzymatically active cryolysates (25 μl, 1,100 c.p.m.) were prepared for SDS–polyacrylamide electrophoresis in 10% slab gels using the procedures and apparatus described previously[24,34]. In the autoradiogram shown the origin of electrophoresis is at the top. *a*, Migration pattern of N4 cryolysates; *b*, migration pattern of intact N4 virion polypeptides.

Although rifampicin-resistant phage-coded RNA polymerases are known to be synthesised in infected cells during the life cycle of T7 (ref. 25), T3 (ref. 26), PBS2 (ref. 27) and gh-1 (ref. 28) bacteriophages, N4 enzyme provides the first example of a virion-associated transcription apparatus in bacterial viruses.

The occurrence of this enzyme as an integral part of N4 may be of evolutionary significance for a virus which replicates exclusively in the polar regions of its host[29]. Besides,

Table 2 Hybridisation–competition of N4 RNA polymerase product by various RNA preparations

Type of non-radioactive competing RNA	Amount of *in vitro* RNA (c.p.m.)	c.p.m. in hybrid	% RNA hybridised
None	3.1×10^3	1.3×10^3	43
Uninfected *E.coli* RNA (200 μg ml^{-1})	3.1×10^3	1.3×10^3	43
RNA isolated from *E.coli* cells 4 min after N4 infection (50 μg ml^{-1})	3.1×10^3	1.2×10^2	3.9
RNA isolated from *E.coli* cells pretreated with rifampicin and chloramphenicol, and infected for 4 min with N4 (50 μg ml^{-1})	3.1×10^3	1.1×10^2	3.5

Labelled RNA synthesised by N4 virion-associated RNA polymerase in the conditions reported in Table 1, was purified from the reaction mixture by phenol extraction[11]. Competitor RNA molecules were prepared from uninfected or N4-infected *E.coli* Hfr 3300 cells as specified previously[11]. Conditions of N4 infection in the presence of chloramphenicol and rifampicin have been described[12]. RNA–DNA hybridisation was carried out as already reported[11] using N4 DNA (2 μg) bound to nitrocellulose filters.

Table 3 Characteristics of N4 virion-associated NAD transferase activity

	Activity (%)
Complete system	100
Omit dithiothreitol	7
Omit Mg^{2+}	52
Substitute lysozyme with the following acceptor proteins:	
Histones	63
E.coli cell-free extract	56
RNase	30
Protamine	9
Bovine serum albumin	7
N4 ghosts	6
Casein	5

N4 cryolysates were obtained by freezing and thawing as specified in Table 1. The viscous lysates were treated with DNase (3 μg ml^{-1}) at 37 °C for 15 min. Ghosts and residual intact virions were removed by centrifugation at 40,000 r.p.m. for 90 min in the 50 rotor of an L3-50 Spinco Ultracentrifuge and the clear extract was used as the source of enzyme.

Complete system for the assay of N4 NAD transferase activity contained 4 μmol Tris-HCl (*p*H 8.2), 7.5 nmol EDTA, 3 μmol dithiothreitol, 4 μmol $MgCl_2$, 30 μg lysozyme (Koch and Light), 50 pmol ^{14}C-NAD (Amersham, England; specific activity 280 Ci mol^{-1}) and 15 μl N4 cryolysate in a total volume of 65 μl. RNase (Boehringer) bovine serum albumin (Sigma), histones (Sigma, fraction II), Protamine (Sigma) and Caseine (Sigma), when used as acceptors, were present in the reaction mixture at a concentration of 30 μg. Hfr 3300 cells grown in 50 ml M9S medium[29] at a concentration of 5×10^8 ml^{-1} were collected by centrifugation, washed in distilled water, resuspended in 1 ml 0.001 M Tris-HCl buffer (*p*H 8.2) and sonicated at 0 °C for 2 min in a Branson sonifier at an output of 70 W. After centrifugation at 10,000 r.p.m. for 10 min, 10 μl of the clear cell-free extract were added to the NAD transferase reaction. Purified N4 ghosts prepared as reported previously[14] were added at a final concentration of 20 μg. After incubation at 25 °C for 60 min the reaction was terminated by addition of 65 μl 10% TCA. The acid-insoluble radioactivity was collected on Whatman GF/C filters, washed with 5% TCA and counted as detailed previously[30]. For the complete system 100% activity was 1,850 c.p.m.

the identification of a rifampicin-resistant RNA polymerase in N4 particles provides a likely explanation for the drug resistance of phage transcription during the early stages of replication[11,12]. This enzyme is injected along with the phage genome at infection. Once in the cell the injected polymerase will immediately direct the synthesis of additional drug-resistant RNA polymerase molecules by transcribing N4 cistrons 3 and 4 (ref. 30) which probably code for this activity. Expression of the early genes then takes place at a suitable rate and the phage DNA is replicated[11,12]. Late genes are next transcribed with the mandatory participation of an N4-modified form of *E. coli* polymerase[31]. During morphogenesis N4-coded RNA polymerase or a catalytically active subassembly of this enzyme is finally packaged into the infectious virions. Mero complex models of N4 gene expression can also be constructed on the basis of present and previous evidence.

When injected into the host, N4-associated NAD transferase catalyses the phosphorylation of about 30 bacterial proteins, which do not include any of the host RNA polymerase subunits[13]. A NAD transferase which 'alters' the α subunit of *E. coli* RNA polymerase[19,32] has been tentatively located by Horvitz[33] in T4 particles. T4 mutants deficient in 'alteration' have been shown to be perfectly viable[33]. It has been suggested that the main role of 'alteration' may reside in the ability to confer a broad host range on T4 phage[33]. Since N4 replicates productively only in the K12 strains of *E. coli*[30], amplification of the host range by possession of the virion-associated NAD transferase seems improbable. Considering the scarcity of receptors for N4 on the surface of sensitive cells[29], we favour the hypothesis that during evolution N4 NAD transferase was retained in the virion because of some positive role it may have in initiating the infectious process. Detailed physicochemical and biochemical characterisation of N4 virion-associated enzymes will be reported elsewhere.

Human cytomegalovirus infection of WI-38 cells stimulates mitochondrial DNA synthesis

HUMAN cytomegalovirus (HCMV) infection has been shown to lead to the stimulation of host cell DNA and RNA synthesis in both permissive and non-permissive cells[1-3]. This effect on DNA synthesis occurred at about 12–16 h after infection, and preceded synthesis of viral DNA by 36 h. The host cell DNA species which are stimulated have not been characterised. We show here that much of the stimulation of DNA synthesis was due to an increased rate of mitochondrial DNA synthesis and that ethidium bromide inhibited HMCV replication.

Confluent cultures of WI-38 cells were infected with HCMV at a multiplicity of infection of 1 plaque-forming unit (PFU) per cell. In all the experiments (unless otherwise noted) WI-38 cells were infected at least 5 d after reaching confluency in minimum essential medium (MEM) plus 10% foetal bovine serum. After infection the cultures were refed with MEM containing 0.4% foetal bovine serum, to minimise the stimulatory effect of serum on cellular DNA, and incubated at 37 °C. In these conditions, typical nuclear inclusion bodies for HCMV were demonstrated in virtually all of the cells 3 d after infection. Total DNA synthesis was measured by labelling the cells for 60 min with ^{3}H-thymidine (^{3}H-dT) at various times after infection. Mock-infected cultures were used as controls.

The incorporation of ^{3}H-dT into cellular DNA and the HCMV infectivity of WI-38 cells at various intervals are shown in Fig. 1. Infectivity was not seen until 48 h after infection, when a small amount of virus was detected; this amount subsequently increased.

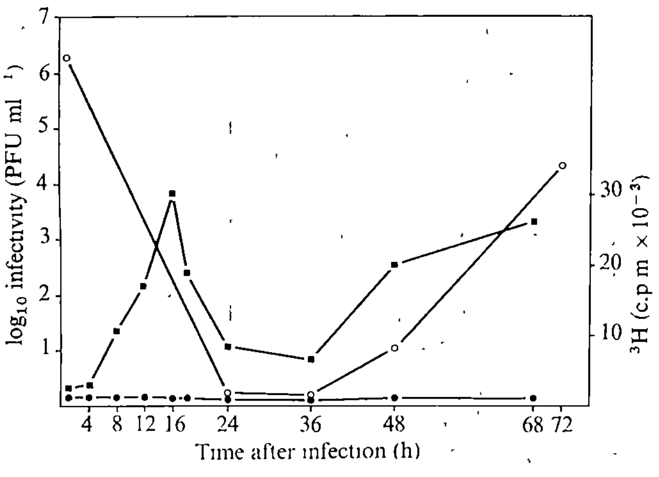
Apparently the incorporation of ^{3}H-dT occurred in two phases· the first reaching a maximum at 16 h after infection, then decreasing until 36 h, when the second phase begins. Previous DNA analysis by equilibrium CsCl centrifugation showed viral DNA only in specimens obtained 36 h after infection (ref. 1) and reached a peak at 96 h.

Mitochondrial DNA was isolated from cytoplasmic extracts by zonal centrifugation in sucrose density gradients and then analysed in equilibrium CsCl–ethidium bromide gradients. Figure 2 presents the incorporation of 3H-dT into the mitochondrial DNA of WI-38 cells labelled for 1 h at 16 h after infection. Most of the radioactive precursor was incorporated into mitochondrial DNA. The rate of ^{3}H-dT incorporation into mitochondrial DNA in infected cells was approximately five times that in control cells. As expected[4], the greater part of the incorporated radioactivity was found in the same fraction as the closed circular SV40 DNA added to the gradient as a marker.

Analysis of mitochondrial DNA at various times after infection revealed that the rate of incorporation of ^{3}H-dT into mitochondrial DNA of infected cells was always 1.5 to 5 times higher than in the control cells and the greatest increase occurred between 12 and 18 h after infection. Mitochondrial DNA labelled with ^{14}C-dT and prepared from mock-infected cells by the same type of CsCl gradient procedure was then mixed with SV40 DNA as marker, and the mixture sedimented through a 5–20% sucrose gradient at neutral *p*H. The peaks of ^{3}H-dT label from infected cells coincided with the peaks of the ^{14}C label from mock-infected cell DNA (Fig. 3).

Greater incorporation of a DNA precursor into mitochondrial DNA is insufficient as evidence of an increase in the rate of synthesis of mitochondrial DNA in the infected cells, because the pool size of thymidine, the kinase levels and the rate of turnover may differ from those in uninfected cells. For these reasons, additional experiments were carried out at 12 and 24 h past infection. Cultures prelabelled with ^{32}P were used to measure specificity of the acid-soluble pool of dT triphosphate. Inorganic $^{32}PO_4$ (5 μCi ml^{-1}) was added to the culture and the cells were continuously labelled for 48 h before infection. ^{3}H-dT (10 μCi ml^{-1}) was added to infected and non-infected cells for 1 h at 12 h and 24 h after infection. The ratio of ^{32}P to ^{3}H in dT triphosphate was measured using the methods for acid-soluble extracts and polyethyleneimine thin-layer chromatography as described by Neuhard *et al.*[5]. The specific activities of the acid-soluble pools of dT triphosphate were unaffected in both infected and uninfected cultures.

Fig. 1 Monolayers of WI-38 cells in 3-cm Petri dishes containing 3×10^5 cells were infected at an input multiplicity of 1. At various times after infection, ^{3}H-dT was added at a concentration of 1 µCi ml^{-1} and the cells incubated at 37 °C for 60 min After incubation the cells were lysed with 0.1% sodium dodecylsulphate and precipitated with 5% trichloroacetic acid. Precipitates were filtered and radioactivity counted. Infectivity of cell-associated virus was assayed after disrupting the cells by sonication[13]. ○, Infectivity; incorporation of ^{3}H-dT, ●, mock-infected cells; ■, infected cells



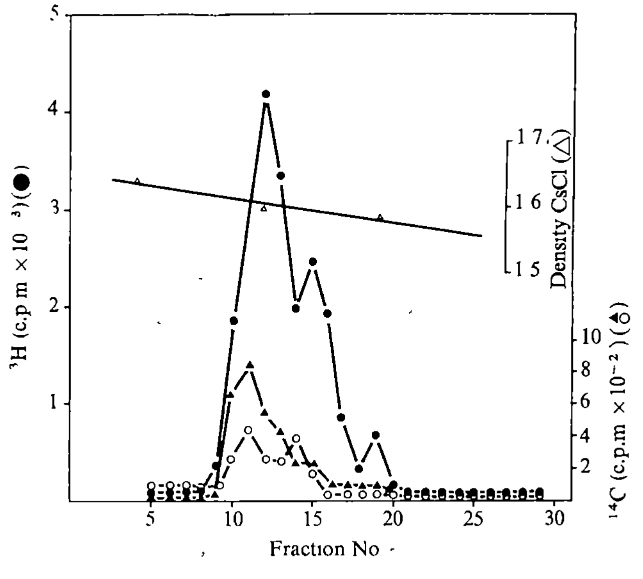


Fig. 2 WI-38 cells (3×10^6) were infected, 5 d after reaching confluent monolayers, with HCMV at a multiplicity of 1 PFU per cell. At 16 h after infection, cells were labelled for 1 h with 5 µCi ml^{-1} of ^{3}H-dT (specific activity 6.7 Ci mmol^{-1}). Mock-infected cells were treated identically. At the end of the incubation cytoplasmic extracts were prepared according to a method previously described[14], and were layered on to 15–30% sucrose–sodium dodecylsulphate gradients and centrifuged at 25,000 r.p.m. in an SW27 rotor for 16 h at 25 °C. Fractions were collected from the gradient. The fractions corresponding to the lower half of the gradient were pooled and precipitated with alcohol. Nucleic acids were resuspended in 10 mM Tris (*p*H 7.6) and 1 mM EDTA made 2 M in CsCl, and left overnight. After centrifugation at 15,000*g* for 10 min, the solution received CsCl to a density of 1.530 g cm^{-1} and ethidium bromide to a concentration of 250 µg ml^{-1}. Centrifugation was carried out in the SW50 Spinco rotor for 36 h at 44,000 r.p.m. at 20 °C. The position of supercoiled DNA molecules was checked using SV40 circular DNA labelled with ^{14}C as a marker. ●, Infected; ○, mock-infected; ▲, SV40 circular DNA.

Because HCMV has a long eclipse period (48–72 h)[6–8], the stimulation of mitochondrial DNA occurs before viral replication. It was interesting, therefore, to determine the effect of ethidium bromide on both mitochondrial DNA and viral production. Confluent monolayers of WI-38 cells were infected with HCMV and after allowing 1 h for virus adsorption, medium containing various concentrations of ethidium bromide was added. At intervals after infection, the total incorporation of ^{3}H-dT into DNA was measured as in the experiment presented in Fig. 1. Infectivity of cell-associated virus was assayed 3 d after infection. At concentrations of 5 and 1 μg ml^{-1}, ethidium bromide completely abolished the HCMV-induced DNA stimulation and decreased infectivity by more than three orders of magnitude. At a concentration of 0.1 μg ml^{-1} of ethidium bromide, incorporation of ^{3}H into DNA was only slightly decreased whereas infectivity was about ten times lower than in the untreated culture (Fig. 4).

The data presented here indicate that HCMV stimulated mitochondrial DNA in cells where DNA synthesis was repressed by contact inhibition or by depletion of serum[9]. The stimulation of mitochondrial DNA preceded viral DNA replication and was thus an expression of an early function of the viral genome. These results are not analogous to those observed in cells infected with simian virus 40 (SV40), polyoma or herpes simplex virus. SV40 and polyoma stimulate mitochondrial DNA synthesis concomitantly with virus-directed induction of nuclear DNA

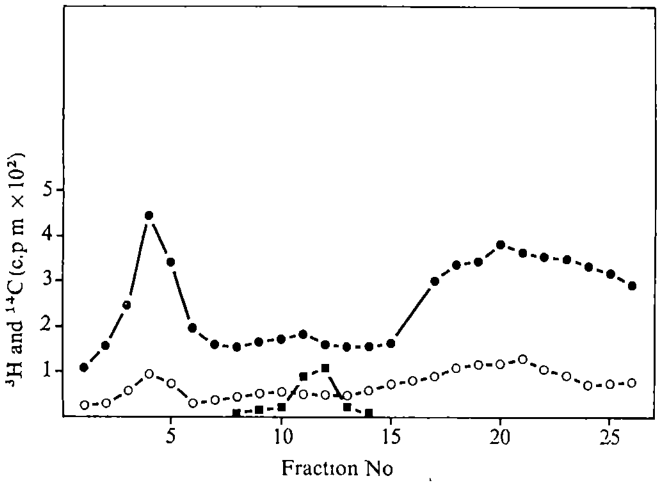

Fig. 3 DNAs from infected or mock-infected cells were first purified by centrifugation in CsCl–ethidium bromide gradients as described in Fig. 2. The two peaks from these gradients (fractions 12 and 15) were then dialysed and sedimented through a neutral 5–20% sucrose gradient for 10 h at 25,000 r.p.m. in an SW27 rotor. Fractions were collected as shown in the figure, and radioactivity measured. A sample of SV40 circular DNA was added to a gradient containing mock-infected cell DNA ●, ^{3}H-DNA from infected cells; ○, ^{14}C-DNA from mock-infected cells; ■, SV40 DNA.

synthesis[4,10,11]. In herpes simplex infection, nucleus-directed macromolecular synthesis is progressively inhibited, and mitochondrial stimulation may reflect the elimination of the nuclear repressor system for mitochondrial DNA replication[11].

That stimulation of mitochondrial DNA synthesis by HCMV is not mediated through a stimulation of nuclear DNA is indicated by the fact that the latter was demonstrated only late in the growth cycle of the virus. Further work is necessary to clarify the relationship between the stimulation of mitochondrial and nuclear DNA.

Although the biological significance of the inhibitory effect of ethidium bromide on the growth of HCMV must remain speculative, two possibilities can be considered. HCMV may require more energy from mitochondria for replication than do other viruses. Alternatively, since, at low concentrations, more ethidium bromide is bound to supercoiled DNAs than to normal double helices[12], the DNA of HCMV may form circular DNA at a certain stage of the replication cycle. In any case it is clear from the data that HCMV acts as a trigger for the stimulation of mitochondrial DNA synthesis and this stimulation may be a necessary factor for subsequent HCMV replication.

Fig. 4 Confluent monolayers of WI-38 cells in Petri dishes (diameter 3 cm) were infected with HCMV. After 1 h absorption, the cells were incubated in media containing various concentrations of ethidium bromide. At the indicated times after infection, ^{3}H-dT was added at a concentration of 1 µCi ml^{-1} for 30 min. Samples to measure radioactivity incorporated into the cells were processed in the same manner as that described in Fig. 1. Infectivity of cell-associated virus was assayed at 4 d after infection. ○, Without drug; □, 0.1 µg ethidium bromide; △, 1 µg ethidium bromide; ●, 5 µg ethidium bromide.

Rhodopsin analogues from highly hindered 7-*cis* isomers of retinal

ALL known visual pigments have as chromophore the sterically hindered 11-*cis* isomer of retinal. Shortly after this was established, an unsuccessful attempt was made to prepare the much more hindered 7-*cis*-retinal by partial reduction of the corresponding 7,8-acetylene[1]. But, four new geometric isomers of retinal, all apparently 7-*cis*, have been synthesised by a six-step non-stereospecific sequence[2]. Structural assignments of the isomers were originally based on spectral data of two fractions of partially separated mixtures of isomers (7-*cis* and 7,9-di*cis*; 7,13-di*cis* and 7,9,13-tri*cis*). Their configurations were, therefore, not completely firm. Since then two of the four isomers (7-*cis* and 7,9-di*cis*) have been isolated by high pressure liquid chromatography (HPLC). Their nuclear magnetic resonance (NMR) spectra unambiguously confirmed the tentative assignments made earlier. That of 7-*cis*-retinal is shown in Fig. 1 as a representative example. The remaining two 13-*cis* isomers remain unseparated in various HPLC conditions. Their structures, however, have since been confirmed through a sterоselective synthesis of 7,9,13-tri*cis*-retinal[3]. We report here preliminary results of the interaction of these 7-*cis*-retinal isomers with cattle opsin.

The ultraviolet absorption spectra of 7-*cis*-, 7,9-di*cis*- and 7,9,13-tri*cis*-retinal are shown in Fig. 2 together with that of all-*trans*-retinal. The relatively small hyposochromic shift of the α-band of the 7-*cis* isomers is consistent with the view of increased non-planarity only near the terminal positions of the polyene chain (that is, about the 6,7-bond) in 7-*cis* isomers[4-7]. Thus, the 7,9,13-tri*cis* isomer has a higher molar absorbance than 11-*cis* (36,600 compared with 26,400 (ref. 8)).

All three isomers were tested with cattle opsin as to their possible formation of 7-*cis* analogues of rhodopsin. Cattle rod outer segment (ROS) membranes were isolated from frozen Hormel retina and stored in buffered solution according to the reported procedures[9,10]. When incubated with opsin in suspen-

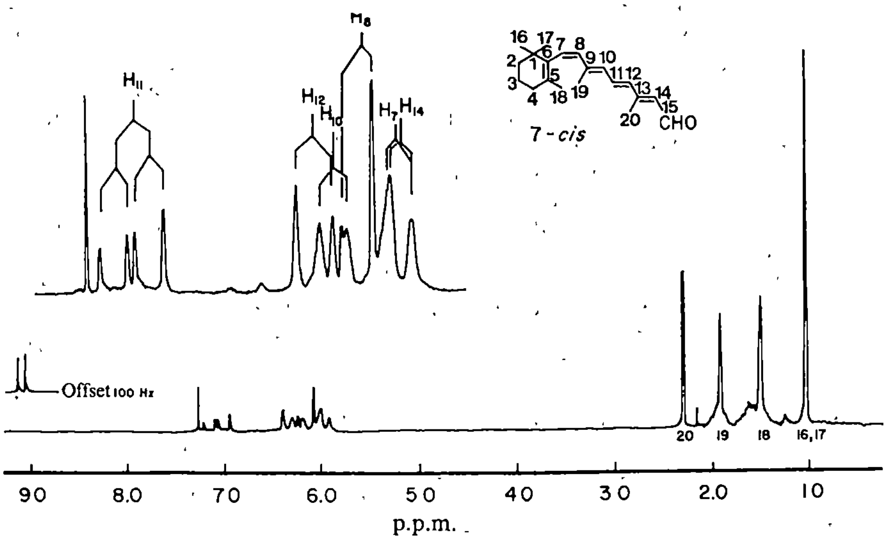

Fig. 1 Fourier-transform NMR spectrum of 7-*cis*-retinal in $CDCl_3$ recorded on a Varian XL-100 spectrometer The inset shows an expansion of the region between δ6 and 7 p.p.m. The 7-*cis* isomers were purified and isolated by HPLC on Corasil II or μ-Porasil columns The major differences between the 7-*trans* and 7-*cis* isomers are the shift of H_{18} and and H_7 from about δ1.7 p.p.m. resp. 6.3 p.p.m. (7-*trans*) to about δ1.5 p.p.m resp. 6.0 p.p.m. (7-*cis*) and the decrease of the coupling constant $J_{7,8}$ from 16 Hz (7-*trans*) to about 12 Hz (7-*cis*)

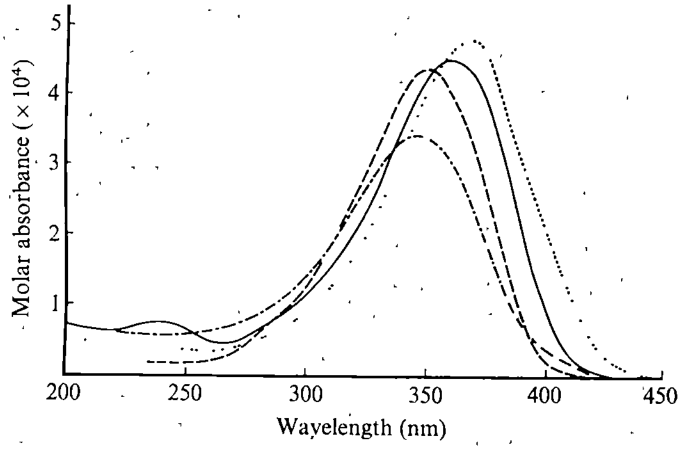
sion or in digitonin solution, the 7-*cis*-retinals as well as the all-*trans* slowly gave new absorption bands near 450 nm. The all-*trans* species, however, is due to random protonated Schiff bases between retinal and the various amoni groups present. With 0.1 M-hydroxylamine these are converted within seconds into retinal oxime (λ_{max} 367 nm), with $NaBH_4$ to retinylamines (λ_{max} 325 nm)[8], while addition of 11-*cis*-retinal immediately generates rhodopsin. On the other hand, the new species formed by all the 7-*cis* isomers are stable in darkness to these reagents. Illumination destroys the 7-*cis* pigments, forming all-*trans*-retinal and opsin. The opsin can again recombine with 11-*cis*-retinal forming rhodopsin.

These data exclude the possibility that the new pigments are due to nonspecific interactions with opsin. The difference spectra before and after illumination in the presence of hydroxylamine show maxima at 450±2 nm (7-*cis*), 460±2 nm (7,9-di*cis*) and 455±3 nm (7,9,13-tri*cis*) (Fig. 3). The rate of pigment formation with the 7-*cis* retinals is only about 1/150 as rapid as with 11-*cis*-retinal.

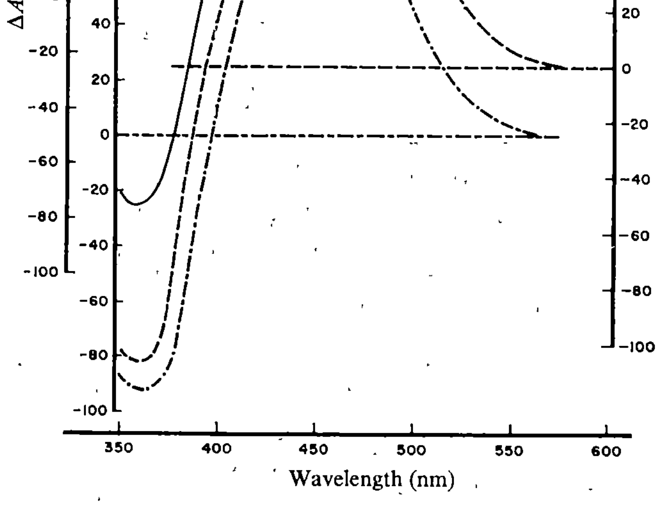
The 7-*cis* photopigments are clearly less stable than rhodopsin. They are bleached in the dark in 1% Triton X-100 or CTAB at room temperature, and seem to have a narrower *p*H-stability profile than rhodopsin. Attempts to purify the new pigments chromatographically have been hampered by this low thermal stability. Preliminary results indicate, however, that the difference spectrum maxima correspond with true absorption maxima. Furthermore, the molar absorbances are not far different from that of rhodopsin.

Fig. 2 Absorbance spectra of all-*trans*-(. . . .), 7-*cis*-(——), 7,9-di*cis*-(- - -) and 7,9,13- tri*cis*-retinal (- · - · -)in *n*-heptane. λ_{max}, in parentheses, and molar absorbance coefficients (last two from ref. 6): all-*trans*, (368) 48,000; 7-*cis*, (359) 44,100; 7,9-di*cis*, (351) 42,500; 7,9,13-tri*cis*, (346) 36,600, 11-*cis*, (365) 26,400, 9-*cis*, (363) 37,700.



Our observations indicate that the active site of opsin is much less exclusive than originally thought. It seems to accept most of the known geometrical isomers of retinal (*cis* at 7-, 9-, 11-, 7,9-, 7,9,13- and 9,13 (ref. 11). Only 13-*cis*- and all-*trans*-retinals do

Fig. 3 Difference spectra of digitonin solutions of the pigments formed from opsin and various 7-*cis* isomers, obtained by subtracting the spectra of the bleached from those of the unbleached pigments in the presence of 0.1 M hydroxylamine. Illumination by a GE 150-W reflector flood light bulb at 35 cm through a 3-cm 6% $CuSO_4$ solution as a heat filter and a Balzers 482-nm interference filter. A mixture of 7,9,13-tri*cis*- and 7,13-di*cis*-retinal (about 1:3) also gives a pigment with a λ_{max} at about 457 nm, indicating that 7,13-di*cis*-retinal also reacts with opsin Although the properties of the new pigments clearly indicate that they are different from each other and from known pigments (rhodopsin, isorhodopsin I, II), we have not yet established rigorously the geometry of the retinals in the new pigments Indirect evidence is our observation that the λ_{max} of the oximes liberated during thermal denaturation in 1% CTAB+0 1 M hydroxylamine corresponds with that obtained with the original retinal isomer (λ_{max} oximes: 7-*cis*, 353 nm; 7,9-di*cis*, 345 nm; 7,9,13-tri*cis*, 344 nm, all-*trans*, 359 nm). ——, 7-*cis*; - - -, 7,9-di*cis*; · - · - · -, 7,9,13,-tri*cis*.



not give rise to special pigments. But the rate of pigment formation and λ_{max} of the resulting pigments differ considerably for the various accepted isomers, 11-*cis* showing by far the highest rate and the largest redshift. As for the 7-*cis* analogues, the low reaction rate, low thermal stability and the smallest redshift observed suggest that conformational changes in the protein and/or the retinals take place in the formation of 7-*cis* pigments and that the final fit involves less interaction between the sidechain of the 7-*cis*-retinals and opsin than in the case of 11-*cis*-retinal. Apparently in the 7-*cis* analogues the protein is in a thermodynamically less stable state and contributes less to the absorbance characteristics of the pigment. The 7,8-*cis* bond introduces a large twist between ring and sidechain and therefore affects the shape of the retinal molecule to a much greater extent than the 9-, 11- or 13-*cis* bonds. This might explain why in the case of 7-*cis* isomers the geometry of the rest of the chain appears to be much less important than in the case of 7-*trans* isomers and has little influence on the reactivity with opsin. As compared with protonated Schiff bases of 7-*cis*-retinals with *n*-butylamine (λ_{max} 410–425 nm in Triton X-100 solution) the 7-*cis* pigments show a smaller redshift (20–25 nm for 7-*cis* and 35–40 nm for the 7,9-di*cis* and 7,9,13-tri*cis*) than those in isorhodopsin and rhodopsin (50–60 nm). Similar to 11-*cis*, we suggest the shifts of the 7-*cis* isomers result from some secondary interaction (but to a lesser extent) between opsin and retinal, which is enhanced by the 9-*cis* geomtetry.

We thank Professor George Wald and Mr Paul Brown for their interest and for facilities. R.S.H.L. expresses appreciation for their hospitality during his stay there. Oxygen and toxicity inhibition of amino acid biosynthesis

ALTHOUGH oxygen is of therapeutic benefit for various human diseases, its usefulness is limited by its toxicity[1,2]. In spite of progress, the cause of the convulsions observed in humans and other animals exposed to hyperbaric oxygen remains unknown[3,4], and the biochemical basis of the lung damage resulting from chronic exposure to increased oxygen tensions is poorly understood[5]. Oxygen toxicity, although necessarily expressed in different ways, affects various life forms from bacteria to man[3,4]. There is considerable theoretical basis and experimental evidence for mechanisms of toxicity shared at the cellular and subcellular levels, and research on basic sites of toxicity has often involved tissue cultures or bacteria[2]. The growth and respiration of *Escherichia coli* is rapidly, but reversibly, inhibited by hyperbaric oxygen in minimal salts medium[6]. Significant protection for some microbes against the growth-inhibitory effects of hyperbaric oxygen has been obtained with nutritional supplements, including yeast extract[7]. We have now found that *E. coli* E-26, the source of which has been identified previously[6], is protected from oxygen toxicity by yeast extract because of its amino acid content: a mixture of 20 amino acids gave similar protection.

A defined basal salts medium containing glucose as the sole carbon source[6] was supplemented with mixtures of the 20 amino acids listed (each 0.65 mM) minus the indicated amino acids. Cultures were adapted to growth in the individual test media with air as the gas phase and grown in small vials with stirring in a vessel which could be pressurised. The vessel was incubated in a constant temperature bath at 37 °C. During exponential growth at an absorbance of 0.1 to 0.2 at 500 nm, the cultures were subjected to a gas phase of 1 atm of air plus 4 atm of oxygen by pressurisation with pure oxygen. After 1 h, the vessel was decompressed. All samples for absorbance measurements were collected in tubes chilled in ice and measured immediately with a Gilford spectrophotometer (the relationship between absorbance and plate colony counts was linear up to 0.8 *A*, all measurements were made below 0.8). Generation times with a gas phase of 1 atm of air were calculated from the slope of best fit relating four determinations of the logarithm of absorbance at 500 nm to minutes of incubation; generation times in hyperbaric oxygen were extrapolated from changes in the logarithm of absorbance during 1 h in hyperbaric oxygen. Values are averages ± s.e. with $n = 8$, except $n = 12$ for methionine and threonine; $n = 4$ for omission of all 20 amino acids, $n = 4$ for omission of 10 amino acids plus threonine, and $n = 4$ for 20 amino acids plus vitamins.

*The quotient obtained by dividing the ratio of the hyperbaric oxygen to air generation times by the value of this ratio with none of the amino acids omitted. This ratio compensates for the differences in growth rates in the various media and is normalised with respect to the protection with all amino acids included. The values of normalised ratios increase as protection of growth in hyperbaric oxygen is reduced.

†Significantly different at $P < 0.05$ from the value obtained with none of the amino acids omitted using Student's *t* test.

‡The amino acids included were: asparagine, cysteine, isoleucine, leucine, methionine, phenylalanine, threonine, tryptophan, tyrosine and valine.

§The amino acids included were the same as indicated in the previous footnote, except that threonine was not included.

¶*p*-Aminobenzoic acid, niacin, and pantothenic acid, each 0.65 mM.

Single deletions of amino acids from the mixture (Table 1) revealed that 10 amino acids were not required for protection against growth inhibition in hyperbaric oxygen, but that deletion of valine, tyrosine, isoleucine, tryptophan, leucine, phenylalanine, cysteine, methionine, asparagine or threonine (listed in order of decreasing effect) caused significant ($P \leqslant 0.05$) loss of the protection afforded by the mixture of 20 amino acids.

The simplest interpretation of these data is that hyperbaric oxygen significantly reduced synthesis of certain amino acids (those which provided protection when included). Presumably, oxygen inhibits specific enzymes involved in synthesis of these amino acids, although proof awaits direct enzyme assay.

To reduce the number of enzymes that might be involved, intermediates of biosynthetic pathways for several amino acids were substituted for the appropriate amino acids to test their ability to protect cells from hyperbaric oxygen (Table 2). α-Ketoisovalerate substituted for leucine (Table 2), suggesting that the pathway, containing four enzymes, from α-ketoisovalerate to leucine, is functional in oxygen-poisoned cells. In the parallel pathway for synthesis of leucine, valine and isoleucine, there is apparently a block (or blocks) in oxygen-poisoned cells of acetohydroxy acid synthetase, acetoxy acid reductoisomerase or dihydroxy acid dehydratase, for α-ketobutyrate did not substitute for isoleucine. Valine transaminase was not sensitive because α-ketoisovalerate substituted for valine. Leucine seemed to be the least critical of the branched-chain amino acids, perhaps because valine transamination is reversible and valine in the medium could provide a source of α-ketoisovalerate for the non-blocked series of reactions leading to leucine synthesis. Valine was among the most critical of the amino acids for protection from oxygen toxicity (Table 1). With valine biosynthesis blocked before α-ketoisovalerate, and no valine in the medium, the cells not only would lack valine for protein synthesis, but could make neither pantothenate nor products (such as coenzyme A) from pantothenate.

The synthesis of cysteine from serine was apparently impaired in hyperbaric oxygen (Table 1). Homocysteine substituted for methionine (Table 2), indicating that inhibition occurred before homocysteine, and that the methyl transferase was relatively insensitive to hyperbaric oxygen. The sensitive site in methionine synthesis probably also accounts for the requirement for threonine during exposure to hyperbaric oxygen (Table 1). Asparagine was apparently required during exposure to hyperbaric oxygen because of inhibition of asparagine synthetase.

The vitamins and vitamin precursor tested (Table 2) revealed no additional protection even though their synthesis was impaired in hyperbaric oxygen (Tables 1 and 2). But failure to synthesise these vitamins probably would not have become growth limiting during the 1 h of exposure.

Explanation of the results obtained with precursors of aromatic amino acids requires consideration of the presence of three isozymes for the production of deoxyheptulosonic acid 2-phosphate and two isozymes for production of prephenic acid, and separate feedback and repression by phenylalanine, tyrosine and tryptophan of the isozymes and the enzyme involved in conversion of chorismate to anthranilate. The permeability of the cell to the intermediates is also a factor. To minimise these problems, cells were preadapted to each different medium before exposure to hyperbaric oxygen.

Shikimate did not substitute for all three aromatic amino acids when absent simultaneously during hyperbaric intoxication, whereas chorismate partially substituted for them (Table 2). This indicated that hyperbaric oxygen significantly impaired the conversion of shikimate to chorismate, but that there was also impairment before chorismate. Deletions of individual aromatic amino acids, with inclusions of each of four intermediates (Table 2), suggested several conclusions. Deletion of phenylalanine decreased protection less than deletion of either tryptophan or tyrosine (Table 2), suggesting that the enzymes in the part of the pathway common to the biosynthesis of all three aromatic amino acids (shikimate kinase, pyruvylshikimate-phosphate synthase or chorismate synthase) were less sensitive than one or more enzymes in the branch pathways from chorismate to tryptophan and tyrosine. There was no significant inhibition of the series of enzymes required for converting anthranilate to tryptophan.

The inconsistency in the failure of prephenate to substitute for phenylalanine (Table 2) could be explained by the known lack of permeability of cells to prephenate. But prephenate apparently penetrated these cells since it reduced the growth inhibition due to hyperbaric oxygen in tyrosine-deprived cells (Table 2). It is conceivable, however, that cells might adapt to prephenate transport when deprived of tyrosine, but not when deprived of phenylalanine.

The inclusion of only the 10 amino acids which, when individually omitted, caused a significant ($P \geqslant 0.05$) decrease in growth in hyperbaric oxygen (Table 1), gave almost as much protection as the 20 amino acids (normalised ratio of 1.38 ± 0.03 compared with 1.00 ± 0.05). The difference between these ratios, however, was significant ($P \geqslant 0.05$), indicating that other

Tryptophan	Anthranilate	29.9±1.2	72.8±2.3	1.35±0.06

Normalised ratio was obtained as described in Table 1

Media and test conditions were as described for Table 1. Precursor concentrations were 0.65 mM except anthranilate (0.5 mM) and shikimate and chorismate (1.3 mM) when substituted for all three aromatic amino acids.

*As for Table 1, except $n = 4$ for all except $n = 8$ for shikimate with phenylalanine omitted, and $n = 11$ for chorismate with tyrosine omitted. Where more than one precursor for a given amino acid was tested, the precursors are listed in the table in the order of their biosynthesis

†As for Table 1.

amino acids, which when omitted singly did not produce significant decrease in protection, may have small protective effects in concert.

The significance of the inhibition of amino acid biosynthesis (which also leads to inability to synthesise nicotinic acid, NAD, NADP, folic acid, pantothenic acid and coenzyme A) is immediately apparent with respect to the growth-inhibitory effects of hyperbaric oxygen for *E. coli* incubated in minimal salts medium, where all its amino acids and the indicated growth factors must be synthesised. The potential significance of these biosynthetic inhibitions for the functioning of mammalian systems is speculative. All the amino acids, except cysteine and asparagine whose biosyntheses were inhibited, are essential for man and rat. The inhibition of synthesis of essential amino acids is obviously irrelevant in higher mammals in terms of protein synthesis and growth. But because of the significant roles of amino acids as precursors for neurotransmitter synthesis, and as neurotransmitters in the central nervous system[8], work is in progress to identify the specific oxygen-sensitive enzymes, and to investigate their potential roles in oxygen toxicity in higher systems.

Reactions involving singlet oxygen and the superoxide anion

In discussing reactions involving the superoxide anion O_2^-, it is generally considered that the radical itself or singlet oxygen generated from O_2^- is harmful to molecules of biological importance[1,2]. Since the demonstration that singlet oxygen participates in reactions is technically difficult, conclusions about its effects are rather speculative. I show here, on thermodynamic grounds, in which reactions singlet oxygen can be formed from O_2^- and in which reactions this is improbable.

By way of illustration I shall use an oxidation state diagram for oxygen at *p*H 7, adapted from Phillips and Williams[3] (see Fig. 1). In this diagram, the free energy per oxygen atom at *p*H 7 ($\Delta G_O'$) is plotted against the formal charge per oxygen atom (n). The ordinate at the left-hand side is related to the one at the right by $\Delta G_O' = nF\Delta E_O'$, in which F is the Faraday. By plotting the values this way, the slope of the line joining the species A and B represents the reduction potential E_O' of the couple A/B. All of the species above the line joining O_2 to H_2O are thermodynamically unstable.

To explain the diagram, I have chosen as examples: the disproportionation of O_2, the Haber–Weiss cycle, the reaction of O_2^- with superoxide dismutase and the reduction of ferricytochrome *c* by O_2^-. First the disproportionation of O_2. O_2^- is not stable; it reacts with itself and forms oxygen and hydrogen peroxide

$$2O_2^- + 2H^+ \rightarrow H_2O_2 + O_2 \qquad (1)$$

where $k = 4.5 \times 10^5\ M^{-1}\ s^{-1}$ at *p*H 7, 22 °C (ref. 7).
Depending on the energy state of the oxygen molecule, the above reaction can have a $\Delta G_O'$ of -29.0 kcalorie ($^3\Sigma_g^- O_2$), -6.4 kcalorie ($^1\Delta_g O_2$) or $+7.6$ kcalorie ($^1\Sigma_g^+ O_2$). Therefore, as the reaction involving $^1\Sigma_g^+ O_2$ has a positive $\Delta G_O'$, O_2^- can be a source of $^1\Delta_g O_2$ but not of $^1\Sigma_g^+ O_2$.

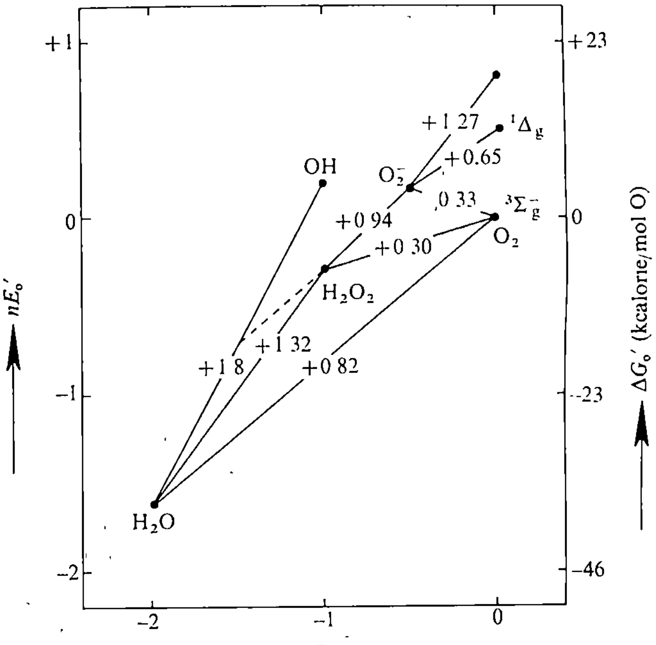

Fig. 1 Oxidation state diagram of oxygen ($P_{O_2} = 1$ atm; $T = 25$ °C) at *p*H 7. Abscissa: formal charge, n, per O atom; ordinate, left: n times reduction potential E_O; right: free energy per oxygen atom at *p*H 7, $\Delta G_O'$. The numbers refer to the slopes of the line E_O' (A/B) denotes the reduction potential of the couple A/B at *p*H 7 under otherwise standard conditions relative to the potential of the normal hydrogen electrode. For this diagram the following data were used: The triangle H_2O_2, O_2 (triplet), O_2^- was constructed using the E_O' values given by Muir Wood[4]. The differences in energy between the $^3\Sigma_g^-$ and $^1\Delta_g$, and between the $^3\Sigma_g^-$ and $^1\Sigma_g^+$ level of oxygen have been given as 22.6 and 37 kcalorie mol^{-1}, respectively[5]. The differences in entropy between the several forms of oxygen can be neglected with respect to the uncertainties in the values of the energy differences. The reduction potentials of the couples H_2O_2/H_2O, OH/H_2O and O_2/H_2O were computed from standard reduction potentials[6].

In 1934 Haber and Weiss[8] proposed a mechanism for the disproportionation of hydrogen peroxide initiated by iron ions. The 'chain' reactions are

$$O_2^- + H_2O_2 + H^+ \rightarrow OH\cdot + H_2O + O_2 \qquad (2)$$

$$OH\cdot + H_2O_2 \rightarrow O_2^- + H_2O + H^+ \qquad (3)$$

Kellog and Fridovich[9] recently postulated that reaction (2) "liberates electronically excited singlet oxygen". Figure 1 shows that this is possible. The reaction can be split up

$$H_2O_2 + H^+ + e^- \rightarrow OH\cdot + H_2O;\ E_O' = +0.8\ V$$

(see dotted line in figure) and

$$O_2^- \rightarrow {}^1\Delta_g O_2 + e^-;\ E_O' = +0.65\ V$$

Since E_O' ($H_2O_2/OH\cdot$, H_2O) is larger than E_O' ($^1\Delta_g O_2/O_2^-$), the formation of $^1\Delta_g O_2$ is possible with $\Delta G_O' = -3.5$ kcalorie. Reaction (3) is also thermodynamically favourable

$$OH\cdot + H^+ + e^- \rightarrow H_2O;\ E_O' = +1.8\ V$$
$$\Delta G_O' = -19.8\ \text{kcalorie}$$

and

$$H_2O_2 \rightarrow O_2^- + 2H^+ + e^-;\ E_O' = +0.94\ V$$

Arneson[10] assumed that singlet oxygen was formed as a product of the chain-terminating reaction

$$OH\cdot + O_2^- + H^+ \rightarrow O_2 + H_2O \qquad (4)$$

It can be shown in the same way that the formation of triplet and both forms of singlet oxygen is possible.

The sum of reactions (2) and (3) is

$$2H_2O_2 \rightarrow O_2+2H_2O \qquad (5)$$

From Fig. 1 it can be seen that hydrogen peroxide is unstable even with respect to $^1\Sigma_g{}^+O_2$ and H_2O: $\Delta G_0' = -5.0$ kcalorie per mol H_2O_2. In the Haber–Weiss cycle, however, $^1\Sigma_g{}^+O_2$ cannot be formed. This may be because the energy released in reaction (3) is not available for the excitation of oxygen.

Superoxide dismutase (SOD) reacts with $O_2{}^-$ at an almost diffusion-controlled rate ($k = (2.37\pm0.18)\times10^9$ M^{-1} s^{-1})[11]. The proposed mechanism is

$$\text{SOD–Cu}^{2+}+O_2{}^- \rightarrow \text{SOD–Cu}^{+}+O_2 \qquad (6)$$

$$\text{SOD–Cu}^{+}+O_2{}^-+2H^+ \rightarrow \text{SOD–Cu}^{2+}+H_2O_2 \qquad (7)$$

The reduction potential of the couple SOD–Cu^{2+}/SOD–Cu$^+$ (+0.42 V (ref. 12)) is too low to oxidise $O_2{}^-$ to $^1\Delta_gO_2$. The energy liberated by reaction (6) is 17.1 kcalorie and that from reaction (7) is 11.9 kcalorie. It has been argued[13] that superoxide dismutase also catalyses the conversion of $^1\Delta_gO_2$ to $^3\Sigma_g{}^-O_2$: $\Delta G_0' = -22.6$ kcalorie per mol O_2. It is not yet known whether this energy is dissipated over the protein molecule and finally transduced to water molecules, or whether is it used for a thermodynamically unfavourable reaction. Apparently the superoxide dismutase molecule can receive energies up to 22.6 kcalorie per mol SOD in single-step reactions without damaging itself. This is probably the reason why only one copper ion at a time is active, as the simultaneous reduction of both copper ions by $O_2{}^-$ would liberate 34.2 kcalorie per mol SOD.

Under suitable conditions ferricytochrome *c* reacts[14] with $O_2{}^-$ (Koppenol and Van Buuren, unpublished). The couple ferri-/ferrocytochrome *c* has a reduction potential of +0.26 V at *p*H 7 (ref. 15). This value is not high enough to cause $^1\Delta O_2$ to be formed. Measurements of the enzymatic activity after reaction with $O_2{}^-$ indicate that the protein is still in its native form (Koppenol and Van Buuren, unpublished).

It is clear that when $O_2{}^-$ reacts with a molecule it can act both as an oxidising or a reducing agent. It is possible that a protein can be damaged by such a reaction, but there is not much evidence for this in the literature[1].

It is unlikely that either of the forms of singlet oxygen will be produced if $O_2{}^-$ reduces the protein molecule, as there are hardly any proteins with redox potentials as high as +0.65 V. Poupko and Rosenthal[16] have reached the same conclusion, but their arguments have to be reconsidered, as they assumed that the ground state of $O_2{}^-$ lies below that of oxygen. This assumption was based on a measurement in the gas phase[17] and is not applicable to reactions in solution.

If $O_2{}^-$ does not react with the protein it is possible that $^1\Delta_gO_2$ and H_2O_2 will be formed by reaction (1). This form of oxygen can react with various groups, for instance unsaturated bonds, and therefore has a destructive effect on the protein. It may be therefore that the main function of superoxide dismutase is to prevent the production of $^1\Delta_gO_2$ by reacting with $O_2{}^-$.

I thank K. J. H. van Buuren, G. H. J. Broers and J. Butler for discussion and comments during the preparation of this paper.

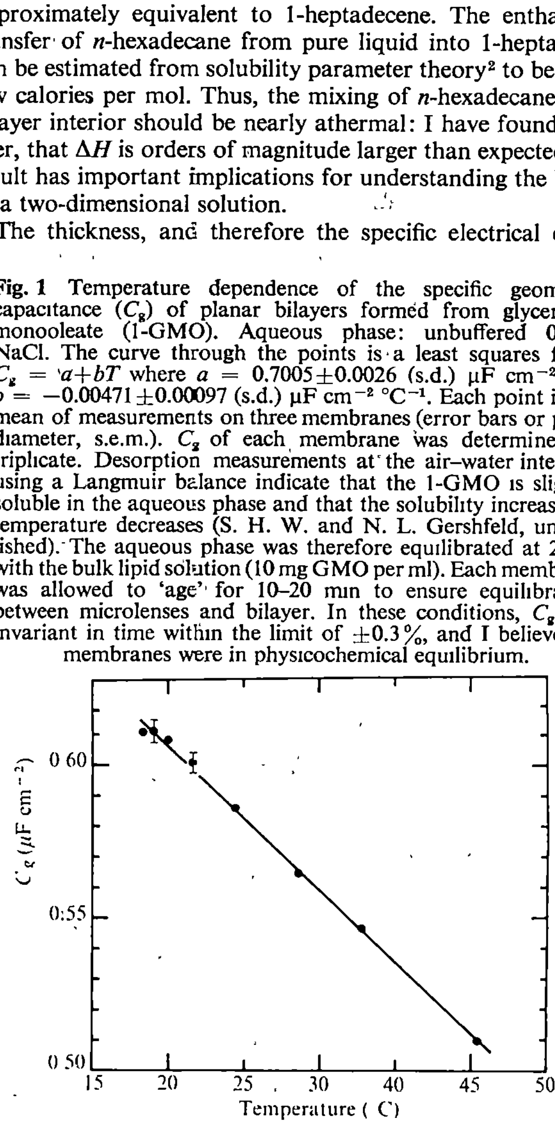
The lipid bilayer as a 'solvent' for small hydrophobic molecules

THE cell membrane is viewed at present as a two-dimensional solution in which the lipid bilayer acts as a viscous 'solvent' for oriented integral proteins[1]. Accepting this model as a working hypothesis, questions arise as to the nature of the hydrophobic interior of the bilayer and what rules proteins, lipoproteins, or polypeptides obey in interacting with it. The simplest hypothesis for the interior is that it is equivalent to a bulk alkyl solvent (albeit a very thin one). If this hypothesis is correct, the enthalpy of transfer (ΔH) of a solute molecule (for example, an alkane) from a bulk alkyl solvent to the bilayer interior should be small. That is, the solute–solvent interaction energy should be about the same in the bilayer as in the bulk alkyl. I have examined this hypothesis experimentally by measuring the solubility of *n*-hexadecane in planar bilayer membranes formed from glycerol-1-monooleate (1-GMO). The acyl chain of 1-GMO is approximately equivalent to 1-heptadecene. The enthalpy of transfer of *n*-hexadecane from pure liquid into 1-heptadecene can be estimated from solubility parameter theory[2] to be only a few calories per mol. Thus, the mixing of *n*-hexadecane in the bilayer interior should be nearly athermal: I have found, however, that ΔH is orders of magnitude larger than expected. This result has important implications for understanding the bilayer as a two-dimensional solution.

The thickness, and therefore the specific electrical capaci-

Fig. 1 Temperature dependence of the specific geometric capacitance (C_g) of planar bilayers formed from glycerol-1-monooleate (1-GMO). Aqueous phase: unbuffered 0.1 M NaCl. The curve through the points is a least squares fit to $C_g = a+bT$ where $a = 0.7005\pm0.0026$ (s.d.) μF cm^{-2} and $b = -0.00471\pm0.00097$ (s.d.) μF cm^{-2} °C^{-1}. Each point is the mean of measurements on three membranes (error bars or point diameter, s.e.m.). C_g of each membrane was determined in triplicate. Desorption measurements at the air–water interface using a Langmuir balance indicate that the 1-GMO is slightly soluble in the aqueous phase and that the solubility increases as temperature decreases (S. H. W. and N. L. Gershfeld, unpublished). The aqueous phase was therefore equilibrated at 20 °C with the bulk lipid solution (10 mg GMO per ml). Each membrane was allowed to 'age' for 10–20 min to ensure equilibration between microlenses and bilayer. In these conditions, C_g was invariant in time within the limit of ±0.3%, and I believe the membranes were in physicochemical equilibrium.



tance, of planar bilayer membranes[3] depends strongly on temperature[4,5], because the bilayer concentration of alkane solvent (used to form the bilayer) is temperature dependent. The bilayer is believed to be in physicochemical equilibrium with the bulk Plateau–Gibbs border (annulus) surrounding it and numerous microlenses[6,7] of excess solvent trapped within it. Consequently, the planar bilayer may be viewed as a bilayer solution at saturation equilibrium with bulk alkane. Therefore, if the composition of the bilayer is measured as a function of temperature, the thermodynamics of transfer of alkane from the bulk state (microlenses and annulus) to the bilayer interior can be estimated using standard equations for saturated solutions[2]. In this way, the interior of the bilayer can be compared directly with the interior of the bulk alkane solvent.

I estimated bilayer composition at various temperatures from measurements of specific geometric capacitance (C_g) using methods described in detail elsewhere[5,8–10] (see Fig. 2 for summary), and the results at equilibrium conditions are shown in Fig. 1. The points can accurately be fitted with a straight line ($r = -0.9987$). The mole fraction (X_S) of *n*-hexadecane was calculated for each point and $\ln X_S$ plotted against $1/T$ and $\ln T$ (Fig. 2*a* and *b*). The enthalpy (ΔH) and entropy (ΔS) of transfer of hexadecane from bulk to bilayer were calculated from these plots and found to be $+3.79 \pm 0.10$ kcalorie mol^{-1} and $+12.6 \pm 0.3$ entropy units (EU) respectively.

These large values of ΔH and ΔS indicate that the *n*-hexadecane molecules are not bound as tightly in the bilayer as in bulk and that they have more motional freedom. One explanation is that, in general, the cohesive forces in the bilayer are not as large as in bulk. The work of Gershfeld and Pagano[12] and Katz[13] however, indicates that the cohesive forces between acyl chains in monolayers and bilayers are the same as in bulk. An alternative explanation is that the hexadecane molecules are located largely in the deep interior[5,7] of the bilayer between the monolayers. Numerous X-ray diffraction studies of bilayers reveal a zone of low electron density in the bilayer mid-plane due to the methyl ($-CH_3$) groups (see, for example, ref. 18). There is thus little interdigitation between the apposed monolayers and a well defined interface must exist between the monolayers. Because the methyl groups have a lower polarisability than methylene ($-CH_2-$) groups, molecules located chiefly in the mid-plane should be subjected to smaller van der Waals' cohesive forces than if they are located parallel to methylene-rich acyl chains within the monolayers. Some hexadecanes must, of course be situated within the monolayers, but simple calculations show that these probably account for $\leqslant 20\%$ of the total

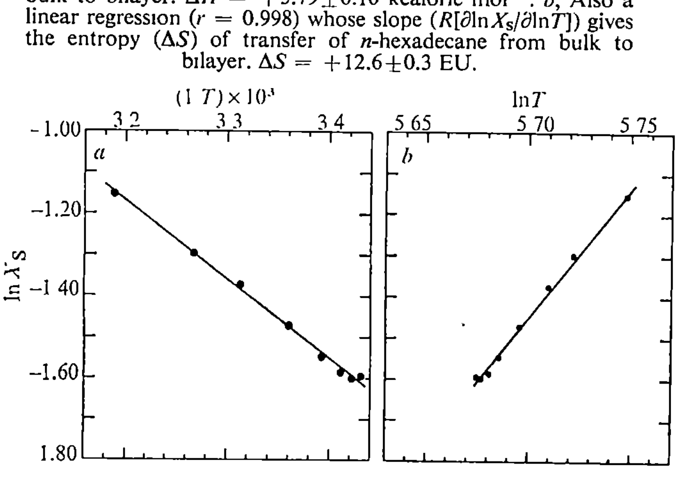


Fig. 2 Temperature dependence of the composition of GMO–hexadecane membranes in a plot of *a*, $\ln X_S$ against $(1/T)$ and *b*, $\ln X_S$ against $\ln T$, where X_S is the mole fraction of *n*-hexadecane in the bilayer. X_S was estimated from the values of C_g using standard techniques[5,10]. Briefly, bilayer thickness δ_B was calculated from $C_g = \varepsilon_0 \varepsilon_B / \delta_B$ where $\varepsilon_0 = 8.85 \times 10^{-14}$ F cm^{-1} and ε_B is the dielectric coefficient of the hydrophobic core. X_S can be calculated straightforwardly using the bulk densities and dielectric coefficients of the acyl chains (AC) (ref. 17) and hexadecane solvent (S), the number n_{AC} of acyl chains per unit area of bilayer, and the equations $\delta_B = v_{AC} n_{AC} + v_S n_S$, $X_S = n_S/(n_S + n_{AC})$; v represents molecular volume. Fettiplace *et al.*[10] and Pagano *et al.*[11] have reported values for n_{AC} at single temperatures; I estimated values at other temperatures using correction procedures similar to those described elsewhere[5]. The corrections are slight and the errors incurred without them are small. At 20 °C, $n_{AC} = 5.26 \times 10^{14}$ cm^{-2} (ref 10) and $X_S = 0\ 205$. *a*, The curve is a linear regression ($r = -0.998$) whose slope ($-R[\partial \ln X_S / \partial (1/T)]$) gives the enthalpy ($\Delta H$) of transfer of *n*-hexadecane from bulk to bilayer. $\Delta H = +3.79 \pm 0.10$ kcalorie mol^{-1}. *b*, Also a linear regression ($r = 0.998$) whose slope ($R[\partial \ln X_S / \partial \ln T]$) gives the entropy ($\Delta S$) of transfer of *n*-hexadecane from bulk to bilayer. $\Delta S = +12.6 \pm 0.3$ EU.

I therefore propose that the mid-plane of the bilayer is a special region because of the high concentration of methyl groups with smaller cohesive forces than found between the methylenes of the acyl chains. Support for this hypothesis is given by Dean and Hayes[15] who measured the heat of sorption of hexane vapour on close-packed stearic acid monolayers at the vapour–water interface. At low partial pressures of hexane (that is, low surface coverage by adsorbed hexanes), the heat of sorption is 4.5 kcalorie mol^{-1}. At high partial pressures (high surface coverage approaching closest packing of hexanes on the stearic acid surface) the heat of sorption becomes identical to the heat of vaporisation of liquid hexane (7.5 kcalorie mol^{-1}). This indicates that the exposed $-CH_3$ surface of the stearic acid does not attract the hexanes as strongly as the fully covered hexane surface or bulk liquid.

Experiments are in progress to examine the thermodynamics of transfer of other alkanes into bilayers containing various acyl chains. Preliminary data for tetradecane–GMO bilayers give values of $\Delta H \simeq 1.2$ kcalorie mol^{-1} and $\Delta S \simeq 4$ EU at 25 °C. The trend of the data suggests that shorter alkane molecules experience cohesive forces closer to bulk values. One reason for this is the larger volume fraction of the bilayer occupied by the smaller alkanes[5,10] which means more nearest-neighbours will be alkanes rather than acyl methyl groups. Results[14] on the solubility of hexane in various phospholipids indicates that significant differences can be expected among different types of acyl chains, and also that the interior of phospholipid bilayer dispersions is different from bulk alkyl solvents.

Finally, I should add that the results reported here for hexadecane depend on the assumptions made about how much the area per molecule of GMO varies with temperature. If the changes are large compared with those used to calculate X_S, then ΔH and ΔS could be much larger. Using a *de novo* method of calculating bilayer composition which predicts relatively large changes in area per molecule[16], I have calculated $\Delta H \simeq +9$ kcalorie mol^{-1} and $\Delta S \simeq 30$ EU. Thus, the values reported here probably represent lower limits.

I thank Dr Sidney Simon for useful and enjoyable discussions and my family for their patience. The research was supported by grants from the NIH and the NSF. The generous support of the Guggenheim Multiple Sclerosis Foundation is also appreciated.

matters arising

Quantification of secondary and tertiary structure base pairs in *E. coli* tRNA$_1^{Val}$

NUCLEAR magnetic resonance (NMR) is useful in the investigation of the base-pairing structure of tRNAs in solution because each Watson–Crick base pair and some tertiary structure base pairs give rise to resonances in the low field (11–15 p.p.m.) region of the spectrum[1,2] To determine the total number of base pairs present in tRNA it is necessary to integrate the low field NMR spectrum We have not been satisfied with previous methods[3-6] used to integrate tRNA spectra and present here a new method, based on using resonances in the aromatic region of the NMR spectrum. More accurate integration became necessary after X-ray diffraction results indicated that there are several tertiary structure base pairs[7,8] in tRNA and after we found evidence for four common resonances in the low field region where are due to tertiary structure interactions[2].

In Fig. 1 the low field NMR spectrum of *Escherichia coli* tRNA$_1^{Val}$ is compared with the resonances in the aromatic region of the spectrum in identical experimental conditions. The intensity in the aromatic region (8.5–6.5 p.p.m.) should correspond to 89 protons (one from each C,G,U and two from each A) and a comparison of the integrated intensity in the two regions indicates there are 23 ± 1 resonances (base pairs) in the low field spectrum. To check the method, we compared relative intensities in the aromatic (8.5–6.5 p p.m.) and ribose regions (6 0–5.0) and found they agreed (± 5%) with the value computed on the basis of sequence. Before commenting on these results, we will first discuss other methods which have been used and state why we believe that the use of the aromatic resonances is superior.

One method previously used by us and others to integrate tRNA spectra was to assume that one (or more) partially resolved resonance in the low field region of the spectrum has a known intensity, and then to use this resonance to calibrate the intensity of the rest of the spectrum[3-6]. One problem is that it is not possible to prove that the reference resonance corresponds to the assumed intensity. Another major problem arises from the Lorentzian line shape of the resonances. For example, for a resonance with a full half width ($\Delta\nu_{1/2}$) of 20 Hz, it is necessary to integrate over $6\Delta\nu_{1/2}=$ 120 Hz to include 90% of its intensity To include >95% of the intensity, the integration must be over $12\Delta\nu_{1/2}$, or 240 Hz If neighbouring resonances are located within 2–4$\Delta\nu_{1/2}$, there are additional problems with the allocation of intensity in the overlap region. Because of contributions from the Lorentzian tails, resolved resonances seem to have less intensity than do resonances which are bunched together. Therefore, if a resolved resonance is used as the intensity standard, the total intensity in the rest of the spectrum will seem to be larger by about 10%. When the collection of aromatic resonances are used as the intensity standard, however, the integration includes a relatively wide spectral range (10–20$\Delta\nu_{1/2}$) and tails of various resonances add together to give a reliable value for the total intensity. It is possible that the line shapes of the resonances observed in tRNA are not Lorentzian (as a result of incomplete motional narrowing, exchange or magnetic field inhomogeneity). A number of tRNA spectra have been simulated through the use of Lorentzian lines and, to within the limitations of experimental signal-to-noise ratio, the lines seem to be Lorentzian. Magnetic field inhomogeneity does not contribute to the line shape with the spectrophotometer we used.

Methyl resonances have also been used as internal standards to calibrate the intensity in the low field spectra[5], but, in addition to the problems already mentioned, there are complications caused by impurities[9] and undermethylation[10]. Impurities in the methyl region can be difficult to detect and the presence of a small amount of contamination can lead to larger percentage errors when this region is used as the integration standard rather than the aromatic region.

We have eliminated these problems by using the aromatic resonances as

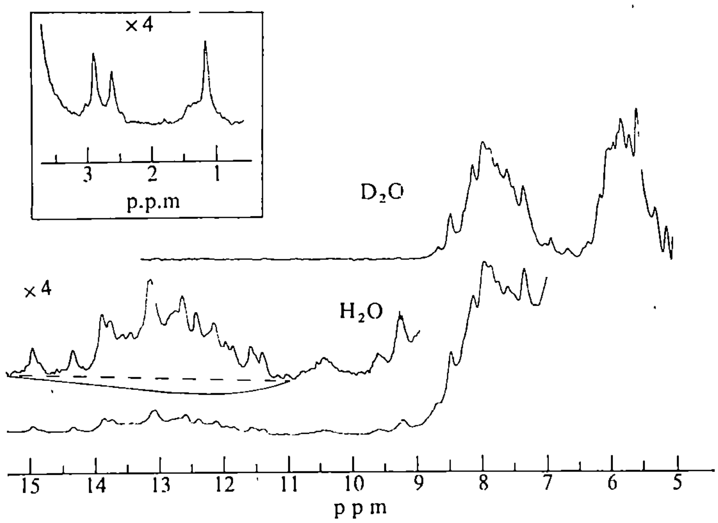

Fig. 1 300-MHz spectrum of tRNA$_1^{Val}$ in various experimental conditions. The spectrum at the bottom is that of tRNA^{Val} in normal NMR conditions, that is, dialysed against 0.1 M NaCl, 10 mM $MgCl_2$ and 10 mM $K_2H_2PO_4$ *p*H 7.0. These spectrum of the methyl region was also obtained in those conditions. The sample was then dried to $\frac{1}{3}$–$\frac{1}{4}$ of its original volume and then returned to its original volume with D_2O. This procedure was repeated several times until the sample was 95–98% D_2O. The spectrum of the aromatic region was obtained with the D_2O sample in experimental conditions identical to those for the H_2O sample. The methyl region of the spectrum was also investigated for the D_2O sample and the intensity compared with that of the H_2O sample. It was found to be within 5% indicating that there was no loss of the sample during the solvent change The aromatic region contains 89 protons. Using the dashed baseline the low field region contains 23 protons, whereas use of the solid baseline gives an intensity of 26 protons for the low field region.

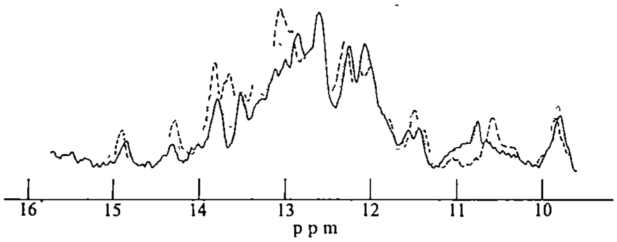

Fig. 2 300-MHz NMR spectrum of *E. coli* tRNA$_1^{\mathrm{Val}}$ in the presence of various amounts of magnesium at 35 °C. The sample was prepared by dissolving desalted tRNA in 0.1 M NaCl, 10 mM K_2H_4PO *p*H 7.0. The intensities of the spectra correspond to 20 ± 1 (no Mg, ——), 21.5 ± 1 (5 mM Mg, · ·) and 23 ± 1 (15 mM Mg, - - -) protons per molecule.

the intensity standard. the signal-to-noise ratio is excellent, there are no problems from impurities, and a large collection of resonances covering some 600 Hz are used to integrate a low field spectrum spanning 900 Hz.

The results with tRNA$_1^{\mathrm{Val}}$ corroborate our earlier suggestion that, in the presence of adequate levels of magnesium (or at sufficiently low temperatures), most *E. coli* tRNA contain 3–4 additional low field resonances due to tertiary structure base pairs[2]. Our result for tRNA$_1^{\mathrm{Val}}$ (23 ± 1) is slightly lower than that (26 ± 1) recently obtained by Reid and Robillard[5] using methyl and low field resonances as integration standards.

The results with *E. coli* tRNA$_1^{\mathrm{Val}}$ indicating the presence of 3–4 extra resonances in addition to those expected from the cloverleaf secondary structure, disagree with our earlier integrations on other tRNA which indicated that the total number of base pairs is somewhat lower (typically around 20)[1,3,4]. The spectra in Fig. 2 illustrate the effect of magnesium on the low field spectrum of tRNA$_1^{\mathrm{Val}}$. As the magnesium level is increased, the intensity in the low field region increases and most of this increase is at positions previously assigned to resonances from common tertiary interactions[2]. By comparing spectra obtained with low and high levels of magnesium present, we estimate that half of the error in our previous integrations was a result of the low level of magnesium we used. The other half of the error can be attributed to the less accurate integration methods used.

Since this paper was submitted, we have re-examined a number of the tRNAs which we originally studied, and find that with higher magnesium levels and our new method of integration, most of the tRNAs contain 3–4 resonances in the low field region (11.5–15 p.p.m.) in addition to those expected from the cloverleaf secondary structure. Details of this work will be presented elsewhere.

REID REPLIES—Bolton and Kearns[1] take exception to our interpretation[2] of the NMR spectrum of tRNA$_1^{\mathrm{Val}}$. Part of their problem arises from the poor resolution in their spectra which is due to either magnetic inhomogeneity or sample impurity, or both. The bumps and shoulders in their spectrum are clearly recognisable as the individually resolved resonances in our spectra[2], but unfortunately cannot be integrated separately in the Bolton and Kearns spectrum[1]. They also object to our use of several resolved single resonances as unit intensities, but we have already pointed out why these resonances cannot contain two protons[2]. More serious objections can be raised concerning the Bolton and Kearns method of integration, which they presumably adopted as a result of their poor spectral resolution. First, the statement that the 8.5–6.5-p.p.m. region should contain 89 protons (the G aromatic proton, both A aromatic protons and one of the two aromatic protons of C and U) has not been verified experimentally and makes the dangerous assumption that no aromatic protons are shifted upfield or downfield out of this region by local ring current effects and that no ribose protons are shifted downfield into this region from the adjacent 'ribose region'. Second, their method of calculating the low field intensity suffers from the inaccuracies inherent in comparing two large numbers. In spite of these problems they have established an intensity that is within 4 protons of the correct value

The fact that Kastrup and Schmidt's samples are contaminated with quaternary ammonium salts from RPC5 (ref. 3), and that careful chromatography resolves (and removes) undermethylated tRNA species[4], is not relevant to either our spectra or our samples.

As Bolton and Kearns admit, the presence of several tertiary base pair resonances in tRNA spectra is in disagreement with their earlier integrations; it is also in disagreement with recently published integrations from that laboratory[4–6] of spectra obtained in the presence of excess magnesium. Since these studies did not acknowledge the presence of tertiary resonances, one can seriously doubt the interpretations made from the observed changes in the NMR spectra.

Finally, I would also add that we are well aware of the Lorentzian nature and line shape of NMR resonances.

Matters arising

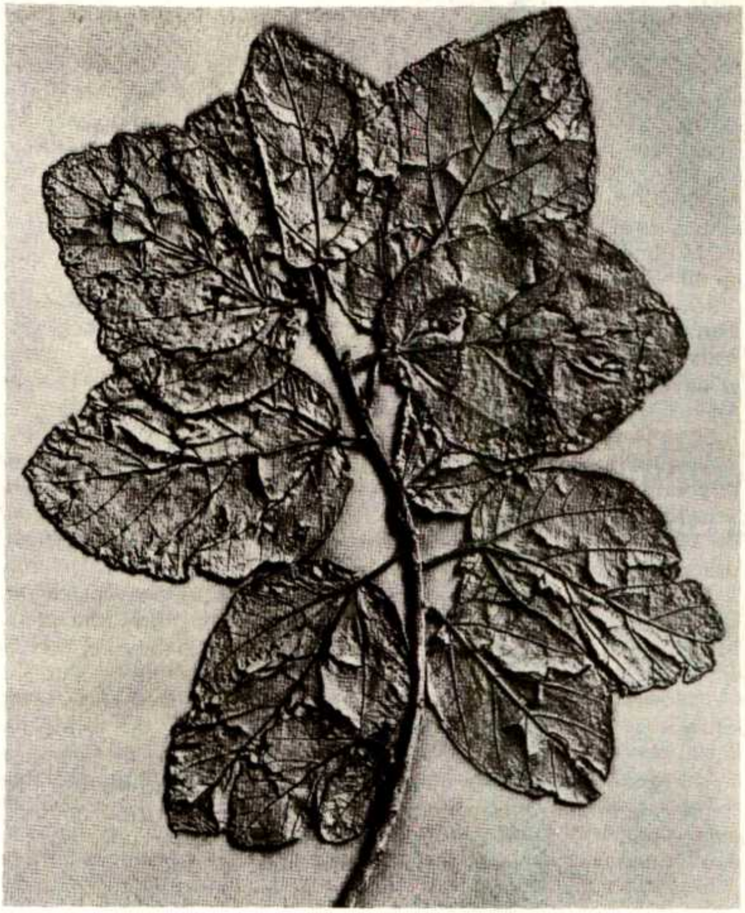
Matters Arising is meant as a vehicle for comment and discussion about papers that appear in *Nature*. The originator of a Matters Arising contribution should initially send his manuscript to the author of the original paper and both parties should, wherever possible, agree on what is to be submitted. Neither contribution nor reply (if one is necessary) should be longer than 300 words and the briefest of replies, to the effect that a point is taken, should be considered.

reviews

Waters of the Nile

Malcolm Coe

The Nile: Biology of an Ancient River. (Monographiae Biologicae, Vol. 29.) Edited by Julian Rzóska. Pp. 417. (Junk: The Hague, 1976.) Dutch Guilders 120.



Branch of sacred sycomore or mulberry fig (*Ficus sycomorus*) from a 20th dynasty Egyptian tomb. The tree is "not indigenous but (has been) cultivated in Egypt since times immemorial. It originates from Arabia and Somaliland. Its ancient name was Nehet-entep, and its fruits have been found in tombs of all ages, the earliest from the first dynasty. It was dedicated to Hathor, the Goddess of love and marriage. Even today a vestige of this belief can be seen in the custom of women visiting the sycamore when troubled by matrimonial cares".

No other river in the world can be as closely woven into the history of mankind as the Nile, sweeping for 32 degrees of latitude from the Equator to the Mediterranean. Such prehistoric and historic associations have been largely due to the fact that the "fluviatile" civilisations that have come and gone along its banks have been dependent not only on its life-giving waters but also on the huge and fertile silt burdens that it has carried from the interior of this vast continent.

For us today the memory of Baker, Burton, and Speke who sought to find the source of the Nile are still comparatively fresh, yet the Nile's origins in snow-covered mountains (the Mountains of the Moon) are almost as old as human written history itself.

The history of the Nile valley begins with the regression of the Mediterranean in the Upper Miocene when about 5.5 Myr ago the sea dried up completely and as a consequence of this low sea bed level the resulting intense erosion led to the formation of the Nile valley. Later the great tectonic and climatic events of the Pleistocene resulted in great changes in the southern water sources, leading eventually to the formation of the Neonile about 30,000 yr ago. In spite of the long history of a 'Nile System', however, the river as we know it today is probably no older than 12,500 yr and possibly even as young as 10,000 yr.

Since this vast artery passes for about two-thirds of its length over arid (water-limited) country, the flora and fauna of much of its surroundings stands in stark contrast to the largely detritus-based biota of the river itself.

The fish fauna of the Nile has for so long formed an important item of diet for the civilisations that have waxed and waned along its banks. In all, the river and lakes located at its origins comprises some 320 species of fish of which 62% of them are endemic.

The problems related to development in the desert environment concern not only the problems of huge silt burdens but also concomitant biological effects such as the invasion of the water hyacinth *Eichhornia crassipes* and the spread of the mollusc vectors of schistosomiasis.

Julian Rzóska has brought together a team of distinguished authors who have described the history, geomorphology, hydrology and biology of this great river and its environs in great detail.

The first four chapters deal largely with the history and prehistory of the Nile system, and later sections describe in detail the biotic and abiotic components of the system and its constituent parts.

Although most of this book is concerned with describing the main biotic and abiotic components of this important system, it is inevitable that a vital part must deal with the effects of human interaction, particularly with regard to the Aswan High Dam.

Considering the huge problems that have faced the editor in attempting to condense such a vast assemblage of data this book will be a valuable source for all students of tropical limnology. If the presentation has a failing it is that the fragmentation under such a large number of chapter headings makes it difficult to view the Nile system as a whole rather than its constituent parts. ☐

Cost–benefit analysis for pesticides

Pesticides: Boon or Bane (Environmental Studies.) By M. B. Green. Pp. x+111. (Elek: London, May 1976.) £2.95.

THIS short book is intended primarily for use in university courses of environmental studies, and by those who are professionally involved with pesticides —farmers, industrialists and legislators. The author is involved in the development of new crop protection products by Imperial Chemical Industries.

The subject of gains and losses from the use of pesticides is developed round the theme of cost–benefit analysis, which is clearly distinguished from investment appraisal. Some of the difficulties are rather glossed-over. How does one optimise costs and benefits for the community as a whole? Those individuals and groups who bear the external losses often gain no compensation except the altruistic satisfaction that their loss is sombody else's gain. Nor is a detailed example given, so that the subject lacks a feel of reality. Does, for example, control of red spider mite count as a credit or debit? Doubtless orchards sprayed to control red spider mite show a profit over those not so sprayed, but this mite only became a pest after insecticides were used.

The quantitative evidence presented for the agricultural benefits of pesticides is disappointing. Figures are given for both Great Briatin and the USA of increases in crop yield, during recent decades, but this will depend on many things besides pesticides—for example, fertilisers, new plant varieties, and irrigation. Estimates are given, mostly for the USA, which has more severe pest problems than we do in Great Britain, for the financial gain from use of pesticides, albeit with no standard error or other indication of these estimates' reliability. The only example for Great Britain (chapter 4) quotes work by Wheatley and Coaker to show that, for at least 30% of the Brussels sprouts grown in 1968/69, increased use of pesticides would have increased the financial loss.

Discussion of biological effects is very limited: virtually no discussion of pest resurgence, development of resistance to pesticides, or of the creation of new pests. The chapter on effects on wildlife is distinctly misleading.

Most of us are probably agreed that pesticides have an important role. This book shows how this role is seen by a scientist whose job it is to produce them. **F. Moriarty**

Dr F. Moriarty has worked at Monks Wood Experimental Station since 1964. His research has been concerned principally with the biological effects of pollutants, especially organochlorine insecticides, on wildlife.

Developments in differentiation

Eukaryotes at the Subcellular Level: Development and Differentiation. (Methods in Molecular Biology.) Edited by Jerold Last. Pp. x+460. (Dekker: New York and Basel, January 1976.) $32.50.

MESSENGER RNA (mRNA) metabolism is one of the important control points in the information flow from DNA to protein. In studies of development and differentiation therefore it is often desirable to measure the concentration or turnover of specific mRNAs. Until recently this could not be done because the concentrations were below the threshold of detection using the available methods. Two developments have altered the situation: first, the purification of specific eukaryotic mRNAs; second, the copying of mRNA by reverse transcriptase. As P. J. Williamson puts it in his chapter on nucleic acid hybridisation methods: "Mother Nature, working in collaboration with Temin and Baltimore, provided the key to an assay in an enzyme from RNA tumor viruses that copies RNA into DNA". By following the instructions in this manual, other research workers should likewise be able to make pure mRNA templates and complementary DNA, sensitive to as little as 1 pg of specific RNA or DNA, which is sufficient for many purposes.

This book strikes a good balance between highly specialised information, peculiar to the differentiating systems at the focus of individual chapters, and more general methods. The latter include the isolation, separation characterisation and transcription of mRNA, and the use of nucleic hybridisation kinetics. The authors place due emphasis on various ways which have been found to avoid common pitfalls, for example, the synthesis of incomplete chains *in vitro*, polypeptides in the case of the popular wheat germ translation system (used to assay messenger activity), or DNA copies of mRNA in the case of reverse transcriptase. Mother Nature does not always collaborate with molecular biologists in her distribution of enzymes. Consequently, readers will appreciate the tips for eliminating or suppressing unwanted nucleases in various preparations. A high degree of specificity is required for many of the bioassays. Nonspecific precipitation can invalidate the results obtained using antibodies to characterise the products of *in vitro* translation, and several authors describe how they keep this to a minimum. A certain overlap between chapters concerning these tricky areas of experimentation is if anything helpful.

The mass of detail on gel electrophoresis of RNA and protein, repeated for a number of systems, is perhaps excessive, especially in view of the abundance of earlier reviews. On the other hand, there is too little space devoted to the manipulative aspects of hybridisation, particularly when the use of small (2 μl) reaction mixtures in capillaries is recommended. The editor rightly celebrates the use of immunoprecipitation to isolate specific polysomes for purification of the less abundant messengers. It was disappointing, however, not to find this method represented anywhere in the text, not even for the isolation of ovalbumin mRNA, which nicely demonstrates its potential. It was refreshing to read about biological systems as diverse as the insect chorion, slime moulds, red blood cells, lung, muscle and oviduct, in successive chapters. One important system is conspicuous by its absence; much progress has been made with immunoglobulin mRNA, and methods used in this work are sufficiently specialised to merit description.

The book is valuable as a timely source of information about *new* methods in molecular biology which are not collected together elsewhere. Like sucrose gradient centrifugation, the new methods will be of enduring value to future molecular biologists. The material in this book is well organised and thoroughly cross-referenced. My only complaint about this, the eighth in the series, is the grouping of the Figures at the ends of the chapters. To use this manual effectively, the reader must be dextrous in using his fingers to mark the appropriate parts of the text, the Figures, and the references, while turning the pages with his right hand. I am glad to possess this book: there should soon be many well-stained copies on laboratory benches everywhere. **H. J. Gould**

Dr Gould is a lecturer in the Department of Biophysics at King's College, University of London, UK.

Scientific approach to art

Beyond Aesthetics: Investigations Into the Nature of Visual Art. Edited by Don Brothwell. Pp. 212+80 photographs. (Thames and Hudson: London, May 1976.) £9.50.

THE writers of the 12 essays collected here have tried to be objective about the visual arts. The task was fairly easy for two of them. Creedy describes the British system of art education, and says it is the best in the world. There is a light-hearted piece on the demography of artists by Cox. Statistics are hard to come by, and classification is capricious, but their pay, hours of work, and expectation of life seem about average. The apparent hazards of being an artist in France become comprehensible when one discovers that the category includes acrobats. Research has unexpected hazards. A chimpanzee bit her keeper for the first time when a drawing was incautiously interfered with. Whiten uses this as evidence for the intensity of the artistic impulse once it is aroused. It is odd that apes, unlike some birds, show little artistry when wild. This latency is perhaps similar to that shown by Eskimos. Decorating clothing and tools was traditional, but Brothwell says that the strikingly vigorous statuettes, now so much admired, were not made before European contact.

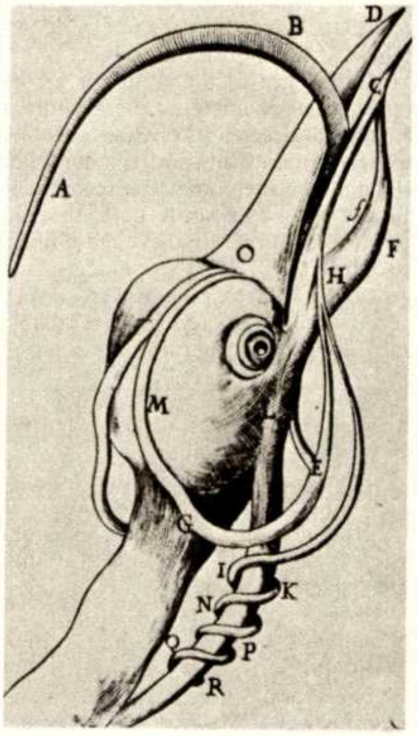
Defects in colour vision are as common among students at several art schools as in the general population. Pickford comments that nearly half of the group was unaware of the defect until tested in early adulthood. He comments also on the greater than average incidence of myopia and astigmatism among artists. He questions the idea that artistic differences between races have a physiological basis, although he comments on the curious absence of precise words for *blue* in many languages. It was this that led to the suggestion that colour perception varied. In a second article Pickford tries to make sense of aesthetic preferences in spite of their fluidity. Fluidity is the theme of Rookmaaker's article on art and morals. Using the depiction of nakedness as an example, he argues that anything can become acceptable if it is introduced in sufficiently small steps.

It is a pity Weale was not given more space to discuss the geometry and physics of art. Compression and too few illustrations make it difficult to understand all the interesting things he has to say on such subjects as deliberate distortion and the *pointilliste* technique. Writing of the use artists make of scientific illustrations he comments ". . . if a pattern appears in a book it is part of science, but if it is brushed on to a canvas it becomes art."

There are two unsurprising articles on children's drawings and paintings, and an article on cross-cultural psychology that is surprising only because of the number of platitudes and tautologies crammed into it.

N. W. Pirie

N. W. Pirie has recently retired as head of the department of biochemistry at Rothamsted Experimental Station, Harpenden, UK.



Tongue and hyobranchial apparatus of a woodpecker. By G. A. Borelli, published in Rome in 1681. Taken from *A History of Comparative Anatomy: From Aristotle to the Eighteenth Century.* By F. J. Cole. Pp. 520. (Dover: New York; Constable: London, March 1976.) £3.90 paper.

Ion transport in plants

Uptake of Ions by Plant Roots. By D. J. F. Bowling. Pp. xi+212. (Chapman and Hall: London, Halsted: New York, March 1976). £6.50.

THE uptake of ions by plant roots is a subject which over the years has probably had more man-hours devoted to it than any other single aspect of plant physiology. In consequence an extensive, very diverse and often contradictory literature has accumulated. From time to time courageous individuals attempt to digest this material and produce a coherent exposition of the process. The would-be author is presumably initially inspired to his task by a conviction that he can see order where others cannot and inevitably therefore there will be; as Dr Bowling states in his preface, "some undue bias and personal foibles". His bias is towards the electrophysiology of roots, a topic which is well described. Realisation of this bias, however, seems to have caused the author to over-compensate to the extent that in a short book (185 pages of text) covering a vast subject he seems to have devoted a disproportionate amount of space to discussion of already well documented topics.

Although covering not merely the uptake of ions by roots, as the book's title implies, but also their transfer to shoots together with related information on leaves and algae has led to some superficiality in presentation, Dr Bowling has, however, produced an interesting and logically presented book. He looks on the overall process as being divisible into four sections or links in a chain: movement of salts in the soil to the root surface; uptake into the root; transport across the root and movement in the xylem to the shoot. Separate chapters deal with what Dr Bowling describes as "the more theoretical aspects of salt uptake".

Finally, there is a chapter which although headed 'Some conclusions and a look into the future' attempts firstly, to analyse results from his laboratory on the absorption of potassium and water by a sunflower plant grown in potting compost in controlled conditions in the light of the previous chapters; and secondly, describes briefly some recent experiments on the existence of specific ion binding proteins in the plasma membrane and the action of ionophores or ion-carrying agents. It is a pity that more space could not have been devoted to the relevance of these latter two aspects to the electrophysiological and kinetic approaches described earlier.

Because of its breadth of coverage the book is a good source of reference to the literature up to 1974 and it should prove useful to students and others specialising in the subject. I hope, however, that before the next printing is set, it will be re-proofed to remove some omissions in the references and misprints in the text.

D. A. Barber

Dr Barber is a Principal Scientific Officer at the Agricultural Research Council's Letcombe Laboratory, Wantage, UK.

Stellar photospheres

The Observation and Analysis of Stellar Photospheres. By David F. Gray. Pp. xv+471. (Wiley-Interscience: New York and London, January 1976.) $27.70; £14.

THE study of stellar atmospheres (or even of just their photospheres, which are the layers emitting the bulk of the radiation) has become too vast a subject to be comprehensively covered in depth in a single book, and so it is natural (and indeed desirable) to find authors concentrating on their own particular fields of research interest while summarising other aspects more briefly. The distinctive and very valuable feature of the present book is that it provides a detailed elementary introduction to the experimental measurement and analysis of stellar spectral characteristics using predominantly Fourier techniques—a subject in which the author has himself done some very useful work and which is coming to be an essential tool in all spectral analysis with the advent of high speed multichannel detectors and digital microdensitometers.

In other respects, the book is a clear, well written and exceptionally well illustrated introduction from the practical point of view with enough of the theory of stellar atmospheres given (accompanied by many numerical formulae and tables) to show the application to the determination of effective temperature, pressure, gravity, radius, chemical composition and velocity fields. Difficult theoretical issues, like the intricacies of iteration to flux constancy and the effect of departures from local thermodynamic equilibrium, are mentioned and summarised as accurately as is possible within a few words supplemented by references, which is quite suitable for a text of finite size. It is always a weakness in this kind of treatment, however, that the reader does not quite get a physical feeling for the subject.

The presence of a few minor errors in places (for example, in the treatment of inward-directed radiation in the theory of radiative transfer) does not help and on these matters the reader will do well to consult both the old classical texts of Woolley and Stibbs, Unsöld and Aller and the modern one by Mihalas. There is, however, a very fine discussion (not otherwise available in textbooks or perhaps anywhere else) of the use of line profiles to sort out rotation and different sorts of 'turbulence'—a field in which the author's Fourier methods offer an enticing vista of new research.

In the spirit of the generally practical approach of this book, there are extensive sections on spectrometers and detectors. These are generally very good, although it is a matter for some regret that the roles of grating blaze angle and camera speed in the efficiency of spectrographs have not been explicitly brought out. The treatment of instrumental profile and scattered light corrections is excellent.

Particularly in its treatment of the practical aspects of stellar spectrum analysis, this is a valuable book that is strongly recommended for all astronomical libraries and could be a worthwhile investment for research workers and graduate students; the price is not too unreasonable in present-day conditions. **Bernard Pagel**

Bernard Pagel is Deputy Chief Scientific Officer at the Royal Greenwich Observatory and Visiting Professor at the Astronomy Centre, University of Sussex, UK.

Membrane research

Mammalian Cell Membranes. Vol. 1: General Concepts. Edited by G. A. Jamieson and D. N. Robinson. Pp. 276. (Butterworth: London and Boston, Massachusetts, 1976.) £18.

IT has been said that a week is a long time in politics and things are becoming almost as fluid in membrane research. Since 1973, for instance, when much of the material in this book was prepared, the complete sequence of a transmembrane protein has been established by Marchesi and his colleagues. The molecular basis of ion conductance across membranes has become clearer at least conceptually in artist's impressions if not in hard fact, and the proteins involved are being characterised. Similarly the importance of microfilaments and microtubules in membrane function in non-muscle cells has been realised.

Some of the treatment understandably has a slightly old-fashioned look. For example, in Rose's short chapter on the anatomy of the mammalian cell discussion of the various forms of junctional complexes in cells must be inadequate in view of the considerable advances made on their structure and function. Two other examples concern surface labelling procedures particularly with lactoperoxidase-catalysed iodination and SDS–polyacrylamide gel electrophoresis. The description is very scanty considering the recent extensive use of these techniques.

The book is the first in a five-volume series, and according to the Editors is an introduction to "the most essential aspects of physical and chemical studies which have contributed to present knowledge of membrane structure." This volume, however, is sharply divided on the basis of these criteria. On the one hand there are clear and straightforward descriptions, respectively, of the cultivation of cells by Robinson and a brief account by Glick of selected methods of plasma membrane preparation largely from cultured cells. Physical methods are covered by Levine and Chapman, and enzyme markers are summarised in a useful chapter by Hinton and Reid. The remainder of the book consists of four short speculative chapters on specialised, even esoteric, topics. Gingell argues for the electrostatic control of diffusion of proteins in membranes. The basic point is that proteins carry high negative charges (mainly due to sialic acid groups) that must be overcome by ligand binding before condensation can occur. Condensation of transmembrane proteins, equated by Gingell with intramembranous particles, is considered to be obligatory for formation of ion channels through the membrane. Well, maybe; but hardly the basic facts required for an introduction to membrane science. One difficulty too is the as yet inconclusive evidence, except in erythrocytes, that intramembranous particles can be clustered by ligand interaction with surface membrane proteins.

The infant science of the mechanical properties of cellular membranes is interestingly reviewed by Canham, and Lenard and Landsberger discuss some models of membrane structure. The biogenesis of mammalian membranes is summarised by Malhotra. I enjoyed reading these four chapters and, for my money, they recommend the book for this year's bookshelf.

On the whole each chapter is well written and free of serious factual or typographical errors. The book should be useful to research workers and to final year undergraduates. The person who discovers on p32 that trypsin "catalyses the hydrolysis of peptide bonds between the carboxy group of arginine or lysine and the amino group of an adjacent amino acid" is likely to have difficulty in following many of the complex arguments that follow elsewhere in the book. The editors are to be congratulated on setting a good standard for the first volume and I look forward to the arrival of the remaining volumes. **R. Colin Hughes**

R. Colin Hughes is a member of the scientific staff of the Medical Research Council at the National Institute for Medical Research, Mill Hill, London, UK.

obituary

ROBIN LAURANCE

Jacques Lucien Monod died at his family home in Cannes on May 31, 1976 at the age of 66. He was one of the foremost leaders of the revolution in molecular biology, helping to lay the framework of our understanding of gene action and protein synthesis. Monod was a scientist of the first rank, both in his experimental work and in his ideas. By his scientific research and by his Essay on the Natural Philosophy of Modern Biology (translated into English as *Chance and Necessity*) he has left an indelible mark on the intellectual history of the 20th century.

Monod was born in Paris in 1910. When he was seven his family moved to Cannes where he lived and studied till he was eighteen, so that he thought of himself more a man of the Midi than a Parisian. His father was a painter, an unusual vocation at that time for one of Huguenot stock, coming from a family which had produced many doctors, pastors, civil servants and academics. His mother was American, a native of Milwaukee, the daughter of a New England mother and a Scottish immigrant father. Early influences were his father, who in addition to his artistic sensibilities had a strong interest in science and in Darwin in particular; also his Greek master, a scholar whom he admired for his civilised attitude to life. Scientifically, he acknowledged among his immediate elders the impact of George Teissier, André Lwoff, Boris Ephrussi and Louis Rapkine. Perhaps most important of all was his year's stay, in 1936, with Morgan's group at Caltech. Their full, free and critical discussions, together with the easy personal relationships between people of different ages, were a revelation to him and strongly influenced his style of organising research.

In his scientific career Monod, though never seriously impeded, did not get off to a flying start as many young men do nowadays. It was at the beginning of the war, after a famous reply to André Lwoff ("L'adaptation enzymatique? Connais pas! ") that he first became aware of the nature of the phenomenon he was studying. Only after the war, when he had joined the Pasteur under Lwoff, did he fully recognise the depth of the problem which was to become his life's work. By then he was 37. But once having recognised it, he pursued it with tenacity, versatility and imagination. His logic was relentless; his intuition variable but profound. No wonder that many of his younger colleagues came to feel that to work with him was a scientific education in itself.

The results are now in every textbook. There is no space here to follow the story in all its details, nor to show how the commonplaces of today grew out of the confusions of yesterday. The concentration on β-galatosidase; the arrival of Mel Cohn ("acquisition précieuse") who knew about proteins and also how to use the Tiselius apparatus; the proof that the appearance of enzyme activity represented *de novo* synthesis (a big surprise at the time); the skilful use of lactose analogues to separate the inductive from the substrate activity and the discovery of the permease and the transacetylase. Finally the grand collaboration with François Jacob (from the other end of the corridor) leading to their immensely skilful dissection of the inductive process by genetics; the realisation, from certain mutants, that the synthesis of all three proteins could be turned on and off together (the operon); the postulate that the *i* gene product was a protein—the inhibitor—and the famous PaJaMo experiment of Pardee, Jacob and Monod which suggested that the message was unstable. It is difficult now to recall that at that time the ribosomal RNA was assumed to be the message. The realisation that the ribosome was a reading head, which could read any message, came as a great flash of understanding. After that the road to the genetic code was wide open.

Meanwhile Monod, with Jacob and Changeux, had recognised that the properties required for the inhibitor were, at first sight, unusual for a protein. On reflection, however, they realised that such properties were in fact common—their existence had simply not been appreciated. Thus was born the theory of allosterie. Various earlier workers (including those studying haemoglobin) had glimpsed the idea but had not recognised its generality and its profound importance. For now one could see how any metabolic pathway could be linked, control-wise, to any other. Without this type of mechanism even the simplest organisms could not regulate themselves and higher organisms could not exist.

In 1969 Monod gave the Robbins Lectures at Pomona College in California. He used the occasion to develop and make precise his general ideas about biology, man and society. The lectures became a book, originally written in English, rewritten by him in French under the title *Le Hasard et la Nécessité*. Its publication made a strong impact and it became a best-seller. It aroused the almost united opposition of the French intellectual establishment which has always preferred Marx, Freud and Teilhard de Chardin to Darwin and Mendel. Written with force and clarity, in an unmistakable personal style, it presented a view of the universe that to many lay readers appeared strange, sombre, arid and austere. This is all the more surprising since the central vision of life that it projected is shared by the great majority of working scientists of any distinction. It would be difficult to find a better example to display the deep rift between science and the rest of our culture.

Monod was not aloof from public affairs. He was a persistent critic of the French University system and of the way in which French science was supported. Thus it was not entirely surprising that in 1971 he accepted the invitation to become Director-General of the Pasteur Institute. This decision came partly from his strong sense of duty; he was naturally reluctant to have to give up his research and his writing, but the Institute was in a bad way, having become desperately short of money. Monod threw himself wholeheartedly into his new job. He tried many things: appeals for funds, both public and private; the setting up of a production subsidiary with the aim to exploit useful ideas from the research side of the Institute; various economies and a limited reduction of staff. Finally he toyed with a scheme, strongly opposed by many of his colleagues, to move the laboratory outside Paris. But the opposition to such a move was too strong and the sums of money required too great; only the government could supply them, a source he somewhat distrusted, as he feared for the Institute's independence. Looking back one can see that the Pasteur had to change and to change radically. It needed a scientist of Monod's stature to make the changes possible and reasonably palatable.

Science was the dominant activity in Monod's life but it was not the only one. During the war he worked for the French underground, receiving recognition for this perilous work from both the French and the American governments. He became a keen mountaineer only to give it up for sailing; the characteristic mixture of discipline and freedom appealed strongly to his temperament. He would sail his 37′ boat single-handed or with the assistance of a mere amateur. Having a wide intellectual curiosity, he was remarkably well read, both in classical and modern authors—Camus was a personal friend. But his main passion outside science was music. He both played the cello and conducted. In his twenties he even wondered whether to give up science for music, and all through his life he tried to find time to make music with his friends.

Monod was a man of great personal charm. His English was perfect, though simpler than his French. Thanks to his good ear and his American mother, he spoke it without any trace of the heavy accent which most Frenchmen find difficult to discard. Good-looking, though small of stature, he commanded attention by his intelligence, his clarity, his incisiveness and by the obvious breadth and depth of his interests. Never lacking in courage, he combined a debonair manner and an impish sense of humour with a deep moral commitment to any issue he regarded as fundamental. He had great warmth for his friends and treated his students with affection and candour, as if they were members of his family. To others he could be charming but somewhat more remote. Though his creative powers flowered most abundantly in his scientific work he combined within himself, in a natural harmony, the scientist, the philosopher, the man of action and the musician. He might well have made a world reputation by concentrating on any one of these roles. Such a range of gifts is rare. It is fortunate for us that he chose science, otherwise the development of molecular biology would have been very different.

The formal outlines of Monod's career will be recorded here only briefly. He obtained his first degree in 1931 and his doctorate in 1941, both from Paris. He joined the Pasteur Institute in 1945 as Chef de Laboratoire, becoming Chef de Service in 1953, head of the department of Cellular Biochemistry in 1954 and Director-General in 1971.

His stay at Caltech in 1936 was supported by the Rockefeller Foundation. While at the Pasteur he held a chair at the University of Paris from 1959 to 1967, followed by a chair in Molecular Biology at the Collège de France from 1967 to 1972. From 1962 onwards he was a non-resident fellow of the Salk Institute.

Monod received many honours, including Foreign Membership of the Royal Society and the US National Academy, among others, and several prizes, culminating in the award of the Nobel Prize for Physiology and Medicine in 1965 which he shared with Lwoff and Jacob.

His wife, the former Odette Bruhl, whom he married in 1938, died in 1972. They had two sons, twins, who survive him. Both are scientists. **F.H.C.C.**

announcements

Meetings

August 30–31, **L'Anthropologie et la Biologie des Populations Andines,** Toulouse, France (Prof Georges Lambert, Centre d'Hemotypologie du CNRS, Colloque d'Anthropologie et Biologie des Populations Andines, Hôpital de Purpan, Avenue de Grande-Bretagne, 31052 Toulouse Cedex, France).

September 2–3, **564th Meeting of the Biochemical Society,** Dublin (The Meetings Officer, The Biochemical Society, 7 Warwick Court, Holborn, London WC1R 5DP).

September 6–8, **Biochemistry of Lipids,** Paris (J. Polonovski, Faculté de Médecine Saint-Antoine, 27, rue Chaligny, F 75571 Paris Cedex 12, France).

September 21–23, **Science and Technology of Water Soluble Polymers,** Cardiff (The Short Courses Secretary, Planning Section, UWIST, King Edward VII Avenue, Cardiff CF1 3NU, UK).

September 24–25, **Joint Radiological Meeting of the RCR and the BIR,** Leeds (The General Secretary, BIR, 32 Welbeck Street, London W1M 7PG).

October 7–8, **Meeting of the South-eastern Cancer Research Association on Membrane Receptors, Regulation of Gene Expression and Chemical Carcinogens,** Atlanta, Georgia (Dr Edward Bresnick, Chairman of the Dept of Cellular and Molecular Biology, Medical College of Georgia, Augusta, Georgia 30902).

Still a lot to learn from the Chinese

TEN thousand, a hundred thousand, a million dead in the latest earthquake at Tangshan in China? It seems as if the Chinese authorities are not at present going to talk about the scale of the disaster, maybe believing that details of fatalities will produce some sort of ghoulish exultation in other countries and result in an indefinable loss of face. Certainly some silly people who, a year ago, would have dubbed the prediction which saved tens of thousands of lives on the Liaoning Peninsula a "spectacular success" have been talking about the present catastrophe as a "spectacular failure" of prediction. Such views can no doubt be discounted as shallow, but they do perhaps show why China will be sensitive to worldwide comment, and they do make it all the more necessary that the Chinese should understand the serious and compelling reasons why earthquake scientists, engineers and social scientists the world over want to learn as many lessons as quickly as possible from China, now an acknowledged leader in the field of prediction.

Even though there do not seem to have been any open alerts about the most recent quake, those who have recently returned from China report that there had been concern over magnetic field changes and that there was a feeling that seismic activity was migrating in the general direction of Tangshan. More remarkably, travellers continue to bring back accounts of unusual phenomena preceding and accompanying earthquakes, which seem to indicate that there is still a lot to learn about the art of prediction.

Animal behaviour as a predictor has now, of course, become an object of popular fascination the world over. For one thing, the jumpiness of cats, dogs and snakes can be understood by a much wider public than can fluctuations in the velocity of elastic waves; for another, it does bring science down to a folksy level at which the good amateur observer is just as valued as the professional. There are few branches of science where this is true today, and it is excellent news that amateur involvement has been given such a good name by the Chinese. Even the most sceptical Western observer will be impressed by the sheer crescendo of reportings of unusual phenomena last year in the weeks before the Liaoning earthquake. The latest addition to the collection is 'earthquake lights'. Like anomalous animal behaviour, this has been a subject attracting practically no attention at all from seismologists, yet there is now a report from a respected Chinese seismologist of a glow in the air at the same time as a quake—something that had previously only been the subject of discounted hearsay.

What the Chinese have succeeded in doing, and what this most recent calamity will certainly not dissuade them from continuing, is to raise the consciousness of people to unusual phenomena, even to the extent of encouraging them to file reports. This is a lesson that should not be lost in California, the Soviet Union, Japan, the Middle East or other places scourged by earthquakes. There are encouraging signs that at least the inhabitants of San Francisco and Los Angeles are prepared to learn from the Chinese experience that the experts need all the help they can get. That is why it is important that the momentum of interest which has been developing should not be stifled by suppression of news and of the interchange of scientists.

There is a lesson in all this for the international organisations, too. Countries which have developed technologies for their home market invariably start to turn their thoughts to export potential before long. And if the technology is one like railways, air-traffic control or defence systems, the inevitable interchange of personnel, training of technicians and stationing of advisers creates a dependency which is a modern form of imperialism. Just because China is at present reeling under a disaster and no other country can yet do any better does not mean that in ten years time there will not be an exportable commodity—and that certain countries, already with tribulations enough of their own, will not be asked to buy an expensive system and absorb a thousand advisers. UNESCO, rather well equipped in this field, should take this matter seriously while it is still a cloud on the horizon. □

The ecology of ecology

"Ecology has become a social movement as well as a branch of biology". Philip Lowe of University College, London, and Michael Worboys of Sheffield City Polytechnic give their view on the role of science in the environmental movement

ENVIRONMENTAL concern, and with it the apparent immediacy of the ecological crisis, has of late receded. A downturn in the business cycle has sets its own limits to growth, and apocryphal warnings of the decline of Western capitalist democracies have superseded the environmentalists' warnings of natural decay. But many environmental problems remain, and one enduring feature of many of these is their implication of modern science, both as cause and as solution.

From the anxiety over radioactive fall-out and pesticides, through to current worries about fluorocarbons, nuclear power and hazards of the workplace, science has often been cast as the villain of the piece. Yet scientists have also been in the forefront in alerting society about these problems and in campaigning for action. Moreover, a leading role for science has been proposed in evaluating risks from pollution, in developing new resources and in the general formulation of solutions and strategies in response to environmental problems.

This ambivalence with regard to science—which is, incidentally, very common where science impinges upon social issues—creates many difficulties. For example, different scientists may regard the same "problem" very differently. Whose assessment or warning do we believe? To solve environmental problems, do we need more science, less science or different science? To which group of scientists, if any, do we turn for solutions? One common response to questions of this sort has been to look to ecology and ecologists as sources of "wisdom" and "healing". The received notion that ecology is about wholeness and the natural has left it seemingly untainted by the reductionist and industrial associations of most modern science.

Indeed, its marginality to mainstream science, of which ecologists have long complained, now proves to be an asset in a period when science generally is being questioned and attacked. Most environmentalists and environmental pressure groups have fallen in behind the banner of Ecology. They have used ecological information vicariously and promoted the adoption of ecological values, giving rise to a whole new genre of social polemic best described as popular ecology. In short, ecology has become a social movement as well as a branch of biology, and it is the connection between these two aspects of ecology that needs to be explored.

Is politics redundant?

The literature of the contemporary environmental movement and popular ecology is characterised by a general rejection of conflict, especially political conflict: the lesson of ecology in its broadest sense is supposedly harmony, balance and symbiosis. As in technocracy, where traditional politics is deemed redundant through the overriding and deterministic effects of man's technological situation, so in popular ecology politics is declared equally redundant because of the imperatives of man's ecological predicament. Compelling physical and natural constraints supersede and replace moral, social and political considerations.

In Britain, the establishment of an Ecology Party indicates the presumption that environmental issues transcend orthodox political alignments. Formed in 1973 as a direct consequence of the appeal in the *Blueprint for Survival* for "a national movement to act at national level, and if need be to assume political status and contest the next general election", it was known initially as the People Party—its subsequent change of name illustrating nicely how ecology has come to be seen as bigger than all of us. The electoral ambitions of the Ecology Party, its commitment to come to power by democratic means and work within the framework of a mixed capitalist economy and a parliamentary democracy, are somewhat at odds with its very radical manifesto proposals for de-growth, decentralisation and population control "to provide a working basis for ecological government". However, recent correspondence in their broadsheet, *Alliance*, has argued that it may in fact be essential for government, composed of an aware elite—the writer used the Spaceship Captain analogy—"to introduce ecology without taking the people into its confidence".

But most environmentalists would not completely abolish politics. Some view politics as the refined tool of environmental management, enabling fine and delicate control of human well-being within the greater and larger purposes of the biosphere. The implication is that, as well as transcending political differences, environmental problems are also non-political in the sense that their solutions are management or technical issues. Hence, politics should no longer be about power, its use and distribution, but, instead, about the forms or techniques of government most appropriate to cope with urgent environmental problems.

Conventional response

The conventional response of the scientific establishment to environmental problems was expressed by the Council for Scientific Policy in 1972, when it urged that "more science will be needed, not less, to provide remedies and to enable society to take precautions against pollution", and called for the "closer integration of science into social policies". Thus, more "scientific" planning, monitoring and management are advocated, in such forms as technology assessment, environmental impact analysis, quantitative environmental forecasting and ecological evaluation—activities viewed by their practitioners as so many exercises in applied rationality, but criticised by others for clothing implicit political assumptions and implications in a pseudo-scientific mystique of "objective" knowledge and "rational" techniques. What is clear is that their practice seems to be based on the assumption of the availability of consensually defined social goals which, if absent, can be summonsed by the persuasive presentation of the facts of the matter.

●

Ecological coalition

Conservation, when treated in these terms, appears to be an unadulterated good thing; equated with applied ecology and with its own quantitative techniques, it seems beyond the realm of politics. The supposed political consensus surrounding the practice of conservation in Britain, however, can also be seen to be the operation of a coalition of powerful rural vested interests, whose use of ecological rhetoric has enjoyed the active support or acquiescence of professional ecologists. In fact, popular ecology has long been very closely linked with the interests and ambitions of professional ecologists.

The institutionalisation of a scientific discipline such as ecology is generally accompanied by the competitive development of a disciplinary ideology which publicises the putative social utility and world-view of the discipline and plays an essential role in the establishment of cohesion and a sense of collective identity amongst its practitioners. In Britain, the emergence of ecology as a distinct discipline dates from the turn of the century. Government recognition of its potential utility came in 1949 with the establishment of the Nature Conservancy as both a research council for ecology and an agency for the formation and management of nature reserves.

Initially, the Nature Conservancy commanded a very much smaller share of resources than the other research councils, and ecology, with its amateur connotations of natural history, had a low status in the scientific community. But the Conservancy proved very successful in lobbying government and popularising ecology, and took the leading role in forging various groups into an effective and dynamic environmental lobby. In the late 1960s members of the Conservancy played a crucial part in popularising the existence of an environmental crisis and figured prominently in the institutional developments that were the outcome of the resulting public and governmental concern. Hence a strong element in ecological propaganda is a direct product of competition within science.

Whose preserve?

The further suggestion that the environmental crisis reflected the pre-eminence of the physical sciences over the environmental sciences has also had considerable currency. It is indeed true that many science-related activities associated with both the generation and control of environmental problems, have been the preserve of chemists and engineers, largely to the exclusion of biologists. Thus, much pollution, such as that due to pesticides, detergents and nuclear radiation, has been seen to be consequent upon faulty and diminutive knowledge of environmental biology as compared with, say, physics and chemistry—indicating to some the need for a greater share of resources to be devoted to research and training in the environmental sciences.

To many others, however, this analysis, in confining itself to relative deficiencies within science, does not go far enough and fails to recognise the economic and social basis of the organisation of science. The preponderance of the chemical control of pests over their biological control, for example, and the resultant pollution and development of pest resistance, may be less a function of the power of chemists over biologists than of the power of the chemical industry within society. Professional competition and interfactional disputes within science often need to be understood in terms of the relationship between scientific disciplines and elites and powerful interests external to science.

Beyond tactical responses

The plausibility of ecologists has been of crucial importance, and was directly involved in their popularisation of the environmental crisis, just as their professional interests are deeply enmeshed in "technical" solutions to environmental problems. In some instances, however, the appeal to ecology has gone beyond the search for tactical responses to particular problems, towards the claim that ecology can contribute to a radical re-ordering of human purposes and a re-orienting of society away from environmental disaster. The findings, concepts and approach of ecology have proved a rich source of ideas and analogies in the construction of environmentally sound social programmes—niche theory, the ecosystem concept, energy flow, materials recycling, limits of tolerance and succession have been deployed in many and varied contexts.

Beyond this have come calls for ecological ideals, an ecological ethic, an ecological morality, ecological values and ecological determinism. Certainly, the synthetic nature of ecology and its claims to transcend the narrowness of other disciplines have always been a source of its popular support. But, in this case, science appears to be adopting a leading role in society as a value-affirming, goal-setting and consensus-generating institution. At a time of change and dissent from established values, when it is generally accepted that traditional institutions have lost much of their authority, science, albeit reunified and chastened by the example of ecology, is turned to by those who value order and stability as the one authoritative voice.

Science assailed

Such appeals to science, however, come at a time when its own moral influence has also been assailed, by the attacks of what many identify as an anti-science movement. The response of critics like Roszak to the social problems of modern science has been to reject science—the objective, rational and calculating consciousness—in favour of a more subjective, intuitive and feeling type of knowledge. For Roszak, the discipline of ecology, and not high energy physics, should be the model science—a view shared by influential and respected proponents of ecology such as Max Nicholson and Barry Commoner.

The separate debate over social responsibility in science has raised other questions about the direction and control of science. The self-doubt that has been generated has prompted some leading scientists to demand greater solidarity and less dissent within the scientific community so as to render it less vulnerable to external attack and to preserve its authority in society. Indeed, internal fragmentation has been identified as one cause of the inability of science to respond effectively to environmental problems, and calls for a "unified science", based on ecology and the related general systems theory, predict the consequent restoration of the weakened position of science in society. The holistic image of ecology, its promise of making whole that which was fragmented, and its widespread popular support, might help revive the moral influence of science, and regenerate consensus both within and outside of science.

Crisis highlighted

The environmental crisus thus highlights a crisis of confidence within science and a crisis of science's authority in society. Mary Douglas, in her essay "Environments at Risk" (*Times Literary Supplement*, October 30, 1970), has supported this view by drawing attention to the problems of credibility that scientists face in warning society of possible environmental dangers. Indeed, the environmental movement has been interpreted by Michael King (*Technology and Society*, **8**, 1; 1973) as a bid by certain scientists to relocate and extend the basis of scientific authority. Science as a mere source of useful knowledge confers upon scientists the very limited and fragile power of technicians, but the ecologists' claim to appreciate the wisdom of Nature, as well as the orthodox scientists' knowledge of natural laws, might legitimate a continuous and central involvement in the formulation of political purposes and values. ☐

Science policy in Poland

Science has not escaped recent developments in Poland. **Below,** a Special Correspondent describes the trends.

AFTER four relatively fat years science in Poland seems to be entering a less happy period. Following the dismissal of Mr Gomulka during the stormy days of December 1969, his successors initiated a more dynamic economic policy and science was declared an essential factor of economic growth. The new leaders were keen to present themselves as scientifically oriented people. A honeymoon for science began with the setting up of a special committee, headed by the well-known sociologist Professor Jan Szczepanski, to develop long term policy in education at all levels. The state pocket was enriched by loans from abroad and was opened wider for science.

As a result of this, research and development expenditure rose from 1.4–1.6% of GNP in 1969 to about 2.5% in 1975. GNP itself rose by about 60% during this period and so the funds available for science were almost doubled—a dramatic increase, especially in comparison with stagnating funds for science in Western countries. These official figures perhaps exaggerate the increase to some extent because the definition of what is meant by science for budgeting purposes is vague and some expenditures not included previously are now under the heading of science. A sharp rise in the money available is, however, an indisputable feature of this period and witnessed by a number of new buildings, better endowment of institutes and laboratories, improvement of the level of scientific work in many fields and wider contacts between Polish and foreign scientists.

The rise of money was not accompanied by a proportional rise of scientific staff or number of students. In the 1950s the relative number of students in Poland was greater than in most Western countries. But since the further rise of the number of students was slow (especially after the student riots in 1968) Poland has been overtaken by most European countries. The accompanying table of numbers from the official Statistical Yearbook, 1975, shows the recent trends.

It has never been easy in Poland to spend all the money allocated for science, and it may be even more difficult in the future. Budgets of Universities and Institutes are being tightened by a large number of regulations more relevant to industry than to science. This is a feature of the five-year plan for the 1976–1980 period for the development of different aspects of technology. Plans of this kind—strange as it sounds—have also been compiled for basic science. A low opinion of the value of the whole time-consuming and inelastic planning system is common in the scientific community.

In spite of the earlier generous flow of money the housing conditions of many scientific institutions remain poor. Many courses in the University of Warsaw are given in buildings belonging to different secondary schools dispersed over the city of Warsaw. The salaries of academic staff are very small in relation both to academic salaries in other countries of the communist block and salaries of other professional groups in Poland. The salary of a senior member of the staff (*adiunkt*) of a research institute is equal to the average salary of those working in the state sector (about 3500 zlotys per month, that is, $120 on the official tourist exchange rate—a figure which gives an accurate impression of the buying power of the earnings). From September 1976 the salaries will rise by about 15%. The rise of salaries previously given to all other professional groups is now reaching the last group of government employees, namely, those working in the scientific institutes.

The honeymoon of the Polish scientific intelligentia was over in 1973, close to the time of the much advertised Second Congress of Polish Sciences. It seems that the reason for this change of the official attitude was related to the disillusion of the government that Polish science will contribute significantly to the immediate improvement of the economy. Unfortunately these idle hopes have been repeatedly supported by a large number of short-sighted Polish scientists eager to satisfy their personal goals.

In Poland as in most eastern-block countries the intermediate link between scientific research and technology, the link responsible for implementation of new products and processes, is very weak. Its functions are frequently performed with doubtful results by purely academic institutions, for example in the institutions of the Polish Academy of Sciences (PAS). Thus the sharp rise of the level of Polish industry in 1970–75 was only marginally based on the achievements of Polish scientists and engineers, and was due mainly to the purchase of know-how from abroad; noting this, the leaders of the country have begun to treat science not as a producer of goods but as a consumer.

The social sciences in Poland depend on official doctrine to a lesser extent than in other countries of the communist block. However, in spite of the official statements made in 1970 interest in their work has declined steadily. The report of the education committee under Szczepanski has been shelved, and the education policy actually introduced bears little relation to its conclusions. Poland was fortunate to have after the war three economists of international distinction, Oscar Lange, Michael Kalecki and Edward Lipinski, but their economic advice has been used in several other countries and never in Poland. Of these three only Professor Lipinski, member of PAS, is alive, but his views expressed in a number of letters having a wide hand-to-hand circulation are not taken into account by the authorities.

In contrast to other groups of Polish intellectuals the scientists are relatively meek. Not many scientists or scholars signed the letters of protest against the recent revision of the Polish constitution legalizing the leading role of the party and friendship to the USSR. Those who did are being punished: younger people are not having their contracts renewed, and others, as for example Professor Stefan Amsterdamski, philosopher, are prohibited from going abroad even to attend conferences.

According to official statements the government is not planning to increase the quota of places for students in universities. This means that the situation of an applicant will be about the same as during the last few years due to the fact that the post-war demographical bulge is now close to its end. The announced quota based on the evaluation of future demands is very conservative and recently it became clear that for example the number of

Student trends in Poland

Year	No. of students per 10,000 of population	No. of resident students per 10,000 of population	No. of students per 1,000 of population in the age group 19–24	No. of resident students per 1,000 of population in the age group 19–24
1970–71	101	64	136	87
1974–75	126	76	139	84

The official number of students per 10,000 of population given in the international part of the Yearbook is 144, but this includes also students in higher schools under the Ministry of Defence and the Ministry of Internal Affairs. In these schools there are about 80,000 students, and the total number of students in other institutions of higher education is 427,000.

physicians needed exceeds the number of accepted medical students.

During the academic year 1975–76 there was a considerable rise of political activity among students. They raised their voices in protest against the changes in the constitution. More recently they protested against the expulsion of their colleague Mr Jacek Smykala from the Medical Academy in Szczecin (during a tutorial class in economics he asked what part of the national budget is allocated to the police force), and against the imprisonment of their colleague Mr Stanislaw Kruszynski from the Catholic University in Lublin (the only private university in Poland), who was sentenced to six months in prison for writing unfavourable opinions about the social system in Poland in private letters to his relatives and friends. From Warsaw University alone about 800 people signed this protest.

At the beginning of 1976 a reduction of staff (up to 10%) took place in many research institutes, including those connected directly with industry. These reductions touched universities and industries of PAS to a lesser extent but it was decided to freeze the number of their staff for the next three years.

The Polish economy, as is commonly accepted, is now entering a very difficult period. One of the signs of this was the government's proposals to increase the food prices in June (meat by about 70%, sugar 100% and so on) which would have caused a fall in the spending power of wages by about 20 to 30%. The wave of strikes (70 to 80% of big factories according to unofficial figures) and unrest in a few places forced the government to rescind this proposal. Science seems to be near the top of the list for economies. According to some sources it has already been decided to halve the rate of investment in science. Considerable political tension in the whole country has not by-passed the scientists. Speculations about personal changes have wide circulation. Meanwhile the repressions against those involved in strikes and protests have already begun.

As in all countries of the communist block, scientists in Poland have no real representation to defend their own interests and those of science. The Polish Academy of Sciences is the agent of the government and provides no more than formal representation. For example, recently, in June 1976, after the abortive attempt to increase prices, the Praesidium of PAS at its meeting in the metallurgical factory in Silesia wrote a letter of adulation to Mr Gierek, the Secretary of the Party. A few months previously, his son, Professor Adam Gierek, was elected to the PAS; perhaps those who voted in his favour had in mind the dire fate of the Romanian Academy, which, as it is said, was a consequence of its refusal to elect Mrs Ceaucescu (wife of the Secretary of the Party in Romania) to the Academy.

Polish leader Edward Gierek

These and similar steps do not contribute to the authority of PAS and do not reflect the views of the Polish scientific community. An interesting new development in this community and in the whole group of intellectuals is the collaboration of differently minded people, rightists and leftists, catholics and even members of the party. This collaboration is an outcome of the common feeling that the present policy endangers not only the further development of science, but also the very existence of independent Poland, and that the most important task confronting the intelligentsia is the defence of the national identity. □

Artificial intelligence in education

Miranda Robertson discusses research aimed at exploiting computers in human communication and teaching

If the principal goal of research in artificial intelligence (AI) has been the development of intelligent machines, an increasingly conspicuous sideline is the promotion of intelligence in human beings. This social orientation has been stimulated partly by Newell and Simon at Carnegie Mellon, and the ideas of Papert and Minsky, at the Massachusetts Institute of Technology, (MIT), who see in artificial intelligence a new way of looking at the nature and development of natural intelligence.

Papert has for some years been an advocate of the use of sophisticated computer programming languages to help children learn how to think. Writing a program in a high-level language involves the expression of thought processes which would not usually be formulated. When there is a mistake ("bug") in the program, the child can retrace his thoughts in the program and understand his own mistake. The result, Papert believes, is to increase the child's intellectual effectiveness in general and make him more articulate.

LOGO learning for children

That is the idea behind experiments which have been going on in the LOGO laboratory at MIT for about three years. LOGO is a high level language which children can use to program various devices, the best known of which is a mechanical "turtle" with a retractable pen.

Usually, the child begins by learning how to draw geometric designs by programming the turtle; later, as the system becomes more familiar, the turtle can be replaced by a somewhat nimbler oscilloscope trace. One important advantage of a LOGO system over more conventional curricula is that children enjoy working with it and it can be used to overcome the resistance that many children develop to learning mathematics.

So far, the experiments at MIT have not been sufficiently systematic to produce clear evidence for Papert's persuasive arguments. Up to now, the children have been drawn largely from the families of MIT research workers and from a local school, neither (probably) very representative; and the classes have been supervised by research staff, in particular Dr Jeanne Bamberger, rather than by professional teachers.

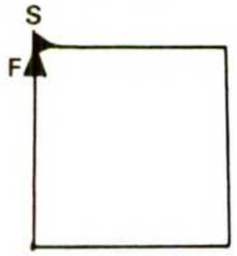
There has for some time been talk of an entire school geared to the LOGO system, and where about half the school curriculum would be undertaken at a computer terminal. But this ambitious project is not expected to start in earnest for another two years, during which a small group of teachers will be trained in LOGO, a pilot LOGO educational project will be run with the cooperation of one of the Cambridge or Boston schools, and some thought will be given to how the children's intellectual development should be evaluated.

Evaluation presents a special problem because it is not clear that the intellectual abilities LOGO is supposed to foster would necessarily be revealed by conventional psychometric tests. Papert and his colleague Marvin Minsky, who specialises in theories of intelligence, maintain not only that conventional tests are inappropriate, but that the qualitative difference they would expect to see in the children would be great enough to make statistical tests unnecessary. On the other hand they do not expect to be able to show those differences with anything short of a total "LOGO environment" and that is two or three years off.

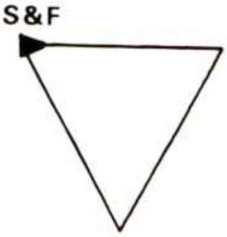
In the meantime, however, their ideas have inspired a number of schools and universities elsewhere to set up their own experiments with LOGO or other similar systems. Of those, a small research project and the Artificial Intelligence Department at the University of Edinburgh is the furthest advanced with a scheme for providing more rigorous experimental evidence. Jim Howe, Tim O'Shea and Ben du Boulay have enlisted the cooperation both of a local school and of a teacher training college with the aim of finding out how learning may not only help pupils to learn, but teachers to teach. Eleven-year-old children from George Herriots, a direct grant Edinburgh boys' school, have now been taking part for a year in LOGO classes in the course of which a LOGO curriculum has been designed, and practical experience has led to various improvements both in the language itself and to the development of new devices.

Children with problems

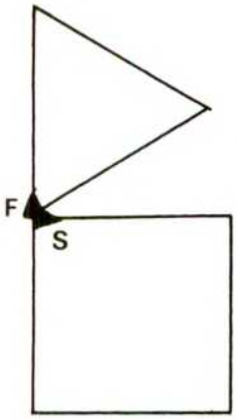
Although the Edinburgh group do not entirely share Minsky's and Papert's contempt for all psychological testing (indeed part of the research project is to design suitable tests), the most striking effects they have seen so far have been precisely of a kind that psychometric tests would miss. Some of the most interesting evidence so far is anecdotal, and the example of one particular child with a problem suggests that a particular advantage of LOGO learning may be in bridging the communications gap between teacher and pupil, especially where for one reason or another that is particularly difficult.



```
w: TO SQUARE
d:1 FORWARD 100
d:2 RIGHT 90
d:3 FORWARD 100
d:4 RIGHT 90
d:5 FORWARD 100
d:6 RIGHT 90
d:7 FORWARD 100
square defined
w:  SQUARE
```



```
w: TO TRIANGLE
d:1 FORWARD 100
d:2 RIGHT 120
d:3 FORWARD 100
d:4 RIGHT 120
d:5 FORWARD 100
d:6 RIGHT 120
d:  END
triangle defined
w:  TRIANGLE
```



```
w:  TO HOUSE
d:1 SQUARE
d:2 TRIANGLE
END
house defined
w:  HOUSE
```

This is an example of a "bug" which is commonly encountered when, having learned to write procedures to draw a square and a triangle, the child puts the two programs together to make a "house". In this particular case, the bug arises because the turtle's change in orientation (indicated by arrows: S=starting position, F=finishing position) in the course of drawing the two shapes has not been correctly predicted.

w : prompt typed when the computer is ready to take a command; d: prompt typed when computer is in the definition mode.

The anecdotal evidence concerns a "dyslexic" boy who was included by chance in the first group of 18 children to be taught LOGO. In spite of remedial lessons from sympathetic and enthusiastic specialists for two years, neither his reading and writing nor his classroom performance had improved, and he was well established in the role of class clown and dunce. LOGO programming, unlike the rest of his school work, however, came relatively easily to him and he rapidly reached a point where he was able to teach other boys. That brought about a change in his classmates' attitude to him and a conspicuous increase in his own self-confidence. O'Shea illustrates the point with an account of an argument between the boy and his teacher during a classroom lesson on sets. Asked to name the set of even numbers divisible by two and the set of odd numbers divisible by two, he responded with, "the set that never finishes and the set that never starts". The textbook answers are the infinite set and the empty set, and the teacher marked him wrong.

In a way that would have been uncharacteristic before he started learning LOGO, the boy argued with his teacher and as a result was awarded half marks. Part of the significance of that story, for Howe and O'Shea, lies in the phrasing of the boy's "wrong" response, which, like the definition of a LOGO program, is expressed in terms of procedures. The implication is that learning LOGO supplied not only the confidence to argue, but the language in which to do so (incidentally, a school inspector spontaneously remarked of other boys in the group that they were exceptionally mathematically argumentative).

LOGO learning for teachers

One of Papert's most important claims has been that learning LOGO provides a descriptive system within which to think and communicate; and this is relevant not only to the private intellectual development of individual children, but to the interaction between pupil and teacher: it can also help the teacher to understand and express what he has to teach. Papert maintains that what makes so many common skills (such as riding a bicycle) so hard to teach is the lack of an adequate way of describing them. Because learning with LOGO is learning within a descriptive system, it makes everything explicit and thus automatically more communicable.

That is the rationale for an experimental LOGO course which Ben du Boulay has been running at a local college for trainee primary school teachers. Primary school mathematics teaching is often a special problem partly because the teachers' own grip on the subject is none too firm. The aim of du Boulay's part of the Edinburgh project is to see whether LOGO learning has a function in helping primary teachers both to understand and to explain mathematics. That research is still at a preliminary stage.

But LOGO learning as a "catalyst" to communication is an important theme of the Edinburgh research. The particular term catalyst has been adopted by Sylvia Weir to describe the effect of LOGO learning on communications between an autistic child and the normal adults who work with him. Weir, working with Ricky Emmanuel, has found that allowing an autistic child to control the turtle from an array of buttons on a box stimulated him to communicate with them in a spontaneous way they had rarely seen in any other context.

She attributes this "humanising" effect to what she calls "shared relevance": the transparent connections between the pressing of the buttons and the movements of the turtle, and between the turtle's actions and the child's own movements in space provide, in her view, a basis of shared relevance, or a common framework, within which the child and the adults can communicate. Building on a framework of shared knowledge is the basis for any intelligent and effective teaching, and educationists acknowledge that good teaching must depend on the teacher's being able to reach out to the child's position and lead him from there. LOGO learning may be a special help where the subnormality of the child makes the gap unusually large and the teacher's task unusually difficult.

Future of LOGO

But the commitment of the Edinburgh group is to find hard evidence for the possible benefits of computer-based teaching systems like LOGO. Most of the known methods of educational assessment will be used for that purpose, and Howe and O'Shea have added one new test specially designed to reflect some of the skills that LOGO is supposed to promote. O'Shea calls it the "articulation test", and it tests the ability of a child sitting on one side of an opaque screen to instruct his partner on the other side on how to construct a particular pattern from coloured blocks. That apparently simple problem has been known to reduce an untutored child to tears of inarticulate frustration, so the results should be interesting; but so far, they are only suggestive.

On what evidence there already is, what part are computer-based systems really likely to play in future education? Papert purports to believe that the future of education and computer-based systems are one and the same, and the next few decades will see the day when each child sits at home at his own computer terminal, without going to school at all. Expense he shrugs off on the grounds that electronics, unlike anything else, are getting exponentially cheaper (consider the cost of the pocket calculator five years ago and now). Nonetheless, equipment of any kind is expensive and computers and their peripherals will remain more expensive than books. And although the Edinburgh research team has been impressed by the way that Papert's educational insights have been borne out, from the practical point of view their attitude is both more conservative and more pragmatic than his.

First, they do not see in LOGO a means of disposing of the teacher: the idea is that such systems may make conventional teaching methods more effective, not that they should replace them. Second, experience is beginning to suggest that the most effective use of computer systems may turn out to be in the education of subnormal children or those with other special problems. If the Edinburgh group can be accused of having a vision, then it is of machines which foster human interactions, rather than making them obsolete. □

BRITAIN •

Benn spells it out

Developments on the British energy front are fast and furious, with nuclear power capturing most attention. Chris Sherwell reports.

FAST moving sectors of the British economy are not in great abundance these days, but there is one that is beginning to behave in a manner representative of a seething hive of activity. Hardly surprising, for it is none other than the energy sector itself. And not a little of this is due to the increasingly voluble debate over nuclear power.

The arguments over whether Britain should have nuclear power already having been settled, the manner in which it is to be deployed and utilised is now at issue. That includes the question of timing, so there are tactical as well as strategic policy decisions to be taken. The latest involves the Steam Generating Heavy Water Reactor (SGHWR), expenditure on which was deferred for a year in the latest round of government spending cuts.

The cut means a saving for 1977–78 of £40 million, and a reduction of £5 million on research for the project. That in turn has made the broadening debate on the future of the SGHWR either more pointless or more controversial, depending on your perspective. But it hasn't prevented a start to the hearings of the House of Commons Select Committee on Science and Technology on the subject. They began this week, Mr Anthony Wedgwood Benn, Secretary of State for Energy, answering questions.

Mr Benn was fresh from his discussions at the end of last week with Sir Arthur Hawkins, chairman of the Central Electricity Generating Board (CEGB), who supported the pressurised water reactor when a choice was being made in Britain in 1974 but has since, on Mr Benn's testimony, given every assistance regarding the SGHWR. Sir Arthur was, however, expected to deploy cost estimates and electricity demand forecasts to advise against an immediate go-ahead, on the SGHWR or anything else. Mr Benn also had before him a report submitted within the past week from Sir John Hill, chairman of the UK Atomic Energy Authority (UKAEA), assessing the progress made so far on the SGHWR.

It was soon apparent that Mr Benn was concerned to make only four main points. One, as he pointed out at the beginning, the middle and the end of his evidence, the British Government has not yet reached a decision to cancel the SGHWR, nor even a preliminary view on the matter. Two, the decision through spending cuts to postpone for a year its commissioning, while possibly having consequences for the nuclear industry outside the SGHWR programme, was the product of deferment presenting itself as an option. This was in turn a result of "natural slippage" on the SGHWR's reference design and safety standards working in the same direction as the effect of falling demand for power stations on energy forecasts.

Third, the initiative which resulted in the circumstances under which the SGHWR was now under scrutiny lay not with the government but with the UKAEA. Sir John Hill had approached Mr Benn and given his view on the SGHWR; Mr Benn had asked him to put this before the UKAEA board for its considered judgment, and that had been done.

It was this, in fact, which made the hearing the more revealing, for the report itself was actually supplied to the committee by Mr Benn before the hearings and was used as a basis for questioning Mr Benn. Inevitably, some of its details came tumbling out.

The UKAEA's view, it emerges, is that, because of lower electricity demand and public expenditure stringency, the SGHWR is less attractive than it was two years ago. The "consensus view" of the board is, with the exception of the historically enthusiastic South of Scotland Electricity Board, that the SGHWR be replaced for the remaining thermal reactor programme by Pressurised Water Reactors (PWRs) or Advanced Gas Cooled Reactors (AGRs)—and that the AGR is the more promising, although operational experience is needed.

The UKAEA went further than this. Subject to a satisfactory outcome of the Nuclear Inspectorate's review of the PWR, there was a "strong argument" that the future needs of the nuclear industry could be met by the construction of PWRs under licence. This, Mr Benn freely acknowledged, would, if acted upon, constitute a reversal of the government's decision taken two years ago when his predecessor, Mr Varley, was at the Department of Energy. And, he said later, in the field of high technology one shouldn't "chop and change" once a decision was taken; he added reassuringly that he himself was "reluctant to be driven off".

The precise extent of his reluctance was twice made quite plain when he made his fourth point. This outlined his response thus far to the UKAEA, and it amounts to a warning. If the SGHWR programme is dropped, says Mr Benn, it could be a setback to the country's whole reactor programme. A decision to go for the PWR would mean re-commencing the whole effort to produce a reference design to meet UK conditions, and thus more delays, and even then it would not certainly provide a solution. It would also set aside the past two years' work, and previous work carried out at Winfrith in Dorset.

Moreover, this would amount to a statement from the UKAEA that it had lost confidence in its own system. That would in turn rebound and damage the credibility not just of the UKAEA, but of the systems it sponsors, including the fast breeder, and of the whole nuclear idea. The nuclear issue, in short, might be thrown right back into the public arena, "where it may belong". ☐

FRANCE

Staying nuclear

France's nuclear programme has come in for some domestic criticism recently, but looks like pressing ahead. A Correspondent reports

It is August, France is on holiday, and that has brought a degree of quiescence to town and country. There is even time for some sort of break from politics, or at least from certain political issues. But it remains uncertain whether, come September, one issue in particular will have been allowed completely to die away. The issue is energy —specifically nuclear energy. Specifically the fast breeder reactor. For, despite all the impressions conveyed abroad, the priority France gives to her nuclear programme in her overall energy strategy does not go totally unchallenged. And the priority given within that to the breeder reactor has not escaped attention.

The whole issue finally blew up early last month, at a place called Creys-Malville, which is near Lyons and on the Rhône. Under construction there is perhaps the most advanced reactor of its type in the world. Superphénix, it is called, and it is expected to be on stream in the early 1980s—all 1,200 MW of it. Like Britain, France already has a prototype breeder reactor, a 250 MW plant known as Phénix situated on the Rhône at Marcoule. But while Britain agonises about whether to go ahead with a demonstration commercial-scale breeder, France is on her way—or looked to be until last month, when there was a new development.

It was Europe's anti-nuclear lobby which stepped in. Superphénix, already the object of trade union protests, became the butt of criticism from ecologists and environmentalists as well. They came in hundreds and camped outside the site where workmen toiled. The jamboree lasted several days. The way it was brought to an end, however, aroused even more indignation than perhaps the construction itself: riot police moved in with tear gas and truncheons to evict the demonstrators, and some of the protesters were hurt.

The criticism in France, as in other industrialised countries contemplating the use of the fast breeder reactor, is emotive inasmuch as it rides on the back of fear, particularly about the implications of the large-scale production of plutonium. It is not less rational, or less important, for that. But its form is characteristic. So, too, is the response from Electricité de France (EDF) and other interests within the French nuclear industry, and from the government too. Just look at France's energy position, they say.

Imports account for something like 75% of the country's energy requirements, a dependence which France must seek to reduce, if only for strategic reasons. What is more, the argument runs, unlike Britain, the country has no oil, and its coal reserves don't compare with those of Britain or Germany. That means nuclear power is likely to make economic sense as well. And the alternative threat of an energy shortage embodies implications as alarming as nuclear power for people's lives.

Of course France, like other industrialised countries, has been forced to revise its energy demand forecasts in light of general economic developments. Energy use last year, for example, dropped by over 5%, more than the fall in national product, and there is increasing emphasis on energy conservation. A fair amount of encouragement is also given to research and development on new sources of energy.

But no one seriously doubts that France needs nuclear power now and will need it even more in the future. Even a special commission examining energy policy in France, formed partly in response to concern expressed last year by 400 academics at the increasing use of nuclear power, has not recommended any slowdown. Following a review of the nuclear programme earlier this year plans for power capacity over the next few years includes construction of 6,000 MW of nuclear power this year and next, and 5,000 MW in 1978. The change this represents on the original programme is marginal, and, despite the protests, the talk is still of 40,000–45,000 MW of nuclear power 1985. By that time most of the country's electricity will be nuclear generated and a substantial proportion of its total energy will be coming from nuclear plants.

●

All of this, moreover, will be taking place within the context of a thoroughly reorganised nuclear industry. Plans for conventional plant will continue to focus on the pressurised water reactors. Looking ahead, France expects that the new generation of fast breeders will be needed in the 1980s. That is why Superphénix received the go-ahead earlier this year. And the fact that France has secured the cooperation on the project of both Italy and Germany while retaining a 51% interest for EDF is of perhaps greater consequence to many of those awaiting a British decision on the fast breeder than the debate on its implications which is now growing in all the industrial countries.

- The final contract for the controversial Franco–South African deal involving the sale by a French consortium of two nuclear power plants to the South African Electricity Supply Commission (Escom) were not signed by the deadline of July 31 last week following the development of a complication, apparently over safeguards attaching to the deal. A South African delegation left Paris after 24 hours of talks without having signed anything, and although French spokesmen sounded confident this raised doubts about whether the deal would go through. It now appears that an agreement concerning safeguards was later initialled in Paris and will be submitted to the International Atomic Energy Agency and Euratom. It is thought that once this is accepted, it will pave the way for the signing of the main contracts.

WEST GERMANY

Exporting for survival

West Germany's nuclear industry is not becoming any less involved in the politically sensitive area of exports. A Correspondent reports.

FURTHER developments in the field of nuclear exports have come with news of additional moves from West Germany exploiting this increasingly lucrative market. Reports quoting West German Economics Ministry officials and spokesmen for the country's leading power station constructor, Kraftwerk Union, indicate that West Germany has been clearing the way with Nigeria for negotiations to begin on the first sale of a 500–600 MW German nuclear plant to a black African country.

The news coincides with the visit to West Germany of the Nigerian Prime Minister, General Yardua. It also comes just a week after Brazil had signed delivery contracts with Kraftwerk Union for the construction of two nuclear reactors as part of last year's government-to-government agreement, and less than a month after the signing in Tehran of the contract between Kraftwerk Union and the Atomic Energy Authority of Iran for the turnkey supply of two 1,200 MW pressurised water reactors.

With the signing of the latter contract, West Germany has become the first western enterprise actually to conclude a nuclear contract with Iran. The reactors, which are to be built near the city of Bushehr on the shore of the Persian Gulf, were begun this time last year after a letter of intent was issued to Kraftwerk Union in November 1974. Of the 3,800 employees presently on site, about 600 are German expatriates.

Kraftwerk Union describes the plants it exports as the most reliable reactor systems, and generally cites the Biblis plant in Germany in support. In fact, as Rheinisch-Westfaelische Elektrizitaeswerk (RWE) confirmed last week, that station has now revealed technical problems in the course of a planned shutdown, and the length of the closure is now likely to be doubled to four months.

What this means in terms of costs for Kraftwerk Union is uncertain, but it does not expect to operate at break-even point until the 1980s anyway. The star of Germany's nuclear industry, the company is crucially dependent on exports to supplement the home market and so render possible the economies of scale necessary to compete favourably with the USA. But some overseas contracts were lost in the first half of 1975. These included the plan for a nuclear power station at Kaliningrad on the Soviet–Polish border, which fell through because of East German objections concerning the supply of electricity, and deals with South Africa, Sweden and Switzerland.

The company also appears to be finding that permits are now taking much longer to obtain, and greater safety measures, among other things, are extending the construction time for the average plant. Germany has its own protectors of the environment too, keen to prevent (or at least delay) construction of plants beyond the ten or so already in operation. ☐

SWEDEN

Suffering without support

Wendy Barnaby reports from Stockholm on the state of basic technical research in Sweden

To live in Sweden is to be impressed by the sophistication of the country's technology: a level of accomplishment which thrives on extensive research and development. There is, however, one part of this body of excellence which is ailing. Basic technical research is, in fact, close to death.

Nobody seems to know exactly what basic technical research is, but everyone agrees that it is conducted for the extension of knowledge, without any specific application in view—although it may of course be used if the necessary techniques are developed. It is also differentiated from pure fundamental research, which has no possible or likely practical application and which is supported in Sweden by the Natural Science Research Council. Opinion is unanimous, too, on the extent to which basic technical research is presently being supported. In the words of a spokesman at the Academy of Engineering Sciences, it is being given "no money at all".

This is hardly an exaggeration. Its needs used to be met by the State Technical Research Council. This body was disbanded in 1968 and replaced by the Swedish Board for Technical Development (STU) whose emphasis has been on supporting applied research, specifically of the sort that will further innovation and technical expertise in Swedish industry. Including governmental and industrial outlays, Sweden spends about Sk4,000 million (about $900 million) annually on research and development. For the 1975–76 financial year, STU's budget amounted to about $56 million, of which—according to a spokesman there—about $10 million was devoted to basic technical research.

Or, rather, to some types of that research. For there has been a reorientation of grant-giving to favour certain areas of "big" science—space and elementary particle research, for example. This has resulted in fewer numbers of bigger grants being given in these areas, rather than a multitude of smaller grants covering a broader range. Dr Gösta Lagermalm, STU's senior policy adviser, agrees that because of this change of emphasis, the complaints of physicists, chemists and biologists trying to pursue "small" basic technical research are justified.

Part of the work of a governmental commission set up in 1972 to survey Swedish research councils and make suggestions for changes in their organisation was to consider this particular problem. During the commission's investigations, STU was asked to indicate those projects supported by its 1971–72 budget which had had their support reduced or cut off entirely in succeeding budgets because they were too much oriented towards basic technical research. STU replied that in 1971–72, it had given about $1.2 million to 49 such projects. This fell in 1972–73 to just over $650,000 for 31 projects, only four of which would be kept on for 1973–74—all for the last time.

But approaching the problem through statistics does not really give the feel of it. Neither can it be gauged by comparing the number of applications for basic technical research grants received with those approved. As one professor at the Institute of Technology explained, colleagues of his who have been refused grants no longer apply for them, even though they still want to pursue their work and believe that it is more important for the country's technical development than the short term projects they are forced to switch to. Another said that some colleagues he knew had tried to get funds by dressing their basic technical research applications to make them look like projects which would yield practicable results quickly.

Various propositions have been put forward to find a new home for basic technical research. Some have suggested that the Natural Science Research Council should take on the job, others that STU should be given more funds in order to bring the research under its umbrella. Another suggestion was that this sort of research should have its own dispensing body. The governmental commission recommended last year that STU assume full responsibility for "support for technical research of a basic nature". This would mean setting up another grant-giving body within the framework of STU, a task which seems hardly likely to be undertaken in view of the fact that yet another commission is presently studying the aims and structure of STU itself, and is not due to report for another 18 months or so.

Thus, while the planners plan, part of the activity they are meant to be stimulating is simply being strangled, with the limiting of scientific enquiry and the lowering of morale of those academics concerned as the result. □

CANADA

Council rift over report

The Science Council of Canada received a little more public attention over a recent incident than it wanted. David Spurgeon reports from Ottawa

THE well-known French-Canadian science broadcaster Fernand Seguin resigned from the Science Council recently when it would not publish his dissenting views on a council report on population, technology and resources. The report calls for a sharp reduction in immigration to slow Canada's population growth and maintain its high standard of living. It also proposes that Canada should use high technology to increase its food production and exports of food and raw materials.

Mr Seguin contended that the large increases in food exports proposed would help create a small club of privileged countries and would support the US stategy which seeks to use food as a political weapon in a way that the OPEC countries have used their oil. He maintained that the high technology called for in the report would require massive participation by multinational companies, a large-scale influx of foreign capital, and construction of more than 100 nuclear power plants in Canada. The upshot would be that Canada would align itself with US "food imperialism", and "hunger-stricken countries would have to come and eat from our hand".

Another council member, Dr Ursula Franklin, professor of metallurgy and materials science at the University of Toronto, also disagreed with the council report. She re-assessed her position on the council as a result of the refusal to issue a minority report, but later decided not to resign, saying she would continue her participation in the council's project on the Conserver Society, of which she is head. (The Conserver Society is one of the three themes around which the council has recently structured its programme. The other two themes are technological independence and industrial strategy, and the health of the Canadian scientific community.)

In a newspaper interview ahead of the council study's publication, the study's chairman (and a former council chairman), Dr Omond Solandt, proposed cutting immigration to Canada from last year's 143,000 to an annual net figure of 50,0000 to produce a population of 28 to 30 million by the end of the century (present population is about 22 million). He argued that Canada can only export food if it does not import people. Furthermore, he said that Canada could feed four or five times as many people by exporting grain as it could if they lived in this country, since people in developing nations consume only about 400 pounds of grain a year compared to 2,000 pounds consumed by North Americans.

Energy would also be a problem, said Dr Solandt, because Canadians consume more energy than do people in developing nations. "If we brought in another 20 million, it would completely disrupt the economy," he said. "We probably wouldn't be able to feed the people brought in, and we certainly wouldn't be able to keep them warm." Dr Franklin has contended that it is not possible for a country with Canada's small population to increase food and raw material production greatly without high technology, and says this will mean that Canada will increasingly have to sell out to foreign capital. It would also require highly centralised planning.

In Dr Franklin's mind, the problem with the Science Council report is not so much with its population targets as with these problems of technology. Immigration levels can be adjusted up and down, but high technology is irreversible, she maintains. It also involves environmental and social costs, and she says council members have demonstrated an unwillingness to come to terms with the inevitable social problems.

The council chairman, Josef Kates, said the minority report was refused because it had nothing constructive to offer. French-Canadian reporters raised the issue at a press conference held to release the council's annual report only a day or two after the controversy surfaced and vice-chairman Claude Fortier, director of the department of physiology at Laval University, acknowledged that the council has published minority reports in the past.

The council accepts the right of members to differ with a majority report, but the council reserves the right to decide the mode of transmission of the minority report, he said. Sometimes this is simply a note, sometimes it is done in the letter of transmissal of the report to the Minister of State for Science and Technology (the method to be followed in this case). Dr Fortier said no report of council had had more discussion than this one (a remark that echoed Dr Solandt's comment that the study was the most difficult ever undertaken by the council). Both Dr Fortier and executive director J. J. Shepherd said they regretted Mr Seguin's departure. □

IN BRIEF

Sea Law, round four

The Law of the Sea Conference convened in New York for another seven-week session this week surrounded by a major new uncertainty, the Presidential campaign in the United States, but with some other problems effectively sidestepped by the sprinkling (not to say, flood) of unilateral declarations of 200-mile fishing limits made in the past few months. The EEC countries have now declared their joint intent to introduce a community fishing limit, even if the conference does not come up with a proper agreement. It is, however, the wider question of how to deal with mineral resources on other parts of the sea bed that is likely to exercise the New York session most. How are these resources to be exploited "for the benefit of mankind as a whole" (to coin a conference phrase)? And would the proposed International Seabed Authority actually wrap up every manganese nodule so inextricably in red tape as to make a good principle impossible to work out in practice? Any real decisions are likely to have to await a fifth round of conference—and the result of the US election in November.

What's happening on Mars?

Two of the three experiments carried on the Viking lander and designed to detect reactions in the soil characteristic of living organisms have so far yielded data. One, measuring the conversion of radioactively-labelled nutrients to labelled carbon dioxide, showed an initial rapid burst of activity which has since died down to almost nothing. In another, the soil released large amounts of oxygen when initially dampened with water, even before the experiment proper (of adding a concentrated 'chicken soup' of nutrients) had begun, but nothing has happened since.

The best guess at the moment is that the Martian soil contains large amounts of bound oxygen, a not improbable speculation as the soil is rich in iron minerals which in some circumstances can readily bind oxygen under the influence of ultaviolet light. This would accord with earlier speculation that oxygen and hydrogen originating from water might be trapped in the iron minerals on Mars. So far it looks as though Mars may be the Mecca of the soil chemist (since no known soil on Earth has ever produced similar reactions, although the search is now on amongst desert soils) but that the question of life there remains as much of an enigma as ever.

Forecasting error

KENNETH MELLANBY

PLANNING must be based on the best possible forecasts of future developments. Unfortunately the best is generally not very good. Dr Walter Marshall told a conference on Renewable Sources of Energy organised recently by the Royal Society of Arts that the only certain thing about forecasts of energy use was that they would always prove to be wrong. Thus the Central Electricity Generating Board's projections made in the early 1960s overestimated the peak load for current used in 1975 by some 40%, which makes one suspicious of their figure foretelling a doubling or even trebling of the use of electricity in the period up to the year 2,000.

Population projections are even more difficult. Thus one report published shortly before the 1939–45 war, when England and Wales had a population of 41 million, suggested that this might fall to 31 million by 1975, and that the chances of a population increase were remote. In fact numbers increased by 8 million. The most recent figures issued by the Office of Population Censuses and Surveys suggest that the present trend to ZPG (zero population growth) will suffer a modest reverse after 1981, and that numbers in England and Wales will grow by about 1½ million by 1991. It will be interesting for those who survive to see what really happens.

Forecasting traffic densities, on which future road programmes are based, is an equally chancy business. Until recently the Department of the Environment decreed that their figures produced by the Road Research Laboratory must not be questioned. This arrogant attitude has at length been somewhat relaxed, but an enormous increase in the number of private cars and of their use is still postulated. Yet there is little reason to believe that traffic projections are any more accurate than those for power or population.

Unfortunately many people seem to think that forecasting is becoming increasingly scientific, and that the use of computers is making the results more reliable. It is true that a great deal of mathematical skill has gone into the study of population trends, energy use and traffic census, and that the calculations arising therefrom have sometimes been speeded up by suitable computer programs, but unfortunately there has been no improvement in obtaining the data used. The whole process has too often been one of "garbage in, garbage out". There are so many unknown and uncontrolled variables that it might be better to rely on crude sums done on the back of envelopes, than to use elegant calculations and expensive machinery which give a spurious illusion of scientific accuracy.

Some errors cannot be eliminated. We could foretell the birthrate accurately for about eight months from any date, and, provided there is no war or major epidemic, estimates of death rates and total population are foreseeable for a similar period. Forecasts for longer periods are simply guesses, affected by social factors which, so far, have defied accurate quantification. Only some form of rigid totalitarianism could improve the statistics.

Unfortunately some projections have a built-in source of error. Our government is committed to the idea of economic growth. Scientists in public employment appear to be expected to assume that this growth will take place, and that there will be increased energy consumption, more consumer goods, more travel and a growing "environmental impact". It is assumed that government policy will stimulate this growth in the economy. Some believe this to be likely, others describe schemes intended to produce growth as "pouring out public funds like water, to create lakes in which lame ducks will sink". It may be impossible to keep politics out of forecasting, but political factors should be identified and not concealed.

Lithium supplies

SIR,—We fully support the contention of Walton and Spooner (June 17, pages 533–5) that there is a pressing need to identify further resources of lithium, but would take issue with them on a few points.

In Table 2 some 50% of their total resources derives from North American brine deposits. However, J. D. Vine (*Journ. Research U.S. Geol. Surv.*, **3**, 4, 479–85; 1975) recently emphasised that the amount of *recoverable* lithium at Silver Peak is, in fact, lower than the published reserves by a factor of 10. Should a similar factor apply to other brine deposits the shortfall between Western world reserves and projected consumption becomes critically magnified.

Our present, limited, understanding of the geochemistry of lithium suggests that more small brine and pegmatite sources may be discovered in the developed countries. Even so, the best prospects for large reserves lie in Africa and South America, sources which for various reasons may not automatically be available to the technologically advanced Western nations. We may be obliged to rely, therefore, on known smaller domestic deposits and on exploration and development of new types of lithium deposit.

Walton and Spooner state that the European countries "possess no presently identified significant lithium resources": though true of reserves it is not so of resources. Small lithium pegmatites and lithia brine flows are known in several European countries, including Great Britain, but none is exploited at present. Given suitable financial inducement to development, they could make a valuable though comparatively small contribution to our requirements.

Of more significance are the lithium-rich portions of the Variscan granites, in which lithium occurs largely in "lithionite" mica. In Cornwall, for example, parts of just such a major lithium resource have been affected by kaolinisation and some of the lithionite could be extracted during the working of china clay. As yet the distribution of lithionite-granite in the Cornubian batholith is imperfectly known and we have only sparse information on the variations in lithium content and none on isotopic composition. Nevertheless, exploitation of zinnwaldite mica from granites of the Czechoslovakian Erzgebirge, albeit under a different economic philosophy, indicates that this type of deposit may have an important role to play in the supply of future lithium requirements and argues for a direct programme of geological and chemical engineering research ino the lithium potentialities in the Western European Variscides.

Bran and sawdust

SIR,—It was suggested by Dr Jukes (May 13, page 92) that bran and sawdust constitute a safe diet. This is not so. There is evidence (Mackarness, *Not All in the Mind* (Pan; 1976)) that, on an evolutionary time scale, cereal is a recent addition to our diet, one to which we have not yet become adapted, and a Stone Age pre-cereal diet was recommended.

As for sawdust, it is highly likely that timber is carcinogenic: wood workers have a high incidence of nasal adenocarcinoma (Acheson *et al.*, *Brit. J. industr. Med.*, **29**, 21; 1972), while mice bedded on wood shavings show an increase in so-called "spontaneous" tumors (Sabine *et al.*, *J. Natl Cancer Inst.*, **50**, 1237; 1973).

It is high time to accept the fact that nothing whatever is completely safe.

Yours faithfully,

VALDA M. CRADDOCK

MRC Toxicology Unit,
Carshalton, Surrey

Canned crab

SIR,—In 1959 Ecuador declared the unoccupied lands of the Galapagos Archipelago a national park; by 1968 a department of national parks and wildlife was created to administer the park. The national park service service started collecting an entrance fee in 1972 that, in part, is used to finance conservation programs in the islands. Although conservation efforts have grown, tourism has grown more spectacularly. For instance, since 1969 the number of tourist boats have more than doubled.

There is currently an effort to extend the national park to protect the marine life near the Galapagos shores. It will be difficult to regulate the fishing but this may become necessary. Packing boats started to visit the islands regularly in 1972, allowing fishermen to go farther and stay out longer. Many of the endemic species such as the Galapagos penguin are dependent on small fish which could become commercially valuable. The Galapagos penguin is subject to total nesting failures suggesting that competing pressure from humans could, over a period of time, reduce their population.

Dramatic decreases in species number or composition will probably be detected but subtle changes could go unremarked. In 1972 when no more than 80 tourists were visiting Pta. Espinosa, Fernandina weekly, a hermit crab with a discarded film can marched through my camp in July and August. Our camp site was a mile from the tourist landing and we had no similar film canisters. The hermit crab's aluminium home should have heated up rapidly in the hot equatorial sun, which may be why the crab stayed in the shade of the mangroves. Pesticides have been found in almost every remote corner of the world; the film canister may be next.

Yours faithfully,

news and views

Anti-idiotypic antibodies: a clinical future?

from L. Brent and P. J. Kilshaw

ONE of the most recent concepts emerging from the witches brew of present-day immunology is the exciting possibility that antibodies directed against the receptor sites of other antibodies may have a role in regulating the immune response.

It is more than a decade ago that Oudin and Michel (*C.r. hebd. Acad Sci Paris*, **257**, 805, 1963) observed that antibody receptor sites (which bind antigens in a highly specific manner) themselves bear antigenic determinants and that these 'idiotypic' determinants (or idiotypes) can evoke antibody production in animals belonging to the same species. Idiotypes owe their existence to the unique configuration of the variable region of specific antibody molecules, and they should not be confused with 'allotypes'—again first described by Oudin—which are antigenic specificities present in the immunoglobulins and other proteins of different groups of individuals of the same species and determined by different alleles of the same gene The vast repertoire of antibody receptor sites within a single individual is associated with a great heterogeneity of idiotypic determinants, and so the production of antibodies with combining sites for the stimulating antigen is matched by the appearance of a limited range of idiotypes. The observation that antibodies can combine with the receptor sites of other antibodies led Jerne (*Ann Immun Inst. Pasteur*, **125C**, 373; 1974) to suggest that the production of anti-idiotypic antibodies might be a normal event that modulates the degree and duration of the response. This could theoretically be the case provided that lymphocytes carry receptor sites on their surface identical to those on immunoglobulin molecules· by combining with these receptors, anti-idiotypic antibodies could prevent contact between lymphocytes and their specific antigens or even cause cell death, thus limiting the immune response. Such a mechanism would presumably depend on the replication of specific idiotypes up to or beyond the threshold at which antibody production against them ensues; that is, by an increase in the antibody titre in the case of B cell responses, and for T cell responses, an increase in the number of cells with specific receptors. At present there is little direct experimental evidence to support this fascinating theory, but over the past few years there have been a number of successful attempts to suppress both humoral and cellular responses by passively administering anti-idiotypic antibodies or by actively stimulating their production.

The urgent need for a specific form of immunosuppression in clinical transplantation has provided an additional incentive for the study of anti-idiotypic antibodies, using T cell receptors or alloantibodies directed against specific transplantation antigens. Ramseier and Lindenmann (*Path. Microbiol.*, **34**, 379; 1969) were the first in the field· they reasoned that if an F_1 hybrid mouse resulting from the mating of animals of two inbred strains (say A and B) is injected with lymphocytes from one of the parental strains (say A), the only antigenic determinants present on the injected cells recognised as foreign by the F_1 recipient would be receptors for antigens of strain B. (A mouse which possesses both A and B antigens on its cells will not have receptors for either). In these circumstances the production of anti-(anti-B) antibodies could be expected. Using a rather indirect and cumbersome test, the PAR (Product of Antigenic Recognition) asay, Ramseier and Lindenmann (see *Transplant. Rev*, **10**, 57; 1972) showed that sera taken from animals sensitised in this manner were capable of suppressing the *in vitro* reactivity of strain A lymphocytes against alloantigens of the B strain. The immunosuppressive moiety responsible for this effect was not, however, fully characterised.

More recently, Binz, Wigzell and their colleagues (see Binz, Kimura and Wigzell, *Scand. J Immun*; **4**, 413; 1975) have adopted a similar approach using the inbred rat strains Lewis and DA They found that anti-receptor site antibodies could be prepared optimally by injecting purified T (thymus-dependent) lymphocytes from one of the parental strains (Lewis say) into F_1 hybrid recipients. In this case then, sera taken from the hybrids would specifically abolish the response of Lewis lymphocytes against DA antigens, and this has been shown with the aid of graft-*versus*-host and mixed lymphocyte culture reactions These assays test the ability of lymphocytes to recognise and respond to specific alloantigens Furthermore the F_1 hybrid antisera formed a precipitate with alloantibodies of the appropriate specificity and they agglutinated alloantibody-coated red cells.

Anti-idiotypic antibodies might be expected to provide a useful tool for characterising the elusive T cell receptors for antigens of various kinds. By absorbing putative anti-receptor site antibodies with purified T cells or with alloantibodies, Binz and Wigzell (*J. exp. Med.*, **142**, 197; 1975) were able to show that the idiotypes on the T cell receptors were closely similar to, or identical with, those present within the combining sites of immunoglobulin molecules Further, they succeeded in identifying receptors from both T and B cells in the body fluids of normal Lewis rats.

In a paper published in *Nature* recently Binz and Wigzell (*Nature*, **262**, 294; 1976) describe the effects of an anti-idiotypic response on the survival of allogeneic rat skin grafts. To evoke the anti-idiotypic response they sensitised Lewis rats with Lewis receptors specific for antigens of the DA strain The receptors were isolated from the serum of normal Lewis rats with the aid of an immunosorbent consisting of antibodies specific for Lewis anti-DA idiotypes coupled to sepharose particles, dissociated from the immunosorbent, treated with gluteraldehyde (this causes cross-linking and increases immunogenicity) and injected in Freund's adjuvant into four Lewis rats. This procedure was repeated three weeks later. DA skin grafts transplanted to these animals 19 days later had a mean survival time of 30 days, one of them surviving for 38 days, compared with 10 days in the untreated controls. (This observation was confirmed in a larger group of recipients, in which the mean survival time proved to be somewhat less, 24 days.) The partial unresponsiveness was specific in that grafts from a third strain (BN) transplanted at the same time were rejected with a mean survival time of 12 days. The lymphocytes of the four immunised Lewis rats were tested for MLC reactivity before skin transplantation and found to be nonreactive to DA but fully responsive to BN antigens. Some time after they had rejected their skin grafts the sera from these rats were subjected to rigorous tests which established without doubt that anti-idiotypic antibodies were still present in significant amounts—a finding that received support from the observation that these animals suffered from an impairment of alloantibody production when they were challenged with (DA×Lewis)F_1 hybrid lymphocytes.

Binz and Wigzell propose that anti-idiotypic antibodies caused the physical elimination of cell clones which were specifically reactive to DA antigens. Whilst the results are impressive and the authors' interpretation entirely plausible a note of caution must nevertheless be sounded, especially in relation to the clinical application suggested by Binz and Wigzell. First, the complexity of the manipulations involved is considerable Second, investigations involving the immunoregulatory powers of anti-idiotypic antibodies in transplantation have been largely dominated by the Lewis and DA rat strains, and it is now vital to show that the phenomenon extends to other strains and to other species. Third, the prolongation of graft survival achieved in these experiments, though considerable, is strictly limited: in view of the apparent presence of anti-idiotypic antibodies long after the grafts had been rejected one may well wonder why survival was not more prolonged or even permanent. It would seem that anti-idiotypic antibodies alone are not sufficient to guarantee complete unresponsiveness. Finally, the active production of these antibodies depends on pretreatment of graft recipients; even if it were possible to apply the rat methodology to human graft recipients (and there must be considerable doubt about that) pretreatment would not be practicable in the transplantation of cadaveric grafts, that is, in a situation in which the intercession of a specific form of immunosuppression is most needed. Perhaps the most likely application to man will be in the control of autoimmune diseases.

Despite these reservations the data of Binz and Wigzell are clearly of the greatest importance, if only because of their impact on theories of antibody formation and control. Anti-idiotypic antibodies with specific immunoregulatory properties have been described in other systems, and these have so far always involved antigens that evoke antibodies of very narrow clonality (that is with a narrow range of idiotypic determinants), such as phosphoryl choline (Cosenza, *Eur. J. Immun.*, **6**, 114; 1976) and group A streptococcal carbohydrate (Eichmann, *Eur. J. Immun*, **5**, 511; 1975). Time alone will tell whether this special feature is a prerequisite for the production and immunoregulatory properties of anti-idiotypic antibodies. ☐

Associated production of charm

from W. T. Toner

A NEW heavy particle with two properties characteristic of the charm scheme (see *News and Views*, **259**, 622; 1976) has been discovered by the Stanford-Berkeley collaboration working on the SPEAR storage ring at Stanford in California (Goldhaber *et al.*, *Phys. Rev. Lett.*, August 2, 1976). It was observed in decay modes containing K mesons and seems always to be produced in association with one or other of two heavier particles whose presence is inferred from indirect evidence.

When the same group discovered the ψ family and showed that the unexpectedly large rate for the annihilation of high energy electrons and positrons began suddenly at the point where the ψ series changed from having uniquely narrow widths to a more normal shape, most particle physicists confidently assumed that the excess was due to the copious production of charmed particles into which the heavier ψ's could decay rapidly· it should be as easy to create two oppositely charmed particles out of the annihilation energy as two charged particles. There should be no difficulty in finding them since theorists predicted frequent decays involving K mesons.

Months later when the only reports from Stanford were of fruitless searches, people began to find excuses. Easily identified decay modes containing K mesons and no neutral particles might be rarer than one had thought. It now seems that everyone had underestimated the amount of careful work needed to find even the most obvious decays. In fact, with hindsight, one can find some evidence for the new particle in the previous negative report (Boyarski *et al*, *Phys. Rev. Lett.*, **35**, 196; 1975).

In the experiment every electron–positron annihilation event which results in two or more charged particles being detected is recorded. After cases with electrons or mu-mesons are eliminated, each event is analysed to test the hypothesis that a particle was produced which decayed into a π and a K meson. Charmed lives, though unusually long, should still be much too short for the charmed particles themselves to leave tracks; only π and K mesons or protons (anti-protons if negatively charged) can be recorded.

From a rough determination of the velocity of each particle and a precise measure of its momentum, the analysis programme first computes the relative probability that the particle was a π meson, a K meson or a proton so that a precise mass can be assigned When the decision is ambiguous between K and π, both possibilities are included and the event is analysed as if it were two (or more) different events each with an appropriate fractional statistical weight. The energy of each particle can now be calculated accurately from Einstein's relation between mass (m) energy (E), momentum (p) and the velocity of light (c)· $E^2-p^2c^2=m^2c^4$.

If an event contains a π and a K meson of opposite charge their energies and momenta are added and the "effective mass" of the pair is calculated. The event is next treated as if no other measurements were available (very few events are complete) and the energy and momentum of the "missing" system containing all other particles produced is found by subtraction from the values given by the storage ring parameters for the annihilation as a whole The mass of the system recoiling against the pair, known loosely as the "missing mass", is now calculated from the mass–energy relation. The analysis is repeated for any other possible ($\pi^{\pm}$ $K^{\mp}$) pairing.

"Effective" and "missing" mass histograms are built up with results from many thousands of individual annihilations. In most cases there is no relationship between the paired particles. Such random pairings give the histograms a smooth shape on which are superimposed peaks at distinct masses corresponding to correct pairings of the decay products of real particles.

The SPEAR effective mass histogram shows an unmistakable peak at a mass of $1.86\,\mathrm{GeV}/c^2$. If the missing mass histogram is restricted to events with a π–K effective mass of this value, a strong signal is seen which more recent data show to be two peaks with "missing masses" of 2.02 and 2.15 GeV/c^2. No decay modes have as yet been reported for these heavy recoils. The widths of the peaks are unusually small for particles with such large masses but the experimental resolution is not fine enough to class them apart on the grounds of width alone. The data strongly suggest but do not yet prove that all non-random π–K pairs with a mass of $1.86\,\mathrm{GeV}/c^2$ are produced in association with recoils in the high mass peaks. Similar features are found in the analysis of $(K^\pm\, \pi^\pm\, \pi^\mp\, \pi^\mp)$ systems.

It is very hard indeed to explain these observations in terms of "just" three more ordinary particles. Besides, were they so they should have been seen in many experiments at proton accelerators The associated production of charmed particles is the only natural explanation.

Progress in the spectroscopy of charmed particles should be rapid now that three masses and two decay modes have been identified. They can be used as tracers to help identify the cascade decays of heavier charmed particles which should contain them. If these particles are the same as those seen decaying with the emission of positrons in the neutrino experiments (*News and Views, loc. cit.*), events not containing positrons should have ($K\pi$) pairs and ($K\pi\pi\pi$) systems at this mass in relative amounts predictable from the SPEAR data. And so on.

The large and extraordinarily productive group working at SPEAR will continue their experiments. If they go on at the present rate the new particles will soon outnumber the experimenters. Further results from the SPEAR group were presented at the recent Tbilisi conference a report of which will be appearing in a forthcoming issue.

Quasi-superheavy nuclei

from P E. Hodgson

THE recent discovery of superheavy nuclei in monazite, a mineral from Madagascar (*News and Views*, **261**, 627; 1976; *Phys. Rev Lett.*, **37**, 11; 1976) will stimulate further interest in the transient quasi-superheavy nuclei that are formed briefly during collisions of heavy ions.

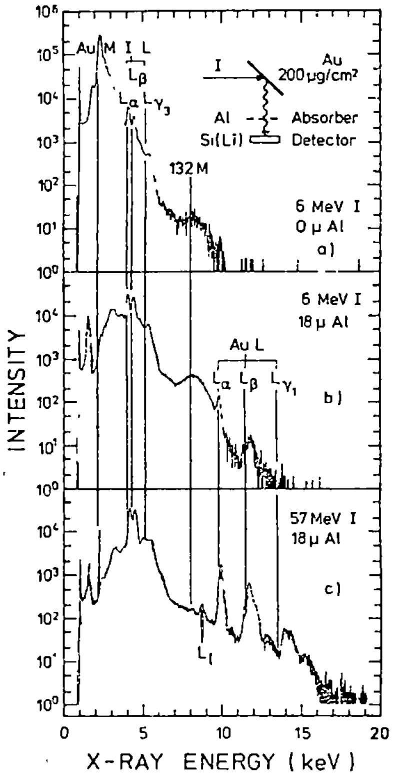
In such collisions, the heavy ions remain near each other for a short time that depends on their relative velocity. Two lead nuclei, for example, one stationary and the other moving with 10 MeV per nucleon remain within two nuclear diameters of each other for about 3×10^{-22} s. Since this separation is far smaller than the radius of the innermost electron orbit there is no difference, from the point of view of the electrons, between two colliding lead nuclei and the single nucleus that would be formed by their fusion.

The electrons in the colliding ions are in the orbits appropriate to lead, and when the two nuclei collide the two electron clouds are in violent interaction. If now the nuclear interaction time is long enough these electron clouds can rearrange themselves in the configuration corresponding to the electron orbits of the combined superheavy nucleus. This system of two colliding nuclei and the electron cloud of the combined nucleus is called a quasi-superheavy nucleus.

The likelihood of formation of such nuclei depends on a delicate balance of interaction and rearrangement times, so that they can only exist, if at all, for a limited range of relative velocity of the colliding ions. If this velocity is too low, the nuclei will not be able sufficiently to overcome their mutual electrostatic repulsion to appear to their electrons as a single entity. If on the other hand the velocity is too high, they will not remain in close contact long enough for the electrons to rearrange themselves into the electronic configuration of the combined system.

Calculations have been made of these limiting velocities, and it is found that the ratio of the upper to the lower velocity is about 0.13, independent of the atomic number or the electron shell. Thus for all electron shells there is a range of velocities for which the system can be considered a quasi-atom The optimum distance of closest approach which corresponds to the greatest lifetime of the quasi-atom gives $T_{\max}=(n^3/Z^2)\times10^{-15}$ seconds where n is the principal quantum number of the electron orbit and Z the nuclear charge.

One way of showing that a quasi-atom has been formed is to detect one or more of the characteristic X rays due to inner shell transitions and to verify that they have the required frequencies This is the classical method due to Moseley for measuring the nuclear charge. For such transitions to take place it is first necessary to form a vacancy by removing an electron from an inner shell.



X-ray spectra from a gold target bombarded with iodine. The broad peak around 8 keV is attributed to X rays from the combined system with $Z=132$.

This can be done by forming a vacancy in the projectile and then transferring it to the combined system. Such vacancies can be produced in heavy ion collisions mainly by electron promotion, in which some of the energy of the interaction is changed to excitation energy. The vacancy then has to live long enough for the X-ray transition to take place and since it can be destroyed by a collision with a nearby atom there is a competition between the transition time and the collision time. The probability of X-ray emission thus depends strongly on the density of the gas.

The first experimental evidence for quasi-molecular X rays was obtained by Saris *et al.* (*Phys. Rev. Lett.*, **28**, 717; 1972) who bombarded argon-saturated silicon targets with 70–600 keV argon ions. This gave a continuous X-ray distribution between the characteristic L and K X-ray lines of argon. These X rays are attributed to transitions to the $2p\pi$ level of the molecular system. In a later experiment they confirmed the density dependence of the X rays and compared the results from various targets. This work has since been extended and confirmed by several other groups.

The X rays from the quasi-superheavy nucleus with $Z=132$ have been found by Mokler *et al.* (*Phys. Rev. Lett.*, **29**, 827; 1972). They bombarded a gold target with iodine and some of their X-ray spectra are shown in the figure. The broad peak at about 8 keV is attributed to transitions in the quasi-superheavy nucleus. This occurs at the expected energy and detailed calculations of other possible processes showed that none of them could account for this peak. Similar results were obtained with other targets.

It is now possible to make relativistic many-electron calculations of the energies of the states during the collision process and hence to find the energies and intensities of the expected X rays for different interacting ions as a function of energy. The detailed experimental confirmation of these results shows that the phenomenon is essentially understood. There still remain many questions that require further study, in particular the possibility of other mechanisms contributing to the X-ray emission and the angular distribution of the emitted radiation. A review of the present status of this work has recently been published by Armbruster (*Enrico Fermi Summer Course*, LXii; 1976). □

Muscle disease at Durango

from Jeremy Brockes

The Fifth International Scientific Conference sponsored by the Muscular Dystrophy Association of America, entitled Pathogenesis of the Human Muscular Dystrophies, was held at Tamarron, Durango, Colorado from June 21 to 25, 1976. The program Coordinator was Dr Lewis P. Rowland of the Columbia-Presbyterian Medical Center, New York.

THE human muscular dystrophies are a complex of hereditary disorders whose underlying mechanisms are completely unknown. It was thus appropriate that the seventy contributors to the Fifth MDA conference considered many aspects of normal and abnormal muscle biology. In this report, I have concentrated on new information that may be of direct relevance for understanding or diagnosing these diseases.

In terms of understanding the mechanism of a muscle disease, the most exciting presentations came on the first day when recent work on the autoimmune basis of myasthenia gravis was presented by J. Lindstrom (Salk Institute) and D. B. Drachman (Johns Hopkins University). It has recently been shown in a number of laboratories that the serum of myasthenia patients contains antibodies that react with acetylcholine receptor. Drachman showed that certain features of the disease can be passively transferred to a mouse with purified gamma globulin from a patient. The mouse exhibits decremental responses to nerve stimulation together with a decrease in endplate acetylcholine receptors and other characteristic features of the myasthenia syndrome. These effects are in part dependent on the third component of complement, as evidenced by the ability of cobra venom factor (which depletes C3) to abrogate the transferred disease, but independent of later components as shown by transfer into the C5 deficient strain. The effects of antibody were further considered by Lindstrom in an animal model. When purified electric eel receptor is injected into rats, the animals mount an immune response which leads to the syndrome of Experimental Autoimmune Myasthenia Gravis (EAMG). In the acute phase of this disease, approximately 10–15 days after injection, cross-reacting antibodies attach to junctional receptors in the synaptic cleft and attract phagocytic cells, mainly macrophages. This leads to a partial disjunction of nerve and muscle, and further morphological abnormalities in the post-synaptic membrane which were described by A. G. Engel (The Mayo Clinic). The acute phase is succeeded about two weeks later by a chronic reaction in which antibody-induced modulation of junctional receptors leads to failure of junctional transmission, progressive weakness and (usually) death. The reason for the apparent breakdown of tolerance to nicotinic acetylcholine receptors in the human disease, and the source of antigen that drives the response, are not known. In view of the close connections between myasthenia and the thymus, one candidate for the responsible antigen is the thymic myoid cell. Drachman reported that cultured rodent myoid cells possess acetylcholine receptors on their surface as evidenced by α-bungarotoxin autoradiography and acetylcholine iontophoresis.

In contrast to myasthenia, the human muscular dystrophies present a confusing picture. Presentations by T. Munsat (University of Southern California) and P Becker (University of Gottingen) attested to the heterogeneity of these disorders, and the problems of classifying them. Most of the investigations on human muscular dystrophy were on the Duchenne type, and several investigators spoke of the problems of obtaining adequate biopsy material. A variety of biochemical, physiological and anatomical abnormalities were described. While there was some talk of an underlying membrane defect, the evidence for this is not yet compelling. Controversies about the neurogenic or myogenic origin of dystrophy continue unabated, with disagreements about counting motor units and interpreting physiological recordings. The interpretation of transplantation or culture experiments in experimental animals with muscular dystrophy is complicated by possibilities of early inductive abnormalities between ectoderm and mesoderm (suggested by A. McComas (McMaster University)), and the failure of dystrophic muscle to retain some of its characteristics in culture.

One approach to muscular dystrophy is to regard it as resulting from a basic defect expressed in all cells, but of particular consequence for muscle. A. D. Roses and S. Appel (Duke University), reported their studies of abnormal phosphorylation of components in or under the erythrocyte membrane. When incubated with labelled ATP, erythrocytes from patients with Duchenne dystrophy show a significant increase in spectrin phosphorylation over controls. If the phosphorylated spectrin is analysed by isoelectric focusing, a subset revealed by this method shows a clear difference from controls. While the molecular basis of this difference is not yet clear, it is not shown by the mothers of dystrophics, and therefore presents an exciting possibility for prenatal diagnosis. In the case of patients with myotonic dystrophy, Appel reported a decrease in the phosphorylation of erythrocyte band 3, a major transmembrane glycoprotein in human erythrocytes thought to be responsible for ion transport. Such erythrocytes also show a defect of Ca^{2+}-dependent K efflux in certain circumstances, and the defect in phosphorylation could be related to decreased Ca^{2+} entry or a failure to activate the K^+ conductance. The relationship of the erythrocyte abnormalities to those in the muscle cell is unclear. In a lucid presentation, R. Layzer (University of California, San Francisco) pointed out that the same hereditary defect, for example in phosphofructokinase isozymes, can have quite different consequences in the two cell types Nonetheless, the erythrocyte work is an encouraging new direction, particularly for diagnosis.

Meanwhile it is possible that less direct approaches to therapy may prove useful. The importance of the balance between rates of protein synthesis and degradation was stressed for general metabolism by A. L. Goldberg (Harvard Medical School), and for the regulation of acetylcholine receptor levels by D. M. Fambrough (Carnegie

Institute). A. Stracher (State University of New York) discussed the properties of low molecular weight, non-toxic, protease inhibitors such as pepstatin and presented interesting preliminary evidence of their effects in retarding degeneration of dystrophic chick muscle explants and monolayers The presence of segmental necrosis in Duchenne muscle fibres was stressed by several speakers, and J. Desmedt (University of Brussels) presented physiological evidence for collateral reinnervation of the resulting aneural segments. It might be possible to promote controlled regeneration in dystrophic muscle, with recovery of function after reinnervation.

While there are new diagnostic possibilities, the basic defects in dystrophic muscle remain as elusive as those in cancer cells. Nonetheless, the progress in myasthenia illustrates how advances in basic research can quickly be important in a clinical context. Thus the breadth of the MDA's support, and their personal involvement as exemplified in an address by Jerry Lewis, the National Chairman, offer cause for hope. □

Protein folding experiments: do proteins cheat?

from Barry Robson

THOSE fundamental components of biological machinery, the proteins, are synthesised by the ribosomes of living cells as linear polymers of twenty different kinds of amino acid. Investigators who seek to explain, and even predict, the functional three-dimensional structures of protein molecules on the basis of their amino acid sequences alone are often criticised for neglecting the presence of the ribosome and other biological structures when the protein folds up. Their defence has been that proteins can be unfolded by certain solvents so that a fully unfolded, flexible and random structure is attained, and then refolded without the aid of the ribosome or anything more complex than water, salts, and a healthy temperature and *p*H. Proving experimentally that the amino acid sequence carries all the information for the three-dimensional biological structure is rather like examining a student, however, for in order to prove that the student knows his stuff it is important to ensure that he can think out the problem set to him without taking any written record into the examination room. The experiments of Garel, Nall, and Baldwin (*Proc. natn. Acad. Sci. U.S.A.*, **73**, 1853; 1976) raise the possibility that some protein molecules at least may cheat because they cannot be fully unfolded but retain some elements of their original three-dimensional structure before refolding.

Baldwin's group unfolded the protein ribonuclease A in aqueous solutions of guanidine hydrochloride or urea, and carefully analysed the kinetics of refolding when the guanidine hydrochloride or urea was diluted out. They conclude that the unfolded protein is an equilibrium mixture of two species, one which slowly refolds to the biologically functional, compact state and one which refolds to the same state but 450 times more rapidly. The protein was described as fully unfolded on the basis of difference spectroscopy techniques, which measure the exposure of aromatic amino acid residues to the solvent. Although there is another instance of complete unfolding in terms of solvent exposure, but not in terms of other criteria (Robson and Pain, *Biochem. J.*, **155**, 331–334; 1976) the fraction of rapidly refolding form (about one fifth) is remarkably constant over a variety of conditions. The report of Baldwin's group is thus a cautionary tale: proteins may sometimes cheat because of the invigilance, perhaps unavoidable, of the investigators. Although four-fifths of the unfolded ribonuclease A molecules presumably do not cheat and eventually also reach the correctly folded state, apparently by initial conversion to the rapidly re-folding form (Hagerman and Baldwin, *Biochemistry*, **15**, 1462–1473; 1976), it is possible that there are many proteins with an even more stable rapid refolding form which constitutes a very much larger fraction of the unfolded population. Such proteins would have no option but to cheat, unless some more thorough method or combination of methods of denaturation were used.

Experiments on other apparently completely unfolded proteins have frequently demonstrated complex refolding kinetics, but have not necessarily implied the presence of a stable unfolded and fast refolding form. The relatively unstable intermediates detected in this way are generally believed to represent partly ordered structures initiating a direct and readily traversable route to the folded state, and so guide the folding process. Such guidance or "nucleation" is in fact theoretically necessary in order to account for the rapidity of folding processes which are many orders of magnitude faster than would be predicted from a purely random search of all possible polymer configurations. The question therefore arises as to whether the fast folding species of ribonuclease A is a partly ordered nucleating structure in the usual sense, which just happens to have a high degree of stability.

The authors note, however, that there is an alternative hypothesis based on the proposal of Brandts, Halvorson, and Brennan (*Biochemistry*, **14**, 4953–4963; 1975) that the amino acid residue proline may undergo *cis-trans* interconversion in the unfolded form of a protein. The fast refolding species could therefore represent forms in which all proline residues are in the correct configuration as found in the correctly folded protein. Although purists might argue that such a form would be a "nucleating structure" in the most general sense, the term usually refers to rapidly formed chain structures in which at least several amino acid residues have a fairly specific position in space relative to one another. It would therefore be rather unfair to accuse the protein molecule of cheating if the only structure it retained were the correct configuration of the proline groups.

Even the most detailed test-tube experiments on the configurational statistics of unfolded proteins may not be able to rule out the possibility of small elements of local structure important to the refolding process. Perhaps the real proof that proteins carry all the information for their own folding resides in computer simulations in which the investigator has full control over the initial conformation of the protein molecule. □

NASA Goddard gamma-ray symposium

from F. W. Stecker and C. E. Fichtel

An international symposium on The Structure and Content of the Galaxy and Galactic Gamma Rays was held at NASA Goddard Space Flight Center in Greenbelt, Maryland on June 2–4, 1976.

THE emphasis of the conference was placed on the relationship of γ-ray astrophysics to other fields of galactic astronomy.

D. Thompson and R. Hartman (Goddard Space Flight Center) presented the results from the Second Small Astronomy Satellite, SAS-2. Evidence for pulsed γ radiation from four radio pulsars, PSR 0531+21, PSR 0833-45, PSR 1818-04 and PSR 1747-46 was reported. Only one radio pulsar has been seen at optical and X-ray wavelengths. In addition, several general features in the γ-ray data were correlated with galactic structural features. The γ rays seen by SAS-2 from the direction of Cygnus were determined to have a periodicity of 4.8 h, matching the frequency and phase of the X-ray source Cygnus X-3.

A description of the COS-B satellite γ-ray detector was given by B. Swanenburg (Huygens Laboratorium). Preliminary results were presented by J. Paul (Saclay), H. Mayer-Hasselwander (Max-Planck Institute, Garching) and R. Buccheri (University of Palermo). These results included confirmation of a strong γ-ray source near galactic coordinates 195°, + 5°, and an indication of a change in the intensity of the Vela source since the time of the SAS-2 observations. The temporal analysis of PSR 0833-45 indicated that the γ-ray pulses were quite narrow.

G. Share (US Naval Research Laboratory) noted that the galactic γ-ray energy spectrum below 30 MeV showed the predicted steep shape characteristic of bremsstrahlung radiation. J. Grindlay (Center for Astrophysics, Cambridge, Massachusetts) noted that there are now two known sources emitting γ rays at energies $\geq 10^{12}$ eV.

P. Sturrock (Stanford University) suggested that a cascade process resulting from electron–positron pair creation in the pulsar magnetic field may be the cause of the pulsed γ radiation. H. Ogelman (Middle East University, Ankara) pointed out that pulsars radiate predominantly in the 1–1,000 MeV range. W. B. Burton (National Radio Astronomy Observatory) and N. Scoville (University of Massachusetts), both presented new observations of the 2 6 mm CO emission line which indicated that molecular clouds in the Galaxy (mostly H_2) are concentrated between galactic radii of 4 and 8 kpc in contrast to the atomic hydrogen, which is relatively uniform in distribution at radii from 4 to 14 kpc. The measurements also show that H_2 clouds are more tightly confined to the galactic plane than atomic hydrogen gas. E Jenkins (Princeton University) noted that ultraviolet measurements of the molecular hydrogen in the local region of the galaxy give a value of the density a factor of four lower than that implied from the CO observations for a galactic radius of 10 kpc, although the results are not necessarily in conflict owing to selection effects.

W. Roberts (University of Virginia) discused the spiral density wave theory of galactic structure and stated that the apparently striking separation of atomic and molecular hydrogen could be the result of stronger compression of gas in the inner galaxy, and an increase of the frequency at which the interstellar gas is periodically compressed.

J Baldwin (Cavendish Laboratory, Cambridge) noted that the non-thermal galactic radiation implies a much broader distribution of the cosmic ray electrons than of matter in the glalaxy. This has been found also to be the case in other spiral galaxies. J. Seiradakis (Max-Planck-Institut, Bonn) showed that, within the present limited statistics, the radial distribution of pulsars is generally correlated with that of other young (Population I) galactic objects. Both G. Fazio (Center for Astrophysics) and J. L. Puget (Observatory Meudon) discussed the significance of the local molecular hydrogen clouds in terms of infrared and γ-ray emissions. Puget concluded that the γ-ray observations indicate that the cosmic ray densities inside and outside clouds are similar.

R. Lingenfelter (University of California, Los Angeles) discussed the γ-ray lines emitted by the excited nuclei produced by interactions of cosmic rays with interstellar matter. He predicted that the 4.4 MeV carbon line would be the most intense. D. Arnett (University of Illinois) described the possibility of studying the results of nucleosynthesis in supernovae by examining the γ-ray lines emitted by the end products, and noted that the time interval after the explosion before the supernova envelope becomes transparent to γ rays was much longer than had been estimated earlier.

E. Parker (University of Chicago) gave a comprehensive lecture on cosmic ray propagation and galactic containment, in which he noted that the cosmic rays, the magnetic field, and the interstellar gas strongly affect each other dynamically. He concluded that if cosmic rays leave the galaxy, it must be as a consequence of collective cosmic-ray pressure.

The part that γ-ray astronomy can play in determining the large-scale galactic structure was then discussed. D Kniffen (Goddard) emphasised that the cosmic ray electrons and protons can be studied independently by looking at different portions of the γ-ray spectrum, and that γ-ray observations should be particularly valuable in searching for spiral structure. F. Stecker (Goddard) showed that galactic γ-ray emission is correlated with the molecular cloud distribution in the galaxy and that the deduced cosmic ray distribution appears to follow the supernova remnant and pulsar distributions in the galaxy, favouring a galactic supernova origin for most cosmic rays. He also discussed γ-ray implications for cosmic ray propagation and the galactic contribution to the high latitude γ-ray background.

After almost two decades of strenuous effort developing instruments of sufficient sophistication and sensitivity, there have been significant advancements in γ-ray astronomy in the past few years Not only has the general level of the galactic radiation been established, but also its broad features. With improved angular resolution and much greater sensitivity, γ-ray astronomy together with astronomy at other wavelengths hold great promise for the study of our Galaxy, other galaxies and high energy processess in astronomical objects. □

A hundred years ago

A FALL of meteorites, we learn from *Aftonblad*, took place on June 28, between 11 and 12 a.m., near Stalldalen, a station on the Swedish Central Railway, in the northernmost part of Örebrolän. Several fell, some on the ground and others in a lake. Two were found, one about the size of the fist and weighing 4½ lbs., the other smaller. Eye-witnesses stated that a loud whistling was first heard in the air from west to east, and a light was plainly distinguishable; although the sky was clear and cloudless, thereafter two very sharp reports were heard, the second succeeding the first after a momentary interval, followed by several others less sharp, resembling thunder, after which the falling stones were observed by eight or ten persons; and finally, there was seen in the air a whirling smoke, not very high up. A meteor was observed simultaneously at Stockholm and at other places. At thirteen English miles south-west of Linkoping it was seen first in a north-westerly direction pretty high up in the sky, and it then sank down in about ten seconds towards the horizon in the west. It had the appearance of a large pear a foot long, which, notwithstanding the bright sunshine, left behind a clear shining streak of six or eight feet in apparent length, which finally broke up into a multitude of starlike sparks. Here no noise was heard. According to a communication from the Stockholm Meteorological Bureau, there is reason to believe that the phenomena arose from the "kulblixt" (*foudre globulaire*), which generally appears as a luminous round object, and often, on approaching the ground, assumes a lengthened form and a blinding white colour, and bursts asunder, commonly with a loud report.

Fundamental research in molecular biology: relevance to medicine[*]

M. F. Perutz[†]

Molecular biology has given us new insights into many phenomena of clinical importance; it has suggested new therapeutic approaches to several diseases and has provided sensitive new methods for detecting chemical carcinogens. None of these applications had been foreseen.

MOLECULAR biology is sometimes said to be of little medical significance because it has not cured anyone yet. A hundred years ago the same might have been said of histology. At that time cellular anatomy and pathology began to improve our understanding of many diseases, today molecular anatomy and pathology give us much deeper insights. I shall illustrate this theme by examples taken from four different fields of research. The first two are from the fields with which I am most familiar, the structure and function of proteins; the second two are from molecular genetics. I shall show first how research on the structure of protein-digesting enzymes has led to an understanding of blood clotting and other important functions whose relationship to digestion no one had suspected. I shall then relate how my own work on the structure of haemoglobin has improved our understanding of genetic diseases and how basic research on autoxidation of haemoglobin has suggested a way of treating certain inherited anaemias. My next two themes are concerned with the effects of ultraviolet light and chemical carcinogens on nucleic acids and their relationship to human cancer. Finally, I shall ask whether any of this research could have been planned from the outset with a view to its medical applications.

Proteolytic enzymes and their inhibitors

In the 1950s the structure and catalytic mechanism of enzymes still ranked as one of the great unsolved problems in biochemistry. At that time two of my colleagues, B. S. Hartley and D. M. Blow, became interested in the proteolytic enzyme chymotrypsin, simply because they regarded it as the most hopeful and interesting one to attack. This enzyme is closely related to two other pancreatic proteolytic enzymes, trypsin and elastase. Chymotrypsin splits fastest those peptide bonds that follow amino acids with aromatic side chains, while trypsin goes for peptide bonds that follow basic side chains, and elastase for those with very short side chains. All three enzymes are secreted into the jejunum in the form of inactive precursors, known as chymotrypsinogen, trypsinogen and proelastase, all three precursors are activated by trypsin.

The pancreas also makes a small protein which scavenges and inhibits any traces of free activated trypsin. This is the pancreatic trypsin inhibitor.

Hartley and his colleagues determined the amino acid sequence of chymotrypsin and chymotrypsinogen[1] while Blow and others solved the three-dimensional structure of chymotrypsin by X-ray analysis[2]. Other workers followed with the structure of chymotrypsinogen, of trypsin, of elastase, of the trypsin inhibitor and of the trypsin–trypsin inhibitor complex. Together, Blow, Hartley and their colleagues worked out the mechanism of activation and catalysis[3], and R. Huber and Blow that of inhibition[4].

Chymotrypsin consists of 242 amino acid residues in three separate chains, which are linked by disulphide bonds. Its active site contains a serine, a histidine and an aspartate juxtaposed so that protons can shuttle backwards and forwards between them, forming what Hartley and Blow called a charge relay system.

The substrate is recognised by a pocket that lies next to the active site and is so tailored that it attracts the side chain of the amino acid preceding the peptide bond to be split. In the inactive precursor that specificity pocket is closed. Trypsin activates the precursors by splitting their chains in a way that allows the pocket to open. The pancreatic trypsin inhibitor mimics a substrate by presenting to the enzyme a side chain which its specificity pocket recognises, but the peptide bond following that side chain is so shielded from water that the enzyme cannot split it. Instead, the inhibitor remains firmly attached to the enzyme in a position resembling the one fleetingly occupied by a substrate at the first intermediate stage of catalysis[3].

The mechanisms of activation, recognition and catalysis of chymotrypsin first became known in outline in 1969, and the way in which the pancreatic trypsin inhibitor blocks trypsin in 1972; some further important details have been added since. Whenever nature has invented an effective and versatile device, it tends to exploit it over and over again for different functions. The same mechanisms of activation, recognition, catalysis and inhibition have now been found in at least four other functions: the clotting of blood, the dissolution of blood clots, the disposal of complexes of antigen and antibody by complement, and the lowering of blood pressure by the release of kinins. The raising of blood pressure by the release of angiotensins is also due to a proteolytic enzyme known as renin, but this is an acid proteinase related to pepsin, and its structure is still unknown. The interplay of protein digesting enzymes and their inhibitors seems to be important also in degenerative diseases such as pulmonary emphysema and rheumatoid arthritis.

---

[*] This paper is an abbreviated version of a paper presented at Ciba Foundation Symposium 44, *Research and Medical Practice*, held in January 1976 under the chairmanship of Sir Douglas Black and to be published by Elsevier/Excerpta Medica/North-Holland, Amsterdam, in summer 1976.

[†] MRC Laboratory of Molecular Biology, Hills Road, Cambridge CB2 2QH.

Suitable stimuli to blood platelets set off a chain reaction which causes blood to clot with very high velocity. This is due to a cascade of proteolytic enzymes and auxiliary proteins whose purpose it is to activate thrombin and liberate it from the platelets into the plasma (Fig. 1). It is now certain that part of the thrombin molecule has a structure which is almost identical to that of trypsin; in the clotting factors XIa, IXa and Xa, the parts of the sequences that have so far been analysed, are also like those of trypsin. The precursor of each of these enzymes is activated by the preceding enzyme in the clotting cascade by the same kind of mechanism by which trypsin opens the specificity pocket in trypsinogen or chymotrypsinogen, and each possesses the same charge relay system for the hydrolysis of peptide bonds. The functioning of the cascade depends on the presence of calcium ions and on nutrition with adequate amounts of vitamin K.

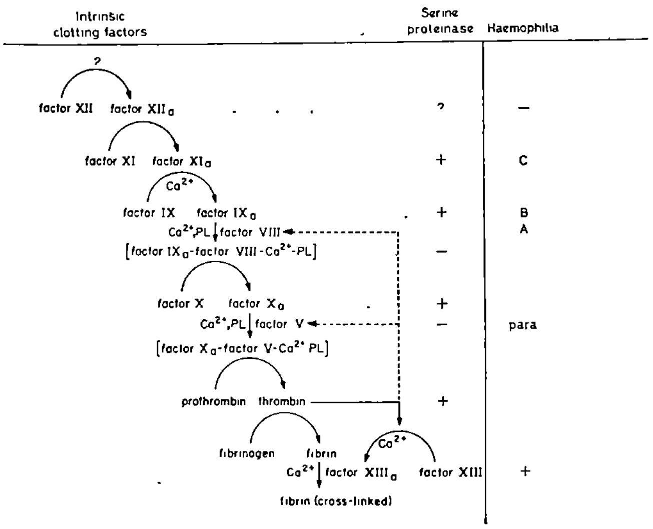

Fig. 1 Cascade of intrinsic clotting factors. Those marked + are enzymes similar to trypsin (reproduced, with permission, from the article by Davie and Kirby[6]).

The clotting factors possess several refinements which the pancreatic enzymes lack. Their specificities are probably greater and they are activated not in free solution, where they would be too widely dispersed, but on the surface of phospholipid membranes of blood platelets where they are crowded together. Prothrombin, the precursor of thrombin, has an extra 274 amino acids which are not found in trypsinogen, forming an attachment which binds it to the membrane, but only in the presence of calcium ions. On activation by factor Xa this attachment is split off and thrombin is released into the plasma. A great advance has recently been made in our understanding of the role of calcium and its dependence on vitamin K. It has been found that calcium ions are bound to prothrombin by 10 residues of a new amino acid, γ-carboxyglutamate; the residues lie near the amino terminus of the chain The new amino acid is made after the polypeptide chain of prothrombin has been assembled in the liver, by an enzyme system that adds a second carboxyl group to each of the first ten glutamates; and this subsidiary enzyme system that adds carboxyl groups requires vitamin K as a cofactor. In the clotting cascade, the other three trypsin-like factors or enzymes also require calcium in order to be activated, which implies that they are subject to the same vitamin K dependent modifications as prothrombin These discoveries explain how vitamin K antagonists interfere with blood clotting: by reducing the calcium affinity of prothrombin and of three other clotting factors they prevent their binding to the phospholipid membrane and thereby inhibit their activation[7].

The therapeutic uses of vitamin K antagonists were discovered long before its mode of action was understood, but the new discoveries will allow the antagonists to be applied more rationally and with greater knowledge of their possible side effects. For example, the presence of the new amino acid γ-carboxyglutamate in prothrombin suggested that it might be worth while to search for it in other calcium binding proteins. This search has led to the isolation of the amino acid from a protein in the bones of 14-week-old chicken, which suggests that it may be needed for the deposition of calcium in developing bones[8], and explains why treatment of women during the first 3 months of pregnancy with anticoagulants of the dicoumarol type has led to bone anomalies in the foetus Quite recently, γ-carboxyglutamate has also been found in a small protein isolated from adult bones of several species, including humans. The amino acid forms part of a peptide whose sequence bears no resemblance to that of the *N*-terminal peptide of prothrombin, showing that it is part of a quite different protein specific to bone, and indicating that vitamin K is essential for the formation and maintenance of bone structure[37].

There are at least two natural anticoagulants which prevent clotting getting out of hand. An excess of free thrombin in the plasma stops activation of more prothrombin by splitting off its first 156 residues, thus detaching it from the phospholipid membrane before it can be activated A plasma inhibitor, AIII antithrombin, inhibits thrombin and other clotting factors by a mechanism apparently similar to that by which the pancreatic inhibitor blocks trypsin, except that by itself AIII antithrombin acts much more slowly. It has recently been found that heparin exerts its instant anticlotting effect by accelerating the reaction of AIII antithrombin with thrombin and with other factors. Patients with a congenital deficiency of AIII antithrombin have an increased tendency to thrombosis[9], which shows that this inhibitor is an essential part of the checks and balances in the clotting system.

AIII antithrombin is one of six different antiproteinases so far discovered in human plasma. Another of the six that has recently assumed medical importance is α_1-antitrypsin, because people with an inherited deficiency of this inhibitor are predisposed to pulmonary emphysema. The mechanism of lung destruction in these patients is still unclear but is believed to be due to digesting enzymes from granulocytes and macrophages. These may cause emphysema even in people with normal levels of α_1-antitrypsin if they are released in excess by chronic lung irritation. It now looks as if pulmonary emphysema may be only one example of a degenerative disease where protein-digesting enzymes have a decisive role. For example, one such enzyme, though of a type different from trypsin, has been found in the joints of rheumatoid arthritis patients. Knowledge of the three-dimensional structure of these enzymes may open the way to the synthesis of tailor-made inhibitors for the treatment of such diseases.

Haemoglobin diseases

In 1949 Pauling, Itano, Singer and Wells published a paper entitled "Sickle Cell Anaemia, a Molecular Disease"[10]. They showed that homozygotes suffering from this autosomal recessive disease had a haemoglobin which differed from the normal by the absence of two negative charges. Ingram later discovered that this was due to the replacement of a single amino acid residue among the 287 in the half molecule of haemoglobin; one glutamate was replaced by a valine. (Recently the same replacement of a single glutamic acid by a valine has been found in a variant human α_1-antitrypsin(S). The replacement is harmless in heterozygotes (SM) carrying both the normal (M) and the variant (S) gene, but it may predispose SS homozygotes to pulmonary emphysema[11].) This was the first time that a genetic mutation was shown to cause the replacement of an amino acid in a protein. A search for other haemoglobin diseases soon followed, and now more than 200 different abnormal haemoglobins are known, which give rise to a variety of haematological disorders whose cause had been unrecognised before, these may affect both the synthesis and life span of red blood cells.

The dual respiratory function of haemoglobin depends on a reversible change of structure. The venous form of haemoglobin has a low affinity for oxygen and a high one for hydrogen ions, CO_2 and 2,3-diphosphoglycerate; in the arterial form these relative affinities are reversed Efficient respiratory transport depends on correct regulation of the equilibrium between the two forms. My colleagues and I have determined their three-dimensional structure in atomic detail[12,13]. H. Lehmann and I then attempted to interpret the clinical symptoms of the haemoglobin diseases in stereochemical terms[14]. In most of them the abnormality consists of the replacement of a single amino acid residue, as it does in sickle cell anaemia, but the position of that residue is crucial in deciding the nature of the symptoms. If the residue lies on the surface, as often happens, there may not be any symptoms, at least in heterozygotes, because the haemoglobin molecule hardly "feels" the wrong residue.

In homozygotes, on the other hand, superficial replacements may reduce the solubility of the haemoglobin in the red cell This happens in sickle cell anaemia where the venous form of haemoglobin actually crystallises out. Prevention of this crystallisation would relieve the disease, but has proved very difficult The structure of the areas of contact between neighbouring molecules of sickle cell haemoglobin is now being worked out in atomic detail and may form the basis for a synthetic approach to the inhibition of crystallisation

The surface of the haemoglobin molecule is studded with electrically charged amino acid side chains which ensure its high solubility in water. Its interior structure, on the other hand, is stabilised by hydrocarbon side chains which make it impenetrable to water. In several abnormal haemoglobins this water-repellent armour is breached, so that they become unstable and form amorphous precipitates in the red cell known as Heinz bodies. Similar denatured precipitates are seen in thalassaemia where the red cells contain unequal numbers of α and β chains. The precipitates make the red cells more rigid and therefore more fragile, and this was believed to be the main cause of the associated haemolytic anaemias Denaturation of haemoglobin is also accompanied by oxidation of the haem iron from its normal ferrous to the ferric state. It has now been found that it is this oxidation rather than the presence of denatured haemoglobin precipitates which mainly causes haemolysis. The mechanism is this. In the first step of the reaction the iron-bound oxygen molecule is reduced to superoxide ion which may then dissociate from the haem and produce hydrogen peroxide ion, hydroxyl radicals and singlet oxygen in the surrounding water[15]. These are all oxidising agents, hydroxyl radical being the most powerful among them, and they attack the lipids of the cell membrane with resulting haemolysis. The obvious remedy is the administration of drugs designed to trap free radicals such as vitamin E or 2,3-dihydrobenzoic acid. These are now under trial[16,17]. In the long term practical results of much wider importance should result from the study of the abnormal haemoglobins. In the first place they have shown that the genetic code in humans is the same as in *E. coli*, which is a prerequisite for relieving congenital diseases by any kind of genetic engineering. They have proved that human genes are subject to a fairly high rate of mutation (the frequency of abnormal haemoglobins in the human population may be greater than 1 in 500), but that these mutations may be harmless if they merely replace residues at the surface of enzymes away from their active sites Interior replacements on the other hand, may affect the function and stability of enzymes. In favourable circumstances knowledge of their three-dimensional structure may allow us to mitigate such effects.

I started to study haemoglobin by X-ray crystallography in 1937 because at that time the structure of proteins seemed the most important unsolved problem in biochemistry, but I never dreamt that its solution would one day throw light on the nature of inherited diseases.

Xeroderma pigmentosum

The mutations which give rise to the abnormal haemoglobins occur spontaneously, perhaps by random errors inherent in the genetic process. It had long been known that the rate of mutation can be enhanced by external factors such as radiation and certain chemicals. It had also been suspected that some of the same factors which produce mutations give rise to cancer, but no exact correlation had been shown.

Ultraviolet light damages DNA by causing two pyrimidine bases, usually, but not always, on the same strand, to become covalently linked. In ultraviolet-sensitive bacteria this linkage inhibits DNA replication and thereby stops further growth. But there are strains of the same bacteria which are resistant to ultraviolet and it turns out that these possess an enzyme system which excises the dimers and repairs the gap, thus allowing growth to start again[18]. Now it appears that normal human skin cells have an enzyme system for the repair of ultraviolet damage similar to that of ultraviolet resistant bacteria. There is a rare autosomal recessive human disease in which the skin is extremely sensitive to ultraviolet light; it is called xeroderma pigmentosum. Sufferers from this disease—the homozygotes—are also very liable to skin cancer. In 1969 J. E. Cleaver discovered that fibroblasts from such patients lack an enzyme necessary for the repair of ultraviolet-damaged DNA[19]. Investigators later found that there are six geneticaly distinct types of enzymatic deficiency, that is six complementation groups, five of which are deficient in DNA repair and the sixth in another as yet unknown function[20]; Japanese workers have now shown that ultraviolet resistance can be restored to all those five types of fibroblasts that are deficient in DNA repair by an enzyme which is an endonuclease from T4 phage infected *E coli*[21] (Fig. 2). Their results are exciting because they suggest that it may become possible to treat patients with this kind of enzyme, even if it is not yet clear how it could be applied. Quite recently, an altered endonuclease concerned with the repair of depurinated sites has been found in fibroblasts from two of the complementation groups that were known to be deficient in DNA repair[38].

Table 1 Correlation between carcinogenic and mutagenic activity of chemicals

	car + mut +	car 0 mut 0	car + mut 0	car 0 mut +	?	correlation (%)

106 non-carcinogens 14% positive, but 86% negative

173 carcinogens 89% positive, but 11% negative

Detection of chemical carcinogens

Discovery of the cause of xeroderma pigmentosum was important because it linked the occurrence of a cancer with a mutagenic event whose nature and repair could be explained in the same molecular terms as in bacteria. Evidence in favour of a causal link between the frequency of somatic mutation and the incidence of cancer has long been accumulating, yet many of the most potent chemical carcinogens seemed to have no mutagenic effect in microorganisms. This paradox was finally resolved by Bruce Ames Ames had devoted nearly 20 years to the study of the control of protein synthesis in *Salmonella typhimurium*. His work, like that of Hartley and Blow on chymotrypsin and mine on haemoglobin, was undertaken without any foreknowledge of possible applications.

The chromosome of *Salmonella* contains an operon that codes for histidine biosynthesis. Transcription of the enzymatic genes of this operon into messenger RNA is controlled by an operator gene which responds to the level of histidine in the cell, switching transcription on when histidine is scarce and switching it off when it is plentiful. Certain mutant strains of *Salmonella* cannot grow unless histidine is supplied in the medium; this has turned out to be due to mutations in the histidine genes Ames selected four such strains. In one of them the DNA differs from that of the wild type by the replacement of a GC by an AT pair, or vice versa. In the remaining three strains the DNA carried mutations of a kind first correctly interpreted by Crick, Barnett, Brenner and Watts-Tobin when they established the nature of the genetic code[22,23] Decoding of the sequence of nucleotide bases makes sense only if the reading frame is positioned correctly with respect to the succession of coding triplets. Certain mutagens such as proflavine intercalate between the base pairs of DNA and thereby interfere with its replication so that base pairs are either added or deleted, and the reading frame is thus shifted.

Three of the four strains of *Salmonella* used by Ames carry mutations of this type in the histidine genes[24,25]. Ames plated these histidine-requiring strains of *Salmonella* on a histidine-free nutrient, applied chemical carcinogens and waited for the growth of colonies in which a reversion of the original mutation had allowed the resumption of histidine biosynthesis. The presence of 10^9 organisms on each plate allowed rare genetic events to be detected. The smallness of the bacterial chromosomes increased the likelihood of reversions of the original mutation to other mutations which might be lethal. The time needed for one experiment was only 2 d.

Initially only some of the known chemical carcinogens caused growth of revertant colonies but Ames and his colleagues improved the sensitivity of his system step by step until he was able to prove a strong correlation between carcinogenicity and reversion. He introduced two additional mutations: one raises the sensitivity by eliminating the repair mechanism already mentioned, that repairs ultraviolet and other damage, and the other strips the bacterial surface of part of its protective lipopolysaccharide layer which makes it more permeable to large molecules. He also increased mutagenesis in his tester strains by incorporating a plasmid[26] which appears to channel DNA damage down an error-prone repair pathway (SOS repair)[27–30].

Ames made one more improvement in the system which proved decisive. It had been discovered that in mammals many compounds are non-carcinogenic as such, but are converted into carcinogens by hydroxylating enzymes in the liver. Ames decided to mimic this conversion by adding rat or human liver homogenate together with a system for generating nicotinamide adenine nucleotide diphosphate to his cultures[31–33]. The results show a strong correlation between carcinogenesis in mammals and mutagenesis in *Salmonella*[34,35]. Ninety per cent (157/175) of the carcinogens were mutagenic in the test including almost all of the known human carcinogens that were tested. Despite the severe limitations inherent in defining non-carcinogenicity, few "non-carcinogens" showed any degree of mutagenicity (Table 1). The mutagens include tar from cigarette smoke and oxidative hair dyes (Fig. 3)[36]. Another mutagen is chloracetaldehyde, a possible metabolite of dichloroethane and of vinylchloride, two chemicals of which several million tons are produced in the USA each year. In the first instance, all these mutagens probably act by stopping DNA replication and thereby inducing the error prone SOS repair mechanism. Mutagens which do not do this, such as EMS, base analogs and deaminating agents, appear to be weakly or not carcinogenic (M. Radman, private communication). Study of the SOS repair mechanism would therefore seem a promising approach to the understanding of radiation and chemically induced carcinogenesis.

Ames' method offers a cheap, quick and sensitive way of screening chemicals for mutagenicity. For instance, 1 ng of 2-aminoanthracene doubled the spontaneous reversion rate of about 20 colonies, and 500 ng gave 11,000 revertant colonies compared with about 30 in the controls. In view of the correlation between mutagens and carcinogens any compound which is a potent mutagen is now suspected also of being carcinogenic. Other screening tests in bacteria and mammalian cells have been reviewed by Bridges[39].

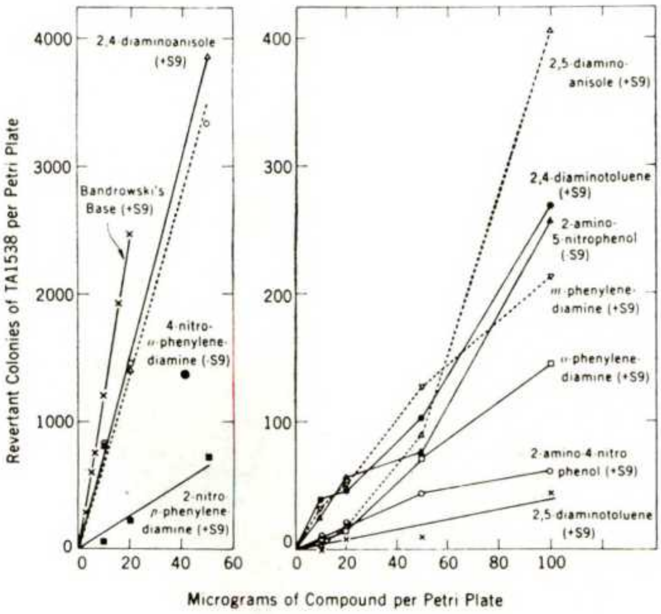

Fig. 3 Dose–response curves of the mutagenicity of chemicals extracted from hair dyes. Revertant colonies were counted after incubating the Petri plates for 48 ha t 37 °C with the chemical mutagen and the microsomal activation system (S9) where indicated. (Reproduced, with permission, from Ames *et al.*[36].)

The first impact of Ames' work should be to eliminate known carcinogens from our food and daily habits so as to reduce the number of carcinogenic events to which we are being exposed—and, incidentally, to let us stop worrying about many other commonly used chemicals which turn out to be harmless. In the long run this research and the work on xeroderma pigmentosum may help us to unravel the exact molecular mechanism by which ultraviolet irradiation and chemicals that revert frame shift and other mutations cause cancer.

What has molecular biology contributed to this work? It has supplied the basic concepts of microbial genetics, mutagenesis, repair and feed-back control; it has supplied the techniques of transferring genetic material from one strain of bacteria to another which Ames used to build up the sensitivity of his system. These concepts and techniques were developed by scientists who set out to interpret fundamental biological processes in physical and chemical terms. Generally the problems were so complex that it took very many years to solve them. At the outset our ignorance was too profound for us to foresee the relationship of our work to human disease, and it became apparent only afterwards. Although we know more now than when we started, molecular biology is still too young a science for it to be clear exactly where it will pay off, whence we may do best if we spread our efforts over a wide field. Since research is the art of the soluble, it is often more profitable to study a basic problem in microorganisms where it can be solved, rather than in mammalian cells which are so much more complex. One of my examples has shown how such an indirect approach has helped to unravel pathogenic events in man. It would be a mistake if all molecular biologists switched to mammalian cells as has recently become the fashion, or as they are being forced to do by policy decisions of supporting agencies. There is a unity of life at the molecular level which implies that anything found to be true in *E. coli* may also hold in man.

In the future, the most important contribution of molecular biology to medical practice may well be genetic engineering, but early hopes that eukaryotic genes could be transcribed and translated in prokaryotes have not yet materialised. Instead, workers may try to see if cultures of animal viruses carrying human genes could be used for the manufacture of therapeutically important human proteins.

Seeing order in 'amorphous' materials

O. L. Krivanek, P. H. Gaskell* & A. Howie

Cavendish Laboratory, Cambridge, UK

Careful analysis of high resolution electron micrographs of amorphous materials, making use of a simple optical simulation technique, provides a means for discriminating between 'meaningful' and 'meaningless' images, and for detecting ordered regions as small as 15 Å in the 'meaningful' ones. Such regions, comprising only about 100 atoms, have been directly observed in 'amorphous' carbon, and it is possible that they exist in a range of other 'amorphous' materials.

THE past decade has witnessed a dramatic improvement in the resolving power of high resolution electron microscopes. Atomic planes spaced less than 1 Å apart have been imaged[1], and heavy single atoms have not only been directly observed[2,3] but their movement between successive exposures followed as well[4]. Routinely attainable point-to-point resolution has come down to around 5 Å and less.

The typical nearest-neighbour distances in most solids are about 2 Å, and many important crystallographic planes have a separation of 3 Å and more. The resolving power of electron microscopes therefore makes it natural to inquire about the possibilities of an atom-by-atom determination of the specimen structure. Such an approach should be particularly fruitful in the case of amorphous (non-crystalline) materials, since in these the conventional structure research based on X-ray, electron or neutron diffraction yields only statistical data averaged over the whole specimen. It describes the probability that an atom A will have a neighbour B a distance r away, but tells us very little about the local deviations from the average structure.

The first step in the direction of structure determination by direct imaging is a search for small ordered domains within the non-crystalline sample. Such investigations have already yielded much useful information, such as the 'wavy onion' structure of the carbon black particles[5,6], and a detailed description of the carbon graphitisation process[6]. In materials other than amorphous carbon the results have been less clear. In amorphous Ge the early dark field (image formed with scattered electrons only) observations of small bright spots about 14 Å in diameter[7,8], interpreted in terms of small wurtzite crystallites[7], have been overtaken by observations of much smaller dark field spots[9,10] and interpretations denying the presence of any crystallites[8,10]. Similarly, bright field observations of small patches of fringes[9–12], interpreted as direct imaging of the crystallite lattice planes[9,11,12], have also given rise to interpretations[10] in terms of relatively ordered regions within the continuous random network model[13,14], or have simply been discarded as statistical peaking in order within an essentially random image[15].

Meaningful images or just random noise?

The diversity of opinions about the images of amorphous materials is the result of two fundamental difficulties, best illustrated by an analogy. An individual telephone conversation may remain identifiable even when received over a line with poor frequency response, but once several conversations are superimposed, the total loses all its information content and becomes just noise, in spite of being made up of individually meaningful signals. Similarly, an atom imaged by an electron microscope with a necessarily limited spatial frequency response may remain individually identifiable, but when the images of several such atoms are superimposed, the total may just become a random, unintelligible noise.

Computing the images of various existing structural models for amorphous materials has shown that, for specimens of sufficient thickness, images of completely different models become qualitatively indistinguishable, and image features corresponding to particular structural configurations within the specimen may become completely washed out[16,17]. This suggests that many experimental images (for which the thickness of the amorphous specimen is usually quite considerable) may indeed be nothing but random, frequency-filtered noise.

Random noise has been the subject of many mathematical studies, mainly in the context of communication engineering.

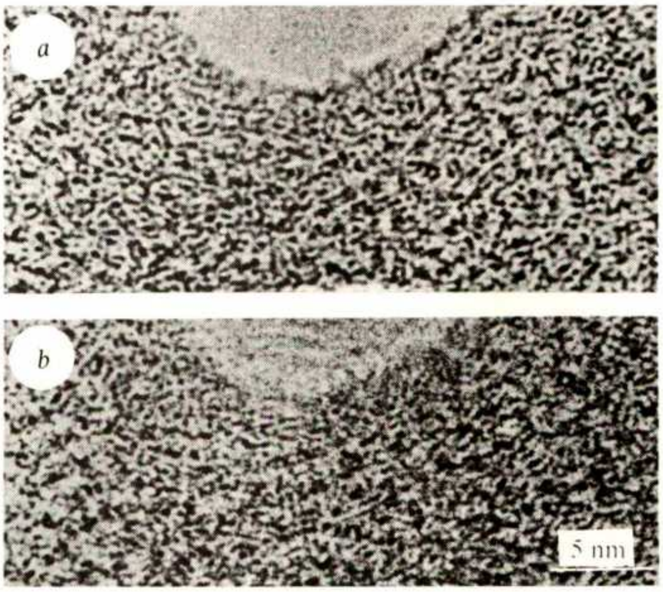

Fig. 1 *a*, Direct reconstruction of an axial bright field micrograph of vapour-deposited amorphous Ge. *b*, Phase-randomised reconstruction of the same image. A Perspex plate, sprayed with transparent lacquer until the droplets (about 0.1 mm in size) just started merging, served as the random phase screen for this and all the other phase-randomised images shown in this article. The resulting surface roughness was enough to ensure that each original patch of fringes was spread over a large area in the reconstruction, rather than merely shifted sideways.

By virtue of the Central Limit Theorem[18], many different mathematical representations of the noise are possible. The one most commonly used is

$$I(\mathbf{r}) = 1 + \sum_{n} c_n \cos(2\pi \mathbf{q}_n.\mathbf{r} + \varphi_n) \qquad (1)$$

$I(\mathbf{r})$ is the intensity at a point $\mathbf{r}$ in the image plane, the c_ns are the coefficients defining the image spatial frequency power spectrum, $\mathbf{q}$ is the spatial frequency variable and φ_n represents the phase. The summation is taken over all the points of the spatial frequency plane needed to define the image area being considered, and the phases φ_n are taken to be distributed randomly in the interval $(0,2\pi)$. The representation (1) then describes the bright field image of a weak random object (with an unscattered beam of intensity 1). It leads to the prediction of many interesting properties of the random function[19,20], some of which are directly applicable to the electron images. For instance, the probability of finding the image intensity I, at an image point selected at random, lying between I and $I + \mathrm{d}I$, follows a Gaussian distribution in I. Dark field images are describable by an expression similar to equation (1), although for these the intensity distribution is a negative exponential[21] rather than a Gaussian one. These distributions can be used to test the randomness of actual electron images[17], but since they treat each image point independently and are therefore incapable of evaluating any patterns within the image, such tests are not particularly sensitive to non-random features. A better test of image randomness that concentrates on groups of image fringes is described here.

An optical simulation technique

It is clear that equation (1), being nothing but a Fourier summation, can be used to represent any image. The random bright field image description only follows upon taking the phases to be random. When the phase information is deliberately removed (by randomising the phases), we obtain an image which has lost all the information on the exact specimen structure the original may have contained. This random image will obviously differ from the original in detail, but it is possible that qualitatively the two images will be identical: every patch of fringes in the original micrograph may be matched by a similar patch of fringes produced in the random image by purely statistical effects. Should this be the case, it is clear that the fringe patches in the original image should not be taken as structurally meaningful. Should the two images display marked differences in the number and regularity of fringe patches present, however, some interesting conclusions about the nature of the specimen should follow from the original.

The randomisation of the phases φ_n can be carried out either computationally or in an optical bench[17]. The second approach enjoys the advantage of greater simplicity and an ability to handle large image areas. It produces the phase-randomised image in three stages: a diffraction pattern (the spatial frequency power spectrum) of the original micrograph is formed, the phases are randomised by inserting a random phase screen into the diffraction plane, and finally a reverse optical transform leads to the phase-randomised reconstruction. To avoid undesirable interference between the main (unscattered) beam and the inserted phase screen, the main beam is allowed to pass through a hole in the screen. The resulting reconstruction is a simulated 'random' micrograph: although its spatial frequency power spectrum is unchanged from the original, it has become just random noise.

Ordered regions in amorphous Ge, SiO_2 and C

Figures 1, 2 and 3 show how the phase-randomisation technique works in practice. In each figure, image *a* is a direct reconstruction of the original micrograph (recorded with the random phase screen removed) and image *b* is its phase-randomised counterpart. The three examples are arranged by the amount of ordered structures visible in the original images. In Fig. 1*a* the 4-Å structures are quite irregular and in Fig. 2*a* some fringes running in the vertical direction appear: even more fringes can be seen in Fig. 3*a*. Such differences may be obvious to the eye, but it is clearly impossible to differentiate between meaningful and fortuitous image features on the basis of such qualitative remarks alone. One can, of course, define objective criteria of fringe regularity such as the signal-to-noise ratio of a group of fringes[17], and then evaluate the significance of the fringes by comparing the experimental values of their signal-to-noise ratio with the theoretical prediction for fringes produced by random effects. Such treatment, however, works with the absolute values of fringe regularity and demands that all the parameters influencing the image formation (such as the amount of inelastic scattering present, astigmatism of the objective lens, specimen drift and so on) be known accurately, which is usually not the case.

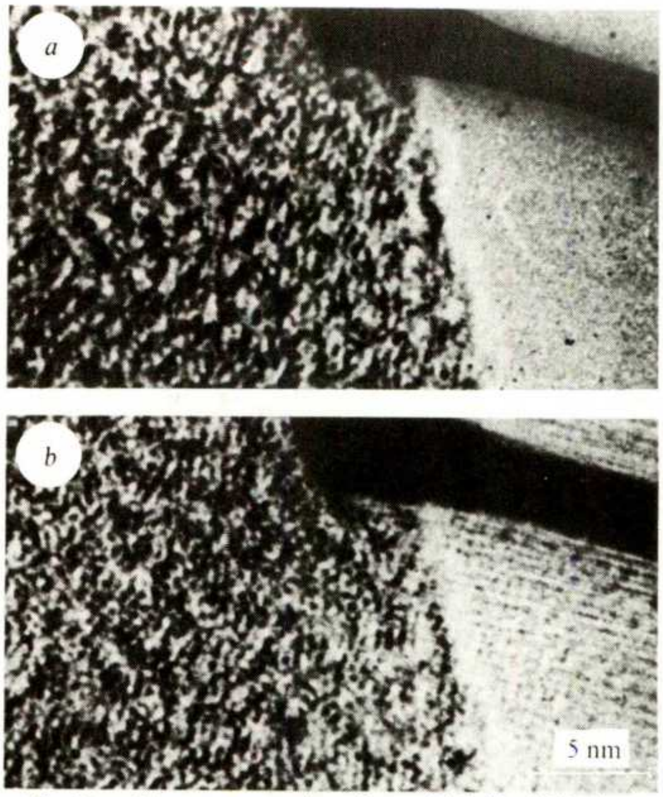

Fig. 2 *a*, Direct reconstruction of an axial bright field micrograph of amphorous SiO_2 prepared by fragmentation of a "Spectrosil" disk. *b*, Phase-randomised reconstruction of the same image.

By creating an individual reference standard with which the original image can be compared, the phase-randomisation technique altogether avoids the need for such considerations. In the case of amorphous germanium (Fig. 1), for example, the phase-randomised reconstruction is completely different from the original in detail, but it is not difficult to see that qualitatively the two images have remained indistinguishable, with the extent of ordering of the 4-Å structures being about the same in either image. The phase-randomised reconstruction for amorphous carbon (Fig. 3*b*), on the other hand, does not show any ordered image structures comparable to those visible in the original image. Specifically, the patches of relatively straight and parallel fringes spaced about 4 Å apart identifiable at several places in Fig. 3*a* (particularly near the edge of the specimen) find no equivalent in the randomised reconstruction.

Optical diffractograms showing the spatial frequency power spectrum of the direct and phase-randomised images of amorphous carbon are shown in Fig. 4. It can be seen that the phase-randomisation procedure has hardly changed the power spectrum at all, so that the different appearance of Fig. 3*a* and *b* is entirely due to the modification of the phases. It is also worth noting that because the lowest spatial frequencies have passed, together with the main beam, through the hole in the random-phase screen, the coarse image detail has not been altered by the phase randomisation, while the fine image structure has been completely changed by it. As a result of the phase randomisation, the fine structures in all the phase-randomised reconstructions extended well over the specimen edge (see Fig. 3*b*), and the marker shown in Fig. 2*a* reappears in Fig. 2*b* decomposed into its individual spatial frequency components, no longer fitting together as before.

By comparison with the amorphous germanium and amorphous carbon examples, the amorphous silica image (Fig. 2) constitutes an intermediate case. Analysis of the spatial frequencies of the original image by optical diffraction indicates that, due to astigmatism, some directional filtering has taken place. Such filtering will lead to a micrograph with fringes running predominantly in one direction, and directional effects will remain even in the phase-randomised image, showing that the original fringes had no structural meaning whatever. Vertical fringes qualitatively similar to the ones in the direct reconstruction do indeed appear in Fig. 2*b*, but since they are somewhat more broken up than those visible in Fig. 2*a*, it is difficult to pronounce judgment on the original image with any certainty.

It should perhaps be emphasised that the intention of this article is to describe a technique for discriminating between meaningful and fortuitous features in high resolution bright field electron micrographs; the three examples used are merely intended to serve as an illustration. It would not be correct to reach any definite conclusion regarding the structure of amorphous materials on the basis of small parts of three electron micrographs, particularly since the structure of these materials is known to depend strongly on the preparation conditions (evaporation rate, substrate temperatures and so on). The possibility of providing a detailed quantitative description of order in such materials in fact constitutes one of the most attractive applications of this technique. Nevertheless, the results obtained with amorphous Ge and C may perhaps be taken as indicative of the results to be expected in these materials. The micrograph of evaporated amorphous Ge (Fig. 1*a*) contained no image features attributable to well defined ordered regions within the specimen. The fringes seen in the image of evaporated amorphous C were, however, shown definitely not to arise from any fortuitous superposition of the images of distant individual atoms, and must therefore be taken as evidence for small (about 10 to 15 Å) ordered regions within the material. These regions most probably consist of a few parallel graphite-like planes lying along the direction of the illuminating electron beam.

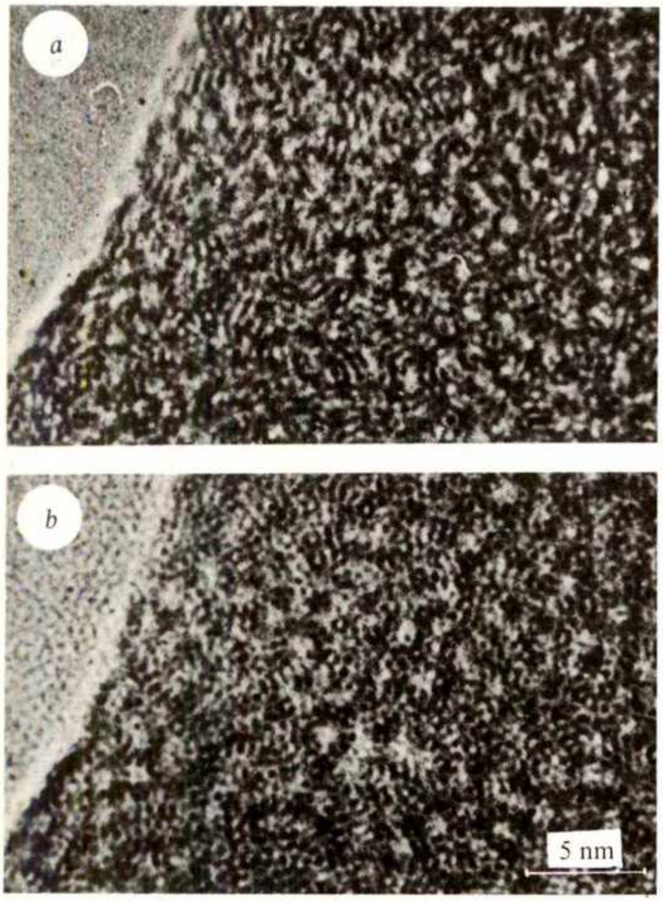

Fig. 3 *a*, Direct reconstruction of an axial bright field micrograph of vapour-deposited amorphous C. *b*, Phase-randomised reconstruction of the same image.

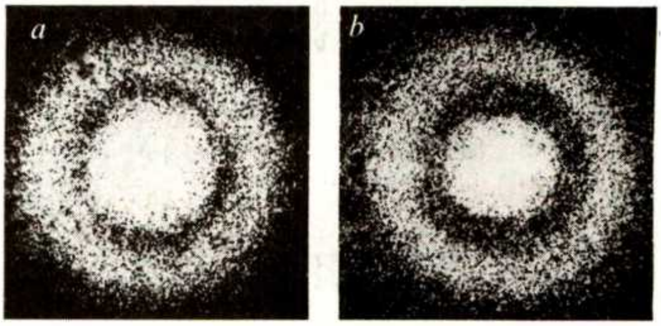

Fig. 4 *a*, Diffractogram of Fig. 3*a*. *b*, Diffractogram of Fig. 3*b*. They show that the micrograph of Fig. 3*a* was recorded at the broad second transfer interval underfocus ($z_0 \simeq -1{,}400$ Å) with negligible astigmatism ($c_a < 20$ Å). The disappearance of the outer part of the first transfer interval in *b* is due to the opaque edge of the hole in the random-phase screen.

The absence of any fringes in the Ge micrograph that could be safely attributed to non-random causes does not, however, mean that the specimen contained no ordered regions at all. It can be shown that in a Ge specimen 100 Å thick the image of a fully diffracting 15-Å crystallite would be obscured by the images of the atoms in the remaining 85 Å. Only crystallites larger than about 18 Å would remain directly visible[17]. A similar result also applies for amorphous silica: in a SiO_2 film 100 Å thick, only ordered regions larger than about 18 Å will remain directly visible, and 15-Å ones will be obscured in films thicker than about 50 Å. In amorphous C this limitation is much less severe, owing mainly to the perfect alignment of the atoms into the graphite planes, which consequently stand out clearly from the amorphous background; 15-Å graphite crystallites should remain visible even when embedded in films up to 150 Å thick.

The average thickness of the Ge specimen (as determined by monitoring its deposition by a quartz crystal oscillator) was about 100 Å. It therefore follows that ordered regions smaller than 18 Å will not be identifiable. Near the specimen edge (top half of Fig. 1*a*) the thickness is, however, likely to be smaller, so that the lack of non-random features there places an upper limit of about 15 Å on the size of ordered regions possibly present. The amorphous C film was also about 100 Å thick, which means that the actual direct observation of the 15-Å ordered domains raises no contradiction. In regions much thicker than 100 Å the fringes attributable to these domains will be obscured.

To summarise, high resolution electron microscopy has given rise to an approach to the study of the structure of amorphous materials that is radically different from the conventional methods based on the analysis of diffraction patterns. The first task confronting a researcher using the new approach is the differentiation between structurally meaningful images and those in which too many overlapping atoms obscure the underlying structure. This problem has been solved by the simple technique of optical simulation of random noise with power spectrum identical to the original image. In the image of amorphous Ge examined here the technique shows no evidence of crystallites, and thus places an upper limit of about 15 Å on the size of ordered regions possibly present. In amorphous C, however, small (~15 Å) ordered regions have been detected with the technique. It seems quite possible that similar ordering will be discovered in many other types of non-crystalline materials.

This research was supported by the SRC.

Isotropic cosmic expansion and the Rubin–Ford effect

S. Michael Fall & Bernard J. T. Jones

nstitute of Astronomy, Madingley Road, Cambridge CB3 0HA, UK

We show that the Rubin–Ford (RFR) data, often taken as evidence for large scale anisotropic cosmic expansion, probably only reflect the inhomogeneous distribution of galaxies in the region of the Rubin–Ford sample. The data RFR have presented are consistent with isotropic expansion, an unperturbed galaxy velocity field and hence a low density Universe.

RUBIN, Ford and Rubin[1] have reported on 'a curious distribution of radial velocities of Sc I galaxies' which has sometimes been taken as evidence for large scale anisotropic cosmic expansion. The Rubin–Ford sample consists of 74 galaxies with measured radial velocities (corrected for galactic rotation) and apparent magnitudes (as determined by Zwicky) in the 'window' $14.0 \leqslant m_{\mathrm{Zw}} \leqslant 15.0$. These galaxies were chosen from a larger sample of 200 galaxies, selected from Palomar Sky Survey plates and classified as being of type Sc I according to the David Dunlap Observatory system[2].

RFR note in ref. 1 that the apparent velocity distribution of their sample is distinctly anisotropic. In one region of the sky (called region I), most of the sample galaxies have radial velocities $v_{\mathrm{I}} \simeq 4{,}950$ km s^{-1}, while in the opposite region (called region II) most of the sample galaxies have radial velocities $v_{\mathrm{II}} \simeq 6{,}400$ km s^{-1}. The mean apparent magnitudes of sample galaxies in the two regions differ by only 0.1 mag and the mean apparent diameters differ by only 14%. Since Sc I galaxies are thought to be good 'standard candles', RFR make the suggestion that their data may be evidence for anisotropic cosmic expansion. If true, this would have important cosmological implications, especially in view of the apparent isotropy of the microwave background radiation. Our purpose in this article is to point out that the Rubin–Ford data are consistent with isotropic expansion and indeed, the effect might have been expected on the hypothesis that the expansion is isotropic.

Inhomogeneities

The idea underlying our argument is illustrated in Fig. 1 where we have plotted the positions of Sc I galaxies in the Rubin–Ford sample with declinations in the range $20° < \delta < 42°$. We have also plotted all galaxy clusters in this declination band with radial velocities $< 10{,}000$ km s^{-1} and tabulated in Noonan's list of clusters with published redshifts[3]. Those clusters classified by Abell[4] as being 'rich' are represented by a circle of radius 10 h^{-1} Mpc (where h is the Hubble constant measured in units of 100 km s^{-1} Mpc^{-1}). From Peebles' Abell cluster–galaxy correlation function[5], this radius corresponds to a rich cluster density contour at some 3 times the background density. The other clusters were plotted with radii of 7 h^{-1} Mpc unless they seemed, from an inspection of Zwicky's catalogue[6] to be particularly small or poor. In that case they were plotted with radii of 4 h^{-1} Mpc. The sizes are only meant to give a rough indication of the distribution of galaxies in the vicinity of clusters. To estimate the completeness of Noonan's list in this region, we have checked the Zwicky catalogue and find only one (or possibly two) additional clusters which are comparable with those of known radial velocities.

The correlation between the positions of Rubin–Ford Sc I galaxies and clusters in Fig. 1 is quite striking. Only one of the Sc I galaxies is significantly isolated from any cluster. RFR point out that some 60% of their sample galaxies life outside the cores of known clusters. Nonetheless, it is apparent from Fig. 1 that they are associated with the Perseus–Pisces complex and Abell's[7] supercluster no. 6 (including Coma and A1367). This would be expected on the 'cloud picture' of the galaxy distribution[8–10]. Figure 1 suggests to us that the apparent anisotropy in the radial velocities of Sc I galaxies may reflect only the inhomogeneities in the distribution of galaxies in the region of the Rubin–Ford sample.

Of course, we have picked the declination band where the effect is most dramatic to illustrate the basic idea underlying our hypothesis. To show that the correlation of Sc I galaxies with clusters is a general phenomenon, we present in Table 1 the number of Rubin–Ford sample galaxies and Noonan clusters in the high and low velocity bands of regions I and II for the whole sky north of $\delta = -3°$. We note that the ratio of the number of clusters to Sc I galaxies in the low velocity band of region I is nearly the same as this ratio for the high velocity band of region II, as expected on our hypothesis. We also note that there is an apparent deficit of high velocity Sc I galaxies in

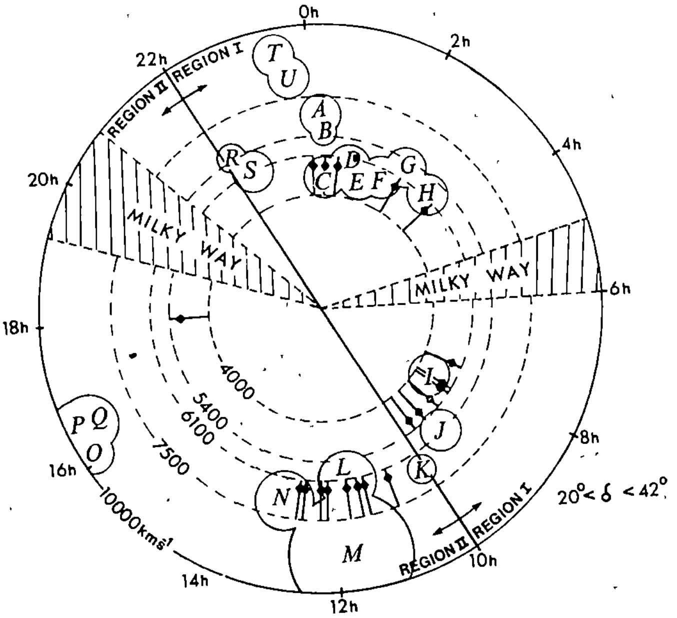

Fig. 1 Clusters (○) and Rubin–Ford Sc I galaxies (-◆-) with $20° < \delta < 42°$. Clusters: *A*, *B*, Anonymous; *C*, Perseus C_2; *D*, Z501–5; *E*, Z501–5; *F*, Z522–9; *G*, A347; *H*, A426, Z540–1 (Perseus); *I*, Z119–1 (Cancer); J, A779, Z181–17; *K*, Z211–58; *L*, A1367, Z127–2; *M*, Abell Supercluster no. 6; *N*, A1656, Z160–1 (Coma); *O*, A2162, Z167–8; *P*, A2199, Z224–12; *Q*, A2197, Z224–12; *R*, Z513–2; *S*, Z514–3; *T*, A2634, Z476–5; *U*, A2666, Z476–5. Numbers preceded by A are entries in Abell's catalogue[4] and numbers preceded by Z are entries in Zwicky's catalogue[6]. All radial velocities are from Noonan[3] except *C* which is from Zwicky[9] and *M* which is from Abell[7]. The circular scale gives RA (h), the radial scale gives velocity (km s^{-1}).

region I. As the high velocity clusters in region I are among the poorest in the sample, however, this fact should not be given equal weight.

The two-cloud model

Figure 1, together with the Rubin–Ford comment that most of their sample galaxies in region I have velocities near 4,950 km s^{-1} and those in region II have velocities near 6,400 km s^{-1}, suggests that we idealise to a model in which galaxies lie in two 'clouds' with those velocities. We shall refer to this model as the 'two-cloud model' and denote the low velocity cloud I and the high velocity cloud II. Of course, the applicability of the model results from the particular magnitude window chosen by RFR and the distribution of clusters within it (compare Fig. 1). In what follows, we shall assume (1) that the Sc I galaxies in both clouds are drawn from a universal urn, that is from the same luminosity function and size distribution, and (2) that there is no anisotropy in the cosmic expansion, that is, distances are given by Hubble's law with a direction independent Hubble constant. We shall then endeavour to show that this model is consistent with the data presented in ref. 1 by RFR; we shall 'predict' (1) the 0.1 apparent magnitude difference between low and high velocity sample galaxies and (2) the 14% difference in mean angular diameters.

First, we compute the mean apparent magnitudes of high and low velocity galaxies expected on the two-cloud model in a manner suggested by Sandage and Tammann's discussion of the Rubin–Ford effect[11]. We adopt the luminosity function for Sc I galaxies suggested by van den Bergh[2] and Sandage and Tammann[11]; a Gaussian with mean absolute (photographic) magnitude

$$\bar{M} = -20.0 + 5\log h \qquad (1)$$

and dispersion

$$\sigma(M) = 0.50 \text{ mag} \qquad (2)$$

With this luminosity function we compute mean apparent magnitudes

$$\bar{m}_{\rm I} = 14.17, \quad \bar{m}_{\rm II} = 14.30 \quad \text{(model)} \qquad (3)$$

for the low and high velocity clouds respectively. The calculation is illustrated in Fig. 2 and is of course independent of *h* and the numbers of galaxies in the clouds. We have adopted a photometric correction of −0.1 mag to Zwicky magnitudes as suggested by Sandage and Tammann[11]. The predicted mean apparent magnitudes (3) are to be compared with the mean apparent magnitudes of the Rubin–Ford sample, corrected for galactic obscuration

$$\bar{m}_{\rm I}^{c} = 14.20 \pm 0.07, \quad \bar{m}_{\rm II}^{c} = 14.30 \pm 0.06 \quad \text{(Rubin–Ford data)} \qquad (4)$$

The agreement is remarkably good. We note that the predicted magnitudes are somewhat sensitive to the adopted magnitude window, but that their near equality is not. This near equality is mainly a consequence of the fact that the one-magnitude window chosen by RFR is comparable with the dispersion in the absolute magnitudes of Sc I galaxies.

Next we estimate the ratio of the mean angular diameters of the low and high velocity galaxies expected on the two-cloud model. We shall assume that galaxy diameters *d* and luminosities *L* are related by

$$d \propto L^{(1-\varepsilon)/2} \qquad (5)$$

where ε is a parameter to be discussed presently. From (5) and the relationship between distances, luminosities and apparent and absolute magnitudes, it follows that the ratio of the mean angular diameters for galaxies in clouds I and II is

$$\bar{\theta}_{\rm I}/\bar{\theta}_{\rm II} = (v_{\rm II}/v_{\rm I})^{\varepsilon}\,[1 + \tfrac{1}{5}(1-\varepsilon)(\bar{m}_{\rm II} - \bar{m}_{\rm I})\ln(10) + \ldots] \qquad (6)$$

to first order in $(\bar{m}_{\rm II} - \bar{m}_{\rm I})$. For the two-cloud model appropriate to the Rubin–Ford data this becomes

$$\bar{\theta}_{\rm I}/\bar{\theta}_{\rm II} \simeq (1.29)^{\varepsilon}\,(1.06 - 0.06\varepsilon) \quad \text{(model)} \qquad (7)$$

with the mean apparent magnitude difference calculated above (equation (3)). The case $\varepsilon = 0$ corresponds to luminosities uncorrelated with mean surface brightness as Hubble[12] found to be appropriate for elliptical galaxies, and the extreme case $\varepsilon = 1$ corresponds to luminosities uncorrelated with diameters.

Unfortunately, it is rather difficult to determine the luminosity–diameter relation for Sc I galaxies because one requires a large sample of galaxies, all at the same distance. It would be surprising if the value of ε appropriate to Sc I galaxies did not lie in the range (0,1) bracketed by the extreme cases mentioned above. We expect it to lie nearer the value $\varepsilon = 0.23$ found by Heidman *et al.*[13] to fit the data on spiral galaxies in the Virgo cluster best. This is similar to the value $\varepsilon = 0.17$ found by Holmberg[14] to fit the data on galaxies of all morphological types. In any case, the dependence of equation (7) on ε is rather weak in this neighbourhood. With $\varepsilon = 0.23$, equation (7) gives the ratio

$$\bar{\theta}_{\rm I}/\bar{\theta}_{\rm II} \simeq 1.11 \quad \text{(model)} \qquad (8)$$

Table 1 Numbers of Rubin–Ford ScI galaxies and Noonan clusters north of $\delta = -3°$

	Low velocity (4,000–5,400 km s^{-1})		High velocity (6,100–7,500 km s^{-1})	
Region	Galaxies	Clusters	Galaxies	Clusters
I	20	5	2	5
II	1	0	12	3

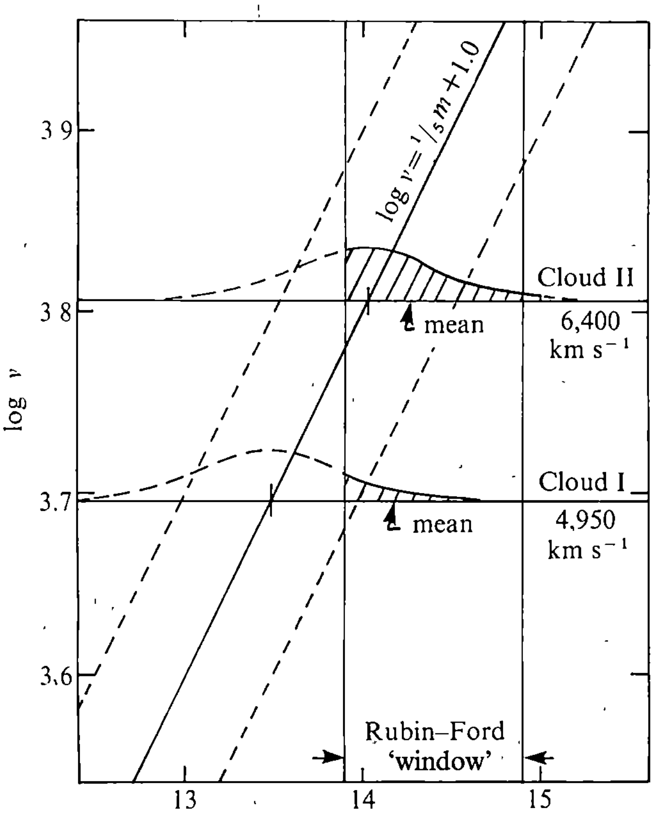

Fig. 2 Graph illustrating the calculation of mean apparent magnitudes for low and high velocity galaxies on the two-cloud model. The dashed diagonal lines are $\sigma = 0.50$ mag away from the mean velocity–magnitude line. All velocities are in km s^{-1}.

which is to be compared with the ratio

$$\bar{\theta}_{I}/\bar{\theta}_{II} = 1.14 \pm 0.10 \quad \text{(Rubin–Ford data)} \qquad (9)$$

quoted by RFR for their sample. In view of the large scatter in the angular diameters of Rubin–Ford galaxies, the agreement between equations (8) and (9) is entirely satisfactory.

The local velocity field

RFR have also pointed out that there is an apparent anisotropy in the radial velocities of the bright Sc I and Sc I–II galaxies studied by van den Bergh[2] and that the effect is similar in magnitude and in direction to that in the Rubin–Ford sample. That is, the van den Bergh galaxies in the Rubin–Ford region I seem to yield a Hubble constant similar to that of Rubin–Ford galaxies in region I but significantly smaller than that of both van den Bergh and Rubin–Ford galaxies in region II. RFR argue from this that inhomogeneity scales of at least 70 h^{-1} Mpc are required by the hypothesis of isotropic expansion. How can this be reconciled with our assumption of isotropic expansion and inhomogeneities on the more reasonable scale of 15 h^{-1} Mpc? We have re-examined the data on van den Bergh's sample of Sc I and Sc I–II galaxies and find that the anomaly arises mainly from those galaxies lying within ~20° of the centre of the Ursa Major complex. This is a small part of Rubin–Ford region I which we shall refer to as subregion U. Most of the van den Bergh galaxies in Rubin–Ford region II lie within ~20° of the Virgo cluster, a subregion which we shall denote by V.

Because of the unknown distribution of galaxies behind the Ursa Major and Virgo complexes, a detailed calculation is out of the question. The following remarks, however, strongly suggest that the anomaly may indeed be caused by inhomogeneities on the smaller scales: (1) the mean velocities of van den Bergh Sc I and Sc I–II galaxies lying in subregion U is very close to the mean velocity of both de Vaucouleurs[15] groups and Turner–Gott[16] groups lying in that subregion; (2) the mean velocity of van den Bergh Sc I and Sc I–II galaxies lying in subregion V is ~2,000 km s^{-1}, almost 1,000 km s^{-1} larger than the mean recessional velocity of the Virgo cluster. The apparent discrepancy could therefore be reconciled with isotropic expansion and moderate inhomogeneities on a theme similar to the two-cloud model if the Virgo complex in fact extends for 15 h^{-1} Mpc or so in the radial direction. Another possibility is simply that the velocities of some of the Sc I and Sc I–II galaxies in subregion V are dominated by the core of the Virgo cluster and are therefore not indicators of their distance. Indeed, according to Tammann[17] the van den Bergh galaxies having NGC numbers 4254, 4303, 4321 and 4535 lie in the core of the Virgo cluster. If these galaxies are put at the distance of the Virgo cluster, the anomaly between subregions U and V nearly disappears, and the remaining difference might be accounted for along the lines mentioned above.

Discussion

The agreement between the 'predictions' of the two-cloud model and the data reported by RFR in ref. 1 is encouraging. We emphasise again that the applicability of the model results from the particular, narrow magnitude window chosen by RFR and the distribution of galaxies (as suggested by the distribution of clusters) within that window. Unfortunately, the radial galaxy distribution at these distances is not yet accurately known over large parts of the sky and that is, of course, the reason for our choosing clusters of galaxies as a reflection of the distribution of galaxies. Recently, Chincarini and Rood have studied the radial velocity distribution of individual galaxies in the direction of the Coma cluster and its surroundings[18] and the Perseus–Pisces complex (G. Chincarini, personal communication) and find distributions quite consistent the cloud picture depicted in Fig. 1. We note that the density enhancements required to produce the Rubin–Ford effect on the hypothesis of isotropic expansion are of ~1 on radial scales ~15 h^{-1} Mpc (corresponding to the Rubin–Ford magnitude window). Studies of the distribution of galaxies within the Local Supercluster[19] indicate that the required matter gradients are not atypical. On the hypotheses of uniform expansion and a uniform matter distribution on the very largest scales, the Rubin–Ford effect should of course vanish. Support for this comes from Evans and Hart[20] who report no anisotropy in the angular diameter–redshift relationship for elliptical galaxies with radial velocities in the range 1,200 km s^{-1} to 25,000 km s^{-1}.

The Rubin–Ford effect should appear, on our hypothesis, in the distribution of any 'standard candles' in a one-magnitude window scaled to the RFR window (that is scaled by the difference in the mean absolute magnitudes of Sc I galaxies and that of the other standard candle). Le Denmat and Vigier[21] have suggested that type I supernovae may be appropriate standard candles and have discovered an effect similar to the RFR effect in their distribution. Considering, however, the methods used in searching for supernovae, their apparent distribution is almost guaranteed to coincide with the distribution of galaxy clusters, and would have been expected to exhibit an anisotropic velocity distribution on our hypothesis. We have re-examined the data on type I and possible type I supernovae[22,23] in the magnitude windows $15.3 \leqslant m \leqslant 16.3$ and $15.7 \leqslant m \leqslant 16.7$. These correspond respectively to supernovae mean absolute magnitudes 1.4 mag (ref. 24) and 1.8 mag (ref. 25) fainter than Sc I galaxies (see equation (1)). We do indeed find that most of these supernovae have occurred in galaxies which are members of the Coma, Cancer and Perseus–Pisces clusters (see Fig. 1). Jaakola *et al.*[26] have also noted an effect similar to the Rubin–Ford effect in the distribution of compact galaxies with absorption spectra. It is not clear, however, that these objects represent standard candles in the sense required to evaluate our hypothesis.

In summary, we have shown that the Rubin–Ford data are consistent with the hypothesis of isotropic cosmic expansion. In view of the similarity of Sandage and Tammann's[11] velocity–magnitude relationship (see their Fig. 4) in the supergalactic centre and anticentre directions, a peculiar anisotropy in the absolute magnitudes of Sc I galaxies which just compensates any anisotropy in the velocities is required if the cosmic expansion is not to be isotropic. We consider such a conspiracy to be less plausible than the hypothesis of isotropic expansion. The issue cannot be finally decided, however, until radial velocities and radial distribution of other kinds of matter at these distances are more accurately known. This will require velocity and magnitude data for several kinds of standard candles ('standard candle' meaning, in this context, a class of objects with an absolute magnitude dispersion $\lesssim 0.50$ mag, corresponding to the inhomogeneity scale $15\,h^{-1}$ Mpc at these distances).

Of course, we do not expect the cosmic expansion to be perfectly isotropic in the direction of clusters and clouds of galaxies because these matter inhomogeneities will have perturbed the expansion to some extent. Since the perturbed galaxy velocities near an inhomogeneity are determined by the absolute amount of matter in the inhomogeneity, its mass and hence the mean matter density of the Universe can, in principle, be determined once the galaxy distribution and velocity field near the inhomogeneity are mapped out[18,27–29]. As we have shown, the Rubin–Ford data are consistent with an unperturbed galaxy velocity field and hence a low density Universe. Paradoxically, the apparent anisotropy of the radial velocities reported by RFR in ref. 1 may impose a rather strong upper limit to the mean matter density of the Universe. To see this, refer back to Fig. 1. Suppose now that matter is decelerated towards the centre of the supercluster at RA 12 h. Then the matter on this side of the supercluster centre will be closer to us than the distance assigned on the two-cloud model from Hubble's law. The galaxies in this cloud would then appear too bright to be consistent with the Rubin–Ford data. At this stage, we refrain from carrying out a calculation of the mean matter density on this basis because of the uncertainties inherent in the limited data at hand. In view of the importance of this parameter and the hypothesis of isotropic expansion to cosmology, it would be very desirable to have more velocity and magnitude data for galaxies at these distances.

We thank Barry Madore, Martin Rees and Simon White for interesting discussions and helpful comments. S.M.F. acknowledges support from the Cambridge Philosophical Society.

Fossil hominids from the Laetolil Beds

M. D. Leakey, R. L. Hay, G. H. Curtis, R. E. Drake & M. K. Jackes

Olduvai Gorge, PO Box 30239, Nairobi, Kenya

T. D. White

Department of Anthropology, University of Michigan, Ann Arbor, Michigan 48104

Remains of 13 early hominids have been found in the Laetolil Beds in northern Tanzania, 30 miles south of Olduvai Gorge. Potassium–argon dating of the fossiliferous deposits gives an upper limit averaging 3.59 Myr and a lower limit of 3.77 Myr. An extensive mammalian fauna is associated. The fossils occur in the upper 30 m of ash-fall and aeolian tuffs whose total measured thickness is 130 m.

THE fossil-bearing deposits referred to variously as the Laetolil Beds, Garusi or Vogel River Series lie in the southern Serengeti Plains, in northern Tanzania, 20–30 miles from the camp site at Olduvai Gorge.

Fossils have been collected from the area on several occasions, the largest collection being made by L. Kohl-Larsen in 1938–39, who also found a small fragment of hominid maxilla which was named *Meganthropus africanus* by Weinert[1]. L. S. B. Leakey and M.D.L. visited the area in 1935 and in 1959, while a day trip was made in 1964 in company with R. L. H. The faunal material recovered on these occasions was all collected before the advent of isotopic dating and the age of the fossils remained uncertain until potassium–argon dating was carried out on samples of biotite obtained during the 1975 field season. In 1974, however, lava flows which unconformably overlie the Laetolil Beds had been dated by G. H. C. at 2.4 Myr.

We now report evidence that fossiliferous deposits of several different ages exist in the Laetolil area and that specimens found on the surface are not necessarily derived from the same beds. There are, however, noticeable variations in the colour and physical condition of the surface fossils which provide indications of their origin.

Discrepancies in the fauna were noted by Dietrich[2] and Maglio[3] who both postulated faunal assemblages of two different ages. In view of this, it was proposed for a time that the name Laetolil should be abandoned in favour of the more generalised term Vogel River Series, based on the colloquial German name for the Garusi river, which abounds in bird life. As the early fossiliferous deposits here referred to as the Laetolil Beds are not confined to the Garusi valley, this change of name seems unnecessary. Furthermore, the name Laetolil embraces a larger area, because it is the anglicised version of the Masai name (laetoli) for *Haemanthus*, a red lily that is abundant in the locality The Laetolil Beds, *sensu stricto*, form a discrete unit, distinguishable from later deposits, and M.D.L. considers that the original name proposed by Kent

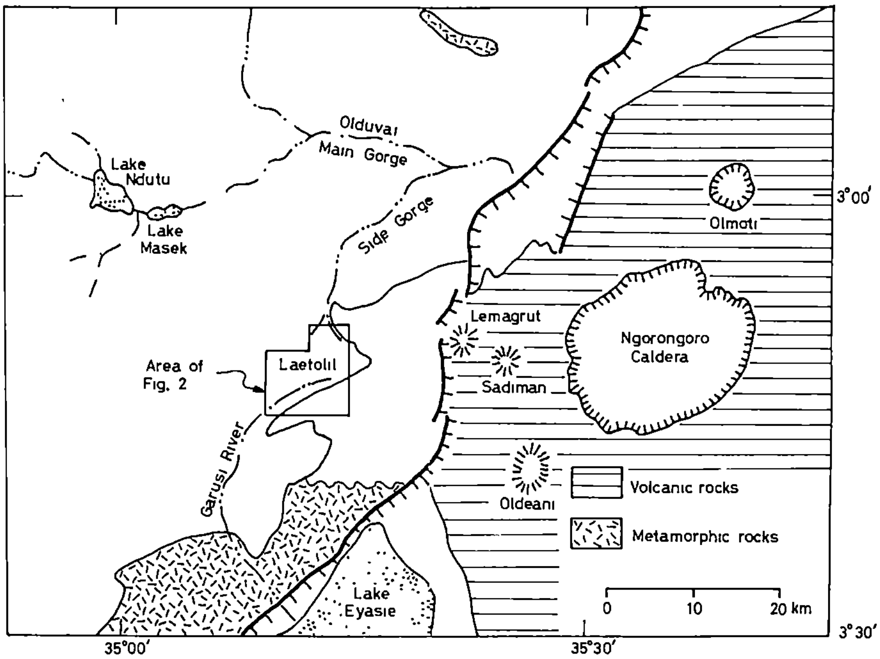

Fig. 1 Map of the southern Serengeti and volcanic highlands.

in 1941[4] should be retained for this part of the sequence.

The relationship of the Laetolil to the Olduvai Beds had been under discussion for some years, but in 1969 R. L. H. noted that they underlay bed I at the Kelogi inselberg in the Side Gorge and established that they antedated the Olduvai sequence. This has been further confirmed when tuffs correlatable with bed I as well as an earlier, fossil-bearing series of tuffs were found to lie unconformably on the Laetolil Beds.

Interest in the area was renewed in 1974 after the discovery by George Dove of fossil equid and bovid teeth in the bed of the Gagjingero river, which drains into Lake Masek at the head of Olduvai Gorge. These fossils were found to be eroding from relatively recent deposits, probably the beds named Ngaloba by Kent[4]. Exposures of the Laetolil Beds, not hitherto seen by M.D.L., were found to the east of the Gagjingero river, at the headwaters of the Garusi river and of the Olduvai Side Gorge (referred to as Marambu by Kohl-Larsen[5]). Several fossils, including a hominid premolar, were found at these localities and subsequent visits yielded further hominid remains.

The possibility of establishing the age of the hominid fossils from the Laetolil Beds by radiometric dating and of clarifying the discrepancies in the faunal material led to a 2-month field season during July and August 1975. Samples from the fossiliferous horizons, collected by R. L. H., have now been dated. On the basis of these results the hominid remains and associated fauna can be bracketed in time between 3.59 and 3.77 Myr.

No trace of stone tools or even of utilised bone or stone was observed in the material from the Laetolil Beds, although handaxes and other artefacts occur in conglomerates which are present in certain areas and which are unconformable to the Laetolil Beds.

Stratigraphy of Laetolil area

The bulk of the faunal remains and all of the hominid remains were found within an area of about 30 km² at the northern margin of the Eyasie plateau and in the divide between the Olduvai and Eyasie drainage systems (Fig. 1).

Kent studied this area as a member of L. S B. Leakey's 1934–35 expedition, and his short paper is the only published description of the stratigraphy. He recognised three main subdivisions of the stratigraphic sequence, which overlies the metamorphic complex of Precambrian age. The lower unit he named the Laetolil Beds and the upper the Ngaloba Beds The middle unit consists of olivine-rich lava flows and agglomerate, which are much closer in age to the Laetolil Beds than to the Ngaloba Beds. Kent briefly noted the local occurrence of tuffs younger than the lavas and older than the Ngaloba Beds. He described the Laetolil Beds as subaerially deposited tuffs, and he gave 30 m as an aggregate thickness in the vicinity of Laetolil. The Ngaloba Beds he described as tuffaceous clays, and he gave a thickness of about 5 m at the type locality. Pickering mapped this area as part of a 1:125,000 quarter degree sheet[6] and extended the known occurrence of the Laetolil Beds. He also recognised that at least some of the tuffs are of nephelinite composition.

This picture was modified considerably by stratigraphic work in 1974 and 1975. The Laetolil Beds proved to be far thicker and more extensive than previously recognised. The thickest section, 130 m, was measured in a valley in the northern part of the area (geological localities *A* to *C*, Fig. 2). The base is not exposed and the full thickness of the Laetolil Beds here is unknown. Sections 100–120 m thick and representing only part of the Laetolil Beds were measured about 10 km south-east of Laetolil. The Laetolil Beds are 15–20 m thick at a distance of 25–30 km to the south-west and 10–15 m thick at Lakes Masek and Ndutu, 30 km to the north-west. The Laetolil Beds are tuffaceous sediments, dominantly of nephelinite composition.

The lavas and agglomerates noted by Kent overlie an irregular surface deeply eroded into the Laetolil Beds. The lavas were erupted from numerous small vents to the south, south-west and west of Lemagrut volcano. Although designated as nephelinite by Kent, the flows proved to be vogesite, a highly mafic lava with interstitial alkali feldspar and phlogopitic biotite. The lavas have reversed polarity as determined by field measurements (personal communication from A. Cox). A sample of lava from geological locality *D* (Fig. 2) gave K–Ar dates of 2.38±0.5 Myr and 2.43±0.7 Myr (Table 1).

The 130-m section of the Laetolil Beds (Fig. 3) is divisible into an upper half consisting largely of wind-worked, or aeolian, tuff[7] and a lower half consisting of interbedded ash-fall and aeolian tuff with minor conglomerate and breccia. Tephra in the lower half are nephelinite, whereas nephelinite and melilitite are subequal in the upper half. Between these two divisions is a distinctive biotite-bearing coarse lithic-crystal tuff 60 cm thick. Hominid remains and nearly all of the other vertebrate remains are confined to the uppermost 30 m of aeolian tuffs beneath a widespread pale yellow vitric tuff 8 m thick (tuff *d* of Fig. 3). Several other marker tuffs, between 1 m and 30 cm thick, can be used for correlating within the fossiliferous 30-m thickness of sediments. The three prominent marker tuffs, designated *a*, *b*, and *c* (Fig. 3, column 2), can be recognised

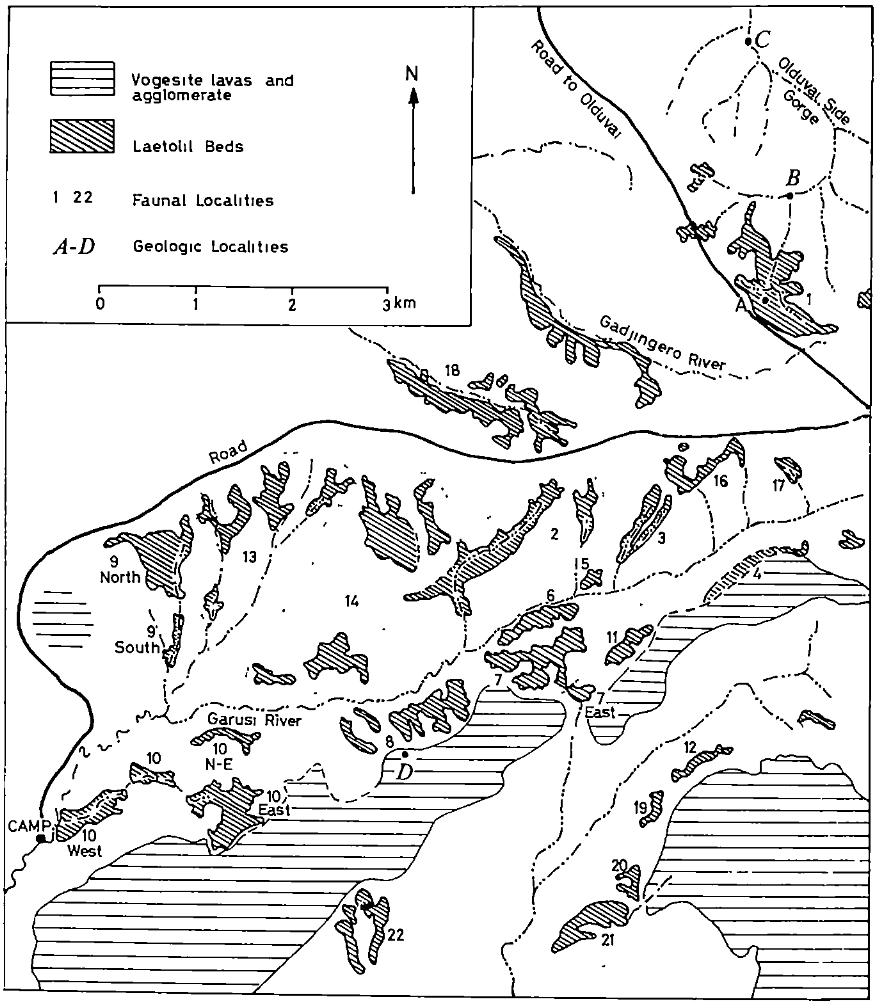

Fig. 2 Map of the Laetolil area showing the fossil beds.

throughout the area shown in Fig. 2. Widespread horizons of ijolite and lava (mostly nephelinite) xenoliths are at several levels in the fossiliferous part of the section and assist in correlating. Biotite is common in some of the ijolite.

Additional fossiliferous deposits, of mineralogical affinity to the Laetolil Beds and 10–15 m thick, lie between tuff *d* and the bed I (?) tuffs at several places. They are locally separated from tuff *d* and the underlying aeolian tuffs of the Laetolil Beds by an erosional surface with a relief of 8 m. These sediments comprise water-worked tuffs, aeolian tuffs, clay-pellet aggregate of aeolian origin and limestone. The tephra are of phonolite and nephelinite composition. It is not yet clear whether or not these sediments should be regarded as part of the Laetolil Beds.

Beds I and II are represented by sedimentary deposits that lie stratigraphically between the lava and the Ngaloba Beds. The bed II deposits locally contain fossils and artefacts.

Sadiman volcano, about 15 km east of the fossiliferous exposures, seems to have been the eruptive source of the Laetolil Beds. The one K–Ar date, of 3.73 Myr, obtained from Sadiman lava, fits with the K–Ar dates on the Laetolil Beds presented here. This date was published previously as K–Ar 2238 (ref. 8), where it was incorrectly assigned to Ngorongoro because of a mistake in listing the sample numbers.

Potassium–argon dating

The vogesite lava is composed of approximately 85–90% olivine and augite. The remainder is principally anorthoclase in the groundmass together with a very small amount of phlogopitic biotite. These two minerals proved too fine-grained and sparse for effective separation, and whole-rock samples were used for dating.

$^{40}K/K = 1.18 \times 10^{-4}$; $^{40}K_{\lambda} = 5.480 \times 10^{-10}\ yr^{-1}$; $^{40}K_{\lambda\beta} = 4.905 \times 4.905 \times 10^{-10}\ yr^{-1}$; $^{40}K_{\lambda\varepsilon} = 0.575 \times 10^{-10}\ yr^{-1}$.

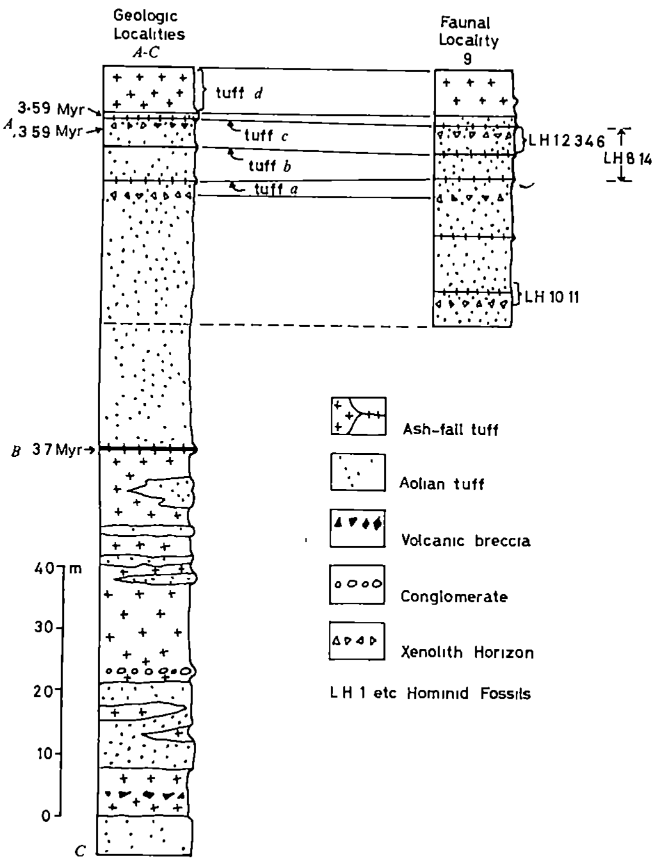

Fig. 3 Stratigraphic column of the Laetolil Beds showing the positions of the dated tuffs and hominid fossils.

In addition to the vogesite lava unconformably overlying the Laetolil Beds, three of the tuffaceous layers within the Laetolil Beds have been dated by the conventional, total degassing K–Ar method (Table 1), and one of these tuffaceous layers has also been dated by the ^{40}Ar/^{39}Ar method, using incremental heating.

Tuff *c* is the uppermost of the dated horizons, lying near the top of the fossiliferous deposits. It is a widespread crystal-lithic air-fall tuff cemented with calcite and generally 10–15 cm thick. Abundant biotite crystals 1–2 cm in diameter occur in the upper part of the tuff, which is composed of nepheline and milelitite. The dated crystals were hand-picked from two outcrops of the tuff at locality *A* (Figs 2 and 3). The cementing calcite adhering to and interleaving the biotite books was removed by treatment with dilute HCl for a few minutes on one sample and with warm dilute acetic acid on two other samples. This treatment was found to have negligible deleterious effects on biotite standard samples. The three dates obtained for tuff *c* (3.41±.08 Myr, 3.68±.09 Myr, and 3.69±.10 Myr) have about equal precision so were averaged to give a date of 3.59 Myr.

Two conventional K–Ar dates and one ^{40}Ar/^{39}Ar were obtained from a single biotite crystal from a xenolithic horizon at locality *A* (Figs 2 and 3) approximately 1–2 m below the youngest tuff dated (tuff *c*). This horizon lies within the upper part of the fossiliferous beds and is distinguished by its ejecta of ijolite xenoliths together with nephelinite lava xenoliths. Although the biotite occurs in some of the ijolite clasts, a large single free crystal picked from the tuff was used for dating. The good agreement between the two conventional K–Ar dates for this sample (3.62±0.09 Myr and 3.59±0.05 Myr) and the ^{40}Ar/^{39}Ar date which yielded an isochron age of 3.55 Myr (Fig. 4) indicates that initial excess ^{40}Ar is not a problem with this sample, and that these dates give an average age for this horizon of 3.59 Myr.

Two dates were obtained from a biotite-bearing crystal-lithic tuff 60 cm thick lying approximately 50 m below tuff *c* near the middle of the thickest section of the Laetolil Beds at location *B* (Fig. 2). The tuff is of nephelinite composition, containing abundant augite and altered nepheline and 2–3% of biotite, some crystals of which are as much as 1 cm in diameter. Calcite cements the crystals and fragments together. Biotite was separated by crushing, screening and hand picking and was cleaned of calcite with dilute HCl. Two dates, 3.82±0.16 Myr and 3.71±0.12 Myr, average 3.77 and give a lower limit to the age of the hominid remains (which occur below but close to the dated xenolithic horizon higher in the section) in the 30 m section at locality *A* (Fig. 2) whose base projects approximately 20 m above this tuff at locality *B* (Fig. 3).

Fauna

The fossiliferous deposits in the Laetolil area have been subdivided, for purposes of collecting, into 26 localities. These subdivisions are based on existing topographic features such as grassy ridges, lines of trees, stream channels and so on. This has provided a means of dividing the fossiliferous area into units of restricted size, but does not relate to the former topography.

Eighteen of these localities are in the Garusi valley, one in the valley at the head of the Olduvai Side Gorge, one in the Gadjingero valley, five in a valley to the south of the Garusi river and one in an isolated position to the west (Fig 2).

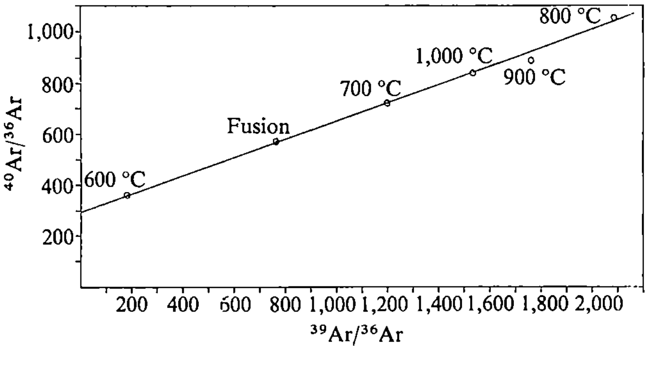
Identifiable fossils noted on the exposures were either collected and registered or listed on the sites. Specimens from the Laetolil Beds were distinctively cream coloured or white and sometimes chalky in texture, but the surface material also included brown, grey or black specimens, often rolled. These have been excluded from the material under review, together with fossils which have adhering matrix clearly dissimilar from the tuffs of the Laetolil Beds. Among these are all remains of *Hippopotamus*, *Equus*, *Theropithecus*, *Phacochoerus* and *Tragelaphus*, formerly included in the Laetolil fauna, with the exception of *Hippopotamus*.

The fossil material from the Laetolil Beds is dispersed and fragmentary and it is not possible to assess the number of individuals represented. In this article, 'numbers of fossils' refer to individual bones and teeth, except in the case of clear association, confined almost entirely to remains of *Serengetilagus* and *Pedetes*, some of which were associated and even articulated.

Table 2 shows the mean percentage frequency of the more common vertebrate groups at several of the richer localities. A total of 6,288 fossil specimens was identified from the localities considered here.

Reptiles are represented by snake vertebrae at three localities and by tortoises at all localities. The latter have an average frequency of 2.2% and include several giant specimens. Avian remains occur widely and at several localities birds' eggs were completely preserved. There is one example of a shattered clutch of at least eight eggs, rather smaller in size than eggs of domestic fowl. Primates were found at 15 localities, and in one area they constitute 3.8% of the fauna. Both cercopithecines and colobines are present (M. G. Leakey, personal communication).

Fig. 4 ^{40}Ar/^{39}Ar incremental heating of biotite from xenolithic horizon, locality *C*. Isochron age, 3.55 Myr; [^{40}Ar/^{39}Ar]$_0$ = 294; ^{10}Ar/^{39}Ar = 0.35318; J = 0.005204.



Rodents are fairly well represented, although not abundant. Of the specimens identified by J.J. Jaeger, the most common are *Pedetes*, *Saccostomus* and *Hystrix*. The carnivore fauna is characterised by a high percentage of viverrids, constituting 32% of all the carnivore specimens. Large carnivores are represented by hyaenids, of which there are several genera, by felids and a machairodont.

Proboscidea include *Deinotherium* and *Loxodonta sp.* (M. Beden, personal communication). There is no evidence that the equid material (other than that derived from later deposits) includes any genus except *Hipparion*. The suids consist only of two genera, *Potamachoerus* and *Notochoerus* (J. Harris, personal communication). The presence of *Ancylotherium* and *Orycteropus*, noted in previous collections, is confirmed and the existence of two rhinocerotids has been established by the discovery of skulls of both *Ceratotherium* and *Diceros*, although only the former was listed previously.

Among the giraffids, *Sivatherium* and a small form of giraffe are equally common. *Giraffe jumae* is also present but is much less well represented. The bovid fauna is chiefly characterised by the very high percentage of *Madoqua* (dikdik). In 18 localities dikdik range from 1.5 to 37.7% of all bovid specimens, with a mean percentage of 15.1%.

Table 2 Mean percentage frequency of bones of more common vertebrate groups

Group	Mean percentage	Range	Nos of localities
Bovidae	43.0	29.5–57.9	18
Lagomorpha	14.4	5.6–24.0	18
Giraffidae	11.2	6.8–23.2	18
Rhinocerotidae	9.7	5.7–17.3	18
Equidae	4.4	1.7–7.1	18
Suidae	3.6	1.0–7.1	18
Proboscidea	3.4	1.0–5.1	18
Rodentia	3.3	0.9–7.2	17
Carnivora	3.1	0.8–8.2	17

The 1975 field season, although mainly confined to surface collection, has established that previous collecting had sampled faunas of several time periods. It is now possible to exclude some genera from the published lists of fauna from the Laetolil Beds[2,9], such as *Theropithecus*, *Tragelaphus*, *Equus* and *Phacochoerus*.

Fossil hominids

Thirteen new fossil hominid specimens were recovered from the Laetolil site during 1974 and 1975. The remains include a maxilla, mandibles and teeth. This sample displays a complex of characters seemingly demonstrative of phylogenetic affinity to the genus *Homo*, but also features some primitive traits concordant with its great age.

The hominid specimens are listed in Table 3. Provisional stratigraphic correlation and dating have placed the hominid remains as shown in Fig. 3. With the exception of Laetolil hominids (LH) 7 and 8, all specimens retain the matrix characteristic of the Laetolil Beds from which they have been weathered or excavated. There is no reason to doubt that all the specimens derive from the Laetolil Beds as reported.

The Laetolil hominid sample consists of teeth and mandibles. Important features of these specimens are described here, followed by a brief preliminary discussion regarding the phylogenetic status of the fossils.

Remains of deciduous and permanent dentitions have been recovered. The dentitions consist of two maxillary and four mandibular partial tooth rows. Compared with the rest of the East African Pliocene/early Pleistocene hominid sample, the Laetolil anterior teeth are large and the postcanine teeth of small to moderate size.

Deciduous dentition

Canines (LH 2, 3) Single upper and lower deciduous canines are known. The lower is a slightly projecting, sharp conical tooth in its damaged state. It is smaller but its overall morphology is similar to its permanent counterpart.

First molars (LH 2, 3) The upper first deciduous molar displays spatial dominance of the protocone and a well-marked mesiobuccal accessory cusp defined by a strong anterior fovea. The lower first deciduous molar is molarised, with four or five main cusps depending on hypoconulid expression. There is a spatially dominant protoconid with a large flat buccal face, a lingually facing anterior fovea, and an inferiorly projecting mesiobuccal enamel line. Vertical dominance of the protoconid and metaconid is marked in lateral view.

Second molars (LH 2, 3, 6) Upper and lower deciduous second molars take the basic form of the analogous permanent first molars but are smaller in overall size. The dM$_2$ of LH 2 is the only lower molar in the Laetolil sample bearing any indication of a tuberculum sextum.

Table 3 Hominid remains recovered in 1974–75

Laetolil hominid (LH)	Locality	Specimen consists of	Discovered by
1	1	RP^4 fragment	M. Muoka
2	3*[1]	Immature mandibular corpus with deciduous and permanent teeth	M. Muluila
3 (a–t)	7*	Isolated deciduous and permanent teeth, upper and lower	M. Muoka
4	7	Adult mandibular corpus with dentition	M. Muluila
5	8	Adult maxillary row: I^2 to M^1	M Muluila
6 (a–e)	7*†	Isolated deciduous and permanent teeth, upper	M. Muoka
7	5	RM^1 or ^{2} fragment	M. Muoka
8	11	RM^2, RM^3	E Kandindi
10	10W	Fragment left mandibular corpus with broken roots	E. Kandindi
11	10W	LM^1 or ^{2}	E. Kandindi
12	5	LM^2 or ^{3} fragment	E. Kandindi
13	8	Fragment right mandibular corpus with broken roots	M. Jackes
14	19	Isolated permanent teeth, lower	E. Kandindi

LH 9 was not valid

**In situ.*

†LH 3 and 6 associated in mixed state.

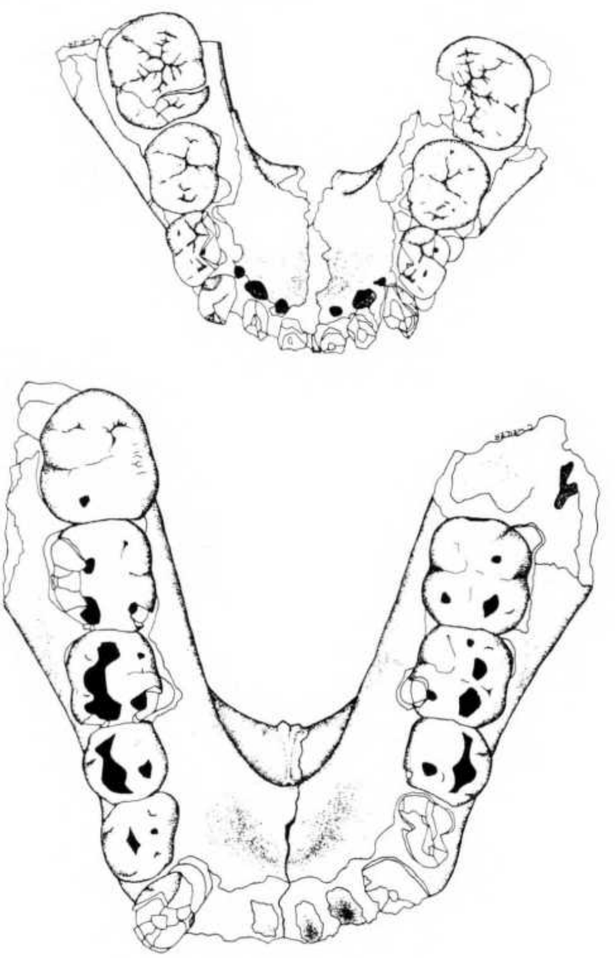


Fig. 5 Occlusal views of juvenile and adult mandibles (LH 2 and 4).

Permanent dentition

Incisors (LH 2, 3, 5, 6, 14) The single upper central incisor is very large and bears pronounced lingual relief. The upper lateral incisors are smaller, with variable lingual relief. The lower incisors are narrow and very tall, with minimal relief.

Canines (LH 2, 3, 4, 5, 6, 14) The incompletely-developed upper canine LH 3 is large, stout and pointed, bearing pronounced lingual relief. LH 6 is slightly smaller, with less lingual relief and a tall, pointed crown. LH 5 bears an elongate dentine exposure on its distal occlusal edge but does not project beyond the occlusal row in its worn state. The lower canines are similar to the uppers in their great size, height and lingual relief.

Premolars (LH 1, 2, 3, 4, 5, 6, 14) The upper premolars tend to be buccolingually elongate and bicuspid, with the lingual cusp placed mesially and an indented mesial crown face. The two lower third premolars each have a dominant buccal cusp with mesial and distal occlusal ridges, and a weak lingual cusp placed mesial of the major crown axis. The long axis of the oval crown crosses the dental arcade contour from mesiobuccal to distolingual, donating a 'skewed' occlusal profile to the tooth. The lower fourth premolars are fairly square in shape with major buccal and lingual cusps and moderate talonids.

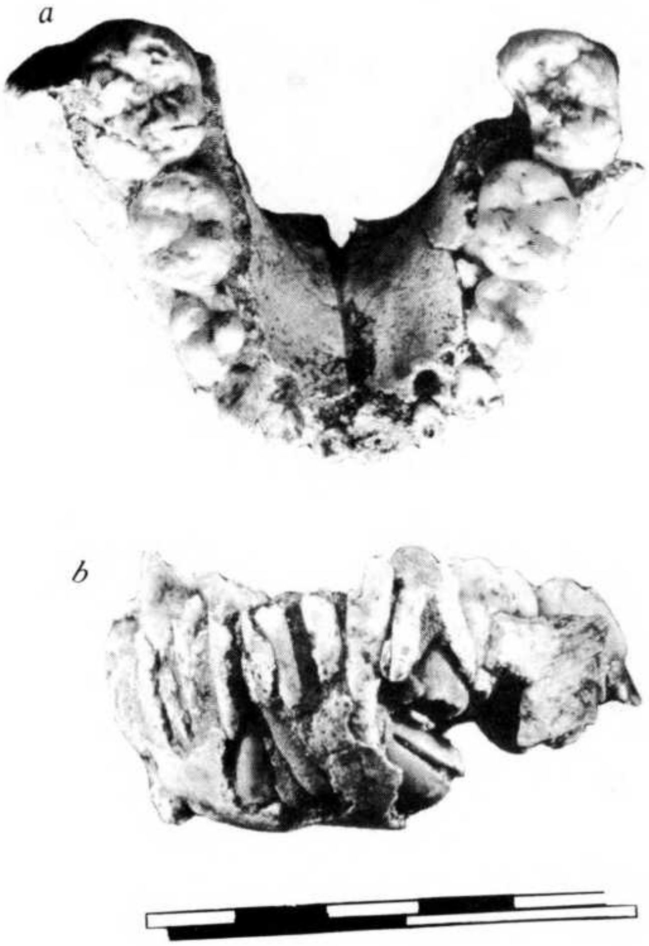
Molars (LH 2, 3, 4, 5, 6, 7, 8, 11, 12, 14) The upper molars are of moderate size, their relative proportions unknown. They show a basic four-cusp pattern with spatial dominance of the protocone and typical expression of a pit-like Carabelli feature. The lower molars display progressive size increase from first to third in LH4. They have a fairly square occlusal outline with hypoconulid apressed anteriorly between hypoconid and entoconid and no trace of a tuberculum sextum. The Y-5 pattern of primary fissuration is constant.

Mandibles

Juvenile mandible (LH 2) This specimen (Figs 5 and 6) is incompletely fused at the midline, and the developing crowns of the permanent canines and premolars are exposed in the broken corpus. The first molars have just reached the occlusal plane. Only the posterior aspect of the symphysis shows fairly intact contours, with a concave post-incisive planum and incipient superior transverse torus. The genioglossal fossa is obscured by midline breakage. Associated distortion has artificially increased the bimolar distances.

Adult mandible (LH 4) The adult mandibular corpus is well preserved, with the rami missing (Figs 5 and 7). The dental arcade is essentially undistorted, and presents fairly straight sides which converge anteriorly. The anterior dentition has suffered *post mortem* damage and loss, except for the right lateral incisor which seems to have been lost in life. Largely resorptive alveolar pathology has obliterated its alveolus and has affected the adjacent teeth. There is development of wide interproximal facets for the canine teeth but no C/P$_3$ contact facet. This combines with observation of extensive wear on the buccal P$_3$ face to suggest that C/P$_3$ interlock has prevented mesial drift from eliminating the C/P$_3$ diastema. Judging from the preserved posterior incisor alveoli, these teeth were set in an evenly rounded arcade, projecting moderately anterior to the bicanine axis. The internal mandibular contour is a very narrow

Fig. 6 Juvenile mandible from the Laetolil Beds (LH 2). *a*, Occlusal view; except for the first molars all the teeth are deciduous. *b*, Front view showing the central incisors, canine and P$_3$ in the bone.



parabola in contrast to the wider basal contour which displays great lateral eversion posteriorly. There are weak to moderate superior and inferior transverse tori, the latter bearing strong mental spines.

The anterior root of the ramus is broken at its origin, lateral to M_2. Occlusal and basal margins diverge strongly anteriorly, resulting in a deep symphysis. The symphysis is angled sharply posteriorly and the anterior symphyseal contour is rounded and bulbous. The lateral aspects of the corpus have very flat posterior portions and distinctive hollowing in the areas above the mental foramina at the P_3 to P_4 position. The corpus is tall and fairly narrow, especially in its anterior portion.

Implications of the specimens

The Laetolil fossil hominid sample, including the original Garusi maxillary fragment[5], seems to be representative of only one phylogenetic entity or lineage. The variations observed in the material seem to be primarily size-based and stem from individual and sexual factors.

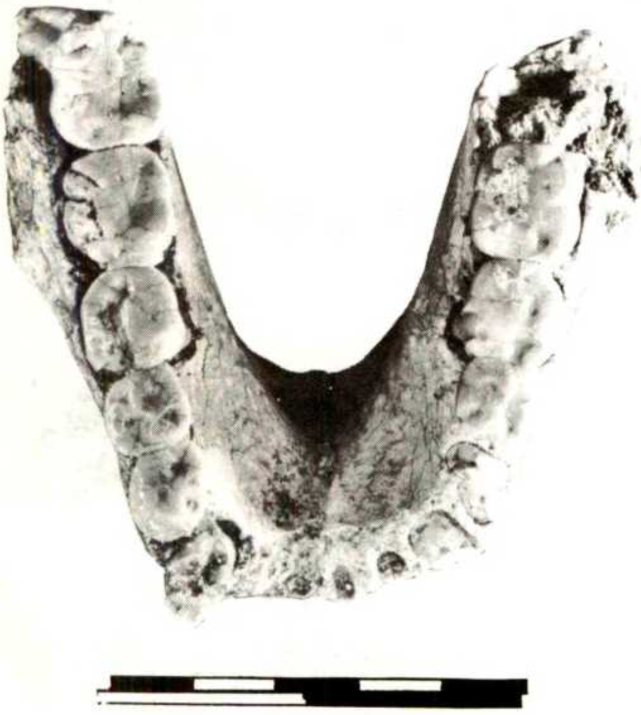


Fig. 7 Adult mandible from the Laetolil Beds (LH 2), occlusal view.

The deciduous teeth, particularly the lower deciduous first molars, display remarkable similarity to hominid specimens from South Africa (Taung; STS 24)[10] as well as to individuals tentatively assigned to *Homo* in East Africa (KNM ER 820, 1507)[11,12]. They depart strongly from the pattern of molarisation displayed in the South African "robust" specimens (TM 1601; SK 61, 64)[10] as well as from East African specimens generally assigned to the same hominid lineage (KNM ER 1477)[13].

The Laetolil permanent canines and incisors are relatively and absolutely large and bear a great deal of lingual relief. They ally themselves similarly to earlier hominid specimens such as STS 3, 50, 51, 52; MLD 11; OH 7, 16; KNM ER 803, 1590 (refs 10, 15, 18–21), as well as to the younger African and Asian specimens usually assigned to *Homo erectus*. These features set the Laetolil specimens apart from the sample including SK 23, 48, 876 and so on; Peninj; KNM CH 1; OH 5, 38; KNM ER 729, 1171 (refs 10, 15, 18–21). The Laetolil permanent premolars show none of the molarisation seen in the latter specimens and bear particularly strong resemblances to South and East African material (STS 51, 52, 55; OH 7, 16, 24; KNM ER 808, 992 (refs 10–12, 14).

The Laetolil permanent molars are consistent in aligning with the South African "gracile" australopithecus and the East African *Homo* material in both size and morphology. The molars do not display the increased size, extra cusps or bulging, expanded, "puffy" development of the individual cusps seen in high frequency among South and East African "robust" forms (SK 6, 13, 48, 52; TM 1517; Peninj; KNM CH 1; KNM ER 729, 801, 802) (refs 10, 17–20). The adult mandible has resemblances to certain East African specimens such as KNM ER 1802, with similar corpus section and basal eversion.

The Laetolil fossil hominids have several features possibly consistent with their radiometric age. These traits include the large crown size and lingual morphology of the permanent canines; the morphology and wear of the C/P_3 complex; the buccolingually elongate upper premolars; the overall square occlusal aspect of the lower permanent molars; the low symphyseal angle; the bulbous anterior symphysis; the relatively straight posterior tooth rows; the low placement of the mental foramina, and the distinctive lateral corpus contours including small, superiorly placed extramolar sulci.

Preliminary assessment indicates strong resemblance between the Laetolil hominids and later radiometrically-dated specimens assigned to the genus *Homo* in East Africa. Such assessment suggests placement of the Laetolil specimens among the earliest firmly dated members of this genus. It should come as no surprise that the earlier members of the genus *Homo* display an increasing frequency of features generally interpreted as "primitive" or "pongid like", which indicate derivation from as yet largely hypothetical ancestors.

Much of the recently discovered comparable fossil hominid material from the Hadar region of Ethiopia shows strong similarity to the Laetolil specimens[23], and further collection combined with detailed comparative analysis of material from both localities is essential for the further understanding of human origins. The Laetolil collection adds to the developing phylogenetic perspective of the early Hominidae and emphasises the need for taxonomic schemes reflective of and consistent with the evolutionary processes involved in the origin and radiation of this family.

Non-genetic individuality: chance in the single cell

John L. Spudich & D. E. Koshland, Jr

Department of Biochemistry, University of California, Berkeley, California 94720

The individuality of bacterial cells grown in homogeneous conditions was demonstrated by showing characteristic behavioural differences which persist over their lifespans. Poissonian fluctuation of small numbers of generator molecules can explain this individuality and may apply to such processes as differentiation and asynchrony of cultures.

BIOLOGICAL systems are constantly confronted with chance occurrences in their environmental conditions and internal processes. An elaborate biological apparatus has evolved to utilise chance in genetics for the survival of the species. Some feedback mechanisms, on the other hand, are designed to insulate the individual against chance fluctuations of environmental conditions. How much influence has chance in internal cellular processes in determining the metabolic state and behaviour of the single cell? More specifically, if cells containing identical chromosomes could be grown in environmentally homogeneous conditions, how similar would they be in their biochemical characteristics?

Uniform growth conditions can be obtained with agitated suspension cultures, since the spatial inhomogeneities which inevitably develop in stationary surface growth (for example, tissue culture plates or agar surfaces) are continuously randomised in swirled liquid culture. The problem of apparently non-genetic variation of cells in such a homogeneous environment has arisen in studies of several phenomena. For example, bacteriophage burst sizes[1], cell division times[2], bacterial flagellar phases[3,4] and β-galactosidase concentrations[5-7] all show variation difficult to attribute to environmental inhomogeneities or genetic causes. The question of individuality is difficult to pursue in these cases because one needs measures of characteristics of individual cells which can be ascertained essentially instantaneously and which do not perturb the cell's biochemical state. With such instantaneous measures an individual cell can be compared with itself at various stages of its life cycle and with other individual cells in an isogenic population. Such measures became available in our studies on chemotaxis and enabled us to approach the question of individuality in bacteria as an illustration.

The chemotactic migration of bacteria can be studied quantitatively. In the absence of chemotactic stimuli a bacterium shows brief periods of swimming in an approximately straight line (smooth swimming), interrupted by a rapid irregular motion, which reorients its swimming direction (tumbling). Tumbling is suppressed when the bacterium swims in a favourable direction in a chemical gradient and this regulation of tumbling frequency results in net migration up gradients of attractants and down gradients of repellents[8-10]. The modulation of tumbling frequency is caused by temporal changes in attractant or repellent concentration which are analysed by the sensing system and transmitted to the flagella[8,11]. For example, if the concentration of an attractant in the bacterial environment is suddenly increased, this temporal gradient transiently suppresses tumbling in the bacteria. Although the details of the temporal gradient sensing mechanism are unknown, control of tumbling can be rationalised as caused by changes in the levels of a tumble regulator[8,12]. The concentration of this tumble regulator is thus a key property of the cell since it provides an important survival mechanism for the bacterium. Its properties can be measured quantitatively in two ways: (1) in the sensitivity to stimuli as measured by recovery from temporal gradients[12,13] and (2) in the tumbling frequency when there is no gradient[9,12] as an indicator of the steady-state level of tumble regulator. These two properties were studied for individual bacteria as a test for non-genetic variability.

Sensitivity to gradients of attractant

Our first study of individual bacteria involved subjecting a bacterial clone of a tumbly mutant strain to a temporal gradient of serine, using the sudden mixing methods described earlier[8,13]. The transient smooth swimming in response to a temporal gradient stimulus is especially easy to quantify with tumbly mutants. The individual bacteria were kept in focus by rough tracking through a movable microscope stage which keeps the

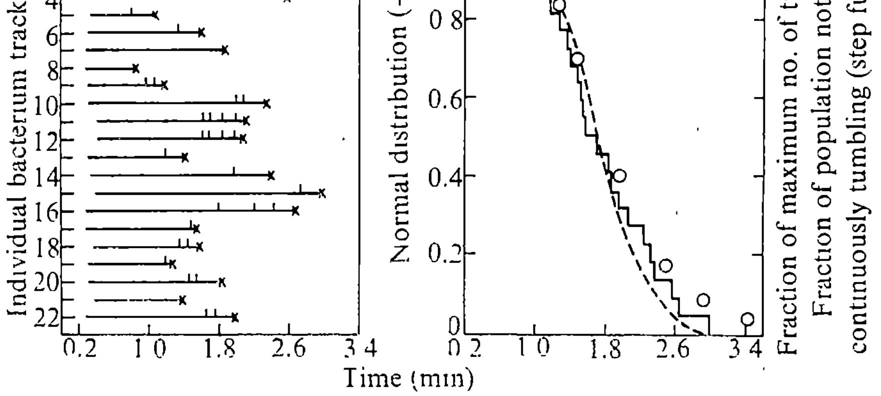

Fig. 1 Tumbly mutant recovery individuality. All bacteria were grown in homogeneous conditions as described previously[13]. In *a* the length of each line represents the time interval over which an individual bacterium was tracked. For each of the 22 lines the temporal gradient stimulus 0→0.5 mM L-serine was delivered to ST171 at time 0 (as previously described[13]) and the bacterium nearest the centre was followed until it tumbled continuously for 30 s. Times at which the bacterium briefly tumbles are are represented as ⊥, and the time at which it began to continuously tumble is represented as ×. From the data in (*a*) the fraction of the bacteria not yet continuously tumbling was plotted against time to yield the step function in (*b*). O, Tumble frequency assay[13] results for ST171 subjected to the same stimulus; – – –, a cumulative normal distribution with the same mean and variance as the data obtained from tracking.

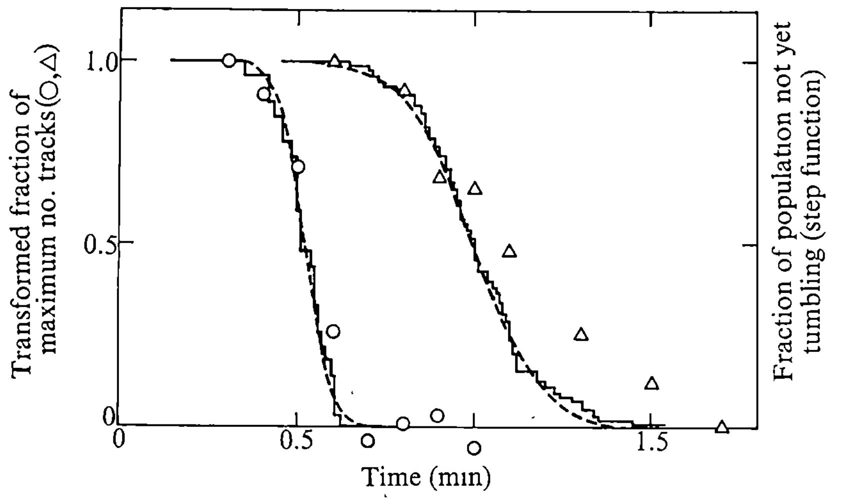

Fig. 2 Wild-type recovery individuality. Points are tumble frequency assay[13] results transformed by equation (1) (see text) for ST1 subjected at time 0 to the temporal gradient stimuli 0→0.01 mM (○) l-aspartate and 0→1.0 mM l-aspartate (△). Step functions are cumulative times to the first tumble after stimulation for these two same stimuli derived from tracking as described in Fig. 1. The dotted lines are cumulative normal distributions with the same means and variances as the two sets of tracking data.

bacterium in the centre of the field. A videotape recording could be played back in slow motion to describe in detail the behaviour over a long period. The results for 22 individuals of a constantly tumbling mutant subjected to a serine stimulus are shown in Fig. 1*a*. There is great variability in the time that individual bacteria take to return to their prestimulus tumbling pattern. Data of the same type (Fig. 2) were obtained for a wild-type strain which also swims smoothly immediately after stimulation and returns to intermittent tumbling (its normal non-gradient state). If data from tracking are plotted on the same graph as a recovery curve for a population subjected to the same stimulus in the tumble frequency assay[13], the curves are superimposable (Fig. 1*b*).

The results of Fig. 1*b* mean that the form of the recovery of a population from a stimulus is caused by the variability of the individuals in the population. In fact, if we define $F(t)$ as the fraction of a population which has recovered at time t after delivery of a stimulus and $S(t)$ as the probability of producing a smooth swimming track, equation (1) describes the behaviour of the bacteria. S_∞ is zero for the constantly tumbling mutant and has a finite value, greater than zero, for wild-type bacteria.

$$1-F(t)=\frac{S(t)-S_\infty}{1-S_\infty} \qquad (1)$$

The bacteria used in these experiments were at most 30 generations away from a single cell parent. An extremely high spontaneous mutation rate would have to be postulated to explain our data in terms of genetic variation, as the following calculation shows. Where m is the probability of occurrence of any mutation affecting chemotaxis per generation, after 30 generations the probability of a bacterium not containing a mutation is $(1-m)^{30}$. Therefore for at least 50% of the bacteria to have acquired one or more mutations affecting chemotaxis,

$$(1-m)^{30}<0.5$$

or

$$m>2.3\times10^{-2}$$

There are only about 10 genes specifically involved in *Salmonella* chemotaxis[14], but even the liberal estimate that a mutation in any one of 100 loci could alter chemotactic behaviour requires that the mutation rate per locus must be greater than 2×10^{-4}, which is at least 10^3 times higher than usual spontaneous mutation rates. Therefore we conclude that (1) there is a large non-genetic individual variability in the response of both tumbling mutants and wild-type bacteria to stimuli and (2) the results of the tumble frequency assay are a direct measurement of this variability.

Individuality and phase of cell cycle

The experiments described above establish that the cell types present do not show identical behaviour, but do not distinguish between the alternatives: (1) that the individuality is created by one or more random events in the history of the bacterium or (2) the cell has no intrinsic individuality but its properties vary according to its position in the cell division cycle. In the latter case the asynchrony of the culture would give the appearance of individuality where it does not in fact exist. To distinguish between these alternatives, the response of the bacteria were compared as a function of cell length. Cell length is known to be correlated with position in the division cycle[15] and bacterial lengths are clearly visible in the measurements from the tumble frequency assay. The lengths of smooth swimming tumbly mutant bacteria following stimuli at a time at which 95% of the bacteria were smooth swimming were compared with the same values when less than 10% of the bacteria were still smooth swimming. The former gives values for the overall population and the latter for the longest responding 10% of the bacteria. The distributions of the bacterial lengths are shown in Table 1. There is no significant shift in the distribution of the lengths as recovery proceeds and therefore the first alternative must be correct.

Repeated stimulation of a bacterium

If the different responses of isogenic bacteria are not related to the phase of the cell cycle, it can then be asked whether they (1) respond differently because of chance events during or

Table 1 Independence of recovery times and position in the cell division cycle

Body length (μm)	Fraction of population of body length indicated with > 95% smooth swimming	Fraction of population of body length indicated with < 10% smooth swimming
< 1.33	0.00	0.00
1.33–2.00	0.05	0.05
2.00–2.67	0.24	0.21
2.67–3.33	0.32	0.33
3.33–4.00	0.26	0.28
4.00–4.67	0.09	0.10
4.67–5.33	0.04	0.03
> 5.33	0.00	0.00

The lengths of ST171 bacterial bodies were measured on projected films from the tumble frequency assay[13]. 186 individual bacterial lengths were measured from photographs at times for which less than 5% of the bacteria had recovered from the serine stimuli to define the distribution designated >95% smooth swimming. 212 individual bacterial lengths were measured after more than 90% had recovered to establish the distribution in the last column.

Table 2 Response times (s) of individual bacteria on repetitive stimulation in growth conditions

Bacterium	*A*	*B*	*C*	*D*	*E*

30	254	164	126	176	134
60	>300	265	191	136	145
75	>300	248	217	144	143
90	>300	253	172	152	148*
Average clockwise (smooth) response (s)	>278	231±18	179±15	155±7	141±3

Bacteria of strain SL3625, a leaky *fla AIII* mutant which produces small numbers of flagella, were tethered with flagella antibody to a coverslip by a modification of the procedure of Silverman and Simon[16]. Bacteria were grown as described[13] except 200 μM *p*-hydroxybenzoic acid (*p*HBA) was added to the growth medium to improve motility (unpublished results of J. Bar-tana, B. Howlett and D.E.K.). The coverslip with attached bacteria was used to cover an open temporal gradient observation cell of the type described by Macnab and Koshland[8]. The observation cell was previously filled with the wash medium to allow a liquid seal to form immediately the coverslip was put in place (time 0 min). The behaviour of bacteria in one microscopic field at ×500 magnification was recorded on videotape as follows. Cells were washed extensively (5 min at 12.7 chamber volumes per min) with the growth medium (without *p*HBA); at the times indicated the output line to the observation cell was switched to a line containing this same medium +10 mM α-methylaspartate and a 15-s pulse of 12.7 chamber volumes of attractant was delivered. The resulting immediate long clockwise rotation interval of an individual bacterium was measured as its "clockwise response". After 5 min, the line was switched back to medium not containing the attractant, and a 1-min pulse of 12.7 chamber volumes per minute delivered. Each bacterium in the field which was rotating for all stimuli was analysed by repetitive playback of the videotape. The doubling time of SL3625 in this medium is 112 min. Mean responses are reported ± 1 s.e.m.

*Bacterium *E* divided 20 s after the delivery of the stimulus at 90 min.

immediately preceding the time of the measurements, that is they are long responders at one time but short responders later, or (2) whether an individual bacterium is committed for an extended period to a certain type of response, that is some bacteria are short responders throughout their lifespan. To test the response of an individual bacterium over its cell division cycle, individual bacteria were tethered to the surface of microscope coverslips by antibodies to individual flagella, as described before[16]. Using this tethering technique, Berg and Tedesco[17] have shown that individual bacteria can be examined over extended periods and that tethered cells differ in their chemotactic behaviour. The tethering method permits attractant to be delivered and washed out at various intervals which are minutes or even hours apart and the response of the same individual bacterium recorded over the entire time span using videotape. Larsen *et al.*[18] established that counterclockwise rotation and clockwise rotation of a tethered cell (observed along the axis from the flagellum to the body) are equivalent to the tumbling and smooth swimming, respectively, of a free swimming cell.

Table 2 shows the results of repetitive stimulation of five tethered bacteria in the same microscopic field with the attractant α-methylaspartate. The attractant was delivered five times and removed completely between stimuli. The delivery of large stimuli of attractant suppressed counterclockwise (tumbling mode) rotation in each bacterium and caused a uniform clockwise (smooth swimming mode) rotation for several minutes with eventual recovery to intermittent clockwise and anticlockwise rotation. All bacteria were observed to increase to nearly double their mass during the measurements, yet the data show that their individual sensitivities to the stimulus were maintained. The same experiment was performed with six bacteria in a non-growth medium and these bacteria also maintained their tendencies to be either long or short responders to α-methylaspartate[19]. Thus, whether growing or not, individuals retain characteristically different sensitivity to stimuli for extended periods and the cells are not continuously randomising with respect to their chemotactic behaviour.

Relationship of unstimulated to stimulus-induced behaviour

If the bacteria differ in their characteristic recovery times, are they also different in some other feature of their sensory system? The unstimulated behaviour of tethered cells consists of alternating clockwise and anticlockwise rotation intervals with each of the two rotation modes terminated by Poissonian (random) processes[17]. The patterns of individual cells showed that the mean clockwise and counterclockwise intervals were not identical for all bacteria. In view of the randomness in lengths of clockwise and counterclockwise intervals for any individual bacterium, the theoretical standard error of the mean was calculated to compare with the empirical s.e.m. obtained from actual measurement of the clockwise and counterclockwise intervals (Table 3). The good agreement between theoretical and empirical values is assurance that the amount of data collected to determine the intervals is sufficient.

On comparison of these spontaneous rotation intervals with the response to stimuli (Table 3) an excellent correlation was observed. The size of the clockwise response to an α-methylaspartate stimulus for an individual bacterium depends nearly linearly on its mean clockwise (smooth swimming mode) interval in non-stimulus conditions as shown in Fig. 3. The size of the anticlockwise interval (tumbly mode) does not seem to influence the stimulus behaviour.

To check this in another way, 82 free swimming cells were examined both for the time to the first tumble after temporal gradient stimulation with aspartate and for the mean time between tumbles for 1 min after the first tumble. Although this measurement is less precise than measurements with tethered cells (because a particular individual can be observed for only one stimulation and for only a short time after the stimulus), we found a correlation coefficient of 0.5 between the average length of a run and the recovery time.

These data provide a correlation between the steady-state tumbling pattern of individual bacteria and their sensitivity and recovery from stimuli. The steady-state pattern of tumbling,

Table 3 Unstimulated behaviour and smooth responses of individual bacteria

Mean clockwise (smooth) response (s):	211±10	152±6	120±8	123±6	247±7

The experiment was performed by a procedure identical to that of Table 2 except: (1) instead of growth medium cells were washed with Vogel Bonner salts + 10^{-5}M EDTA; (2) attractant (10 mM α-methyl aspartate) was prepared in Vogel Bonner salts + 10^{-5}M EDTA; (3) after the initial wash of 5 min of 12.7 chamber volumes per min, a continuous flow rate of 1.6 chamber volumes per min was maintained throughout the experiment; (4) at 5 min intervals the input line was switched between attractant and buffer solutions to give a total of six repetitive stimuli. About 2 min of video recordings of the bacteria in periods immediately preceding delivery of attractant were examined in slow motion (sevenfold) replays. Keyboard inputs to a Data Span 500 paper tape punch with timing circuitry[28] were punched when the bacterium being analysed reversed rotation direction for at least 1/4 of a full turn. The paper tape containing the reversal information and the automatically entered times of keyboard entries was processed by computer. The calculated s.e.m. was determined with the assumptions that (1) the measured mean is the true mean and (2) both clockwise and anticlockwise intervals are distributed exponentially[17]. Clockwise responses are reported as the mean ± 1 s.e.m.

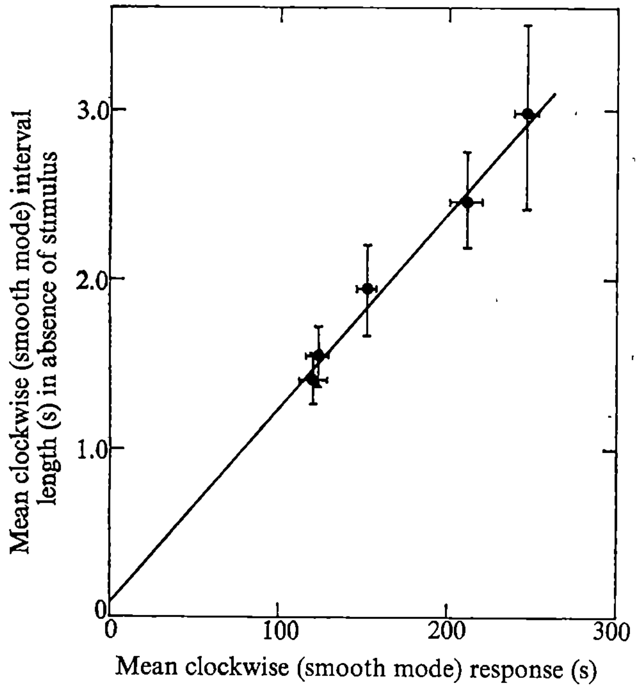

Fig. 3 Unstimulated clockwise (smooth mode) rotation related to stimulus induced clockwise (smooth mode) rotation. The prestimulus clockwise (CW) mean interval length and the mean CW response were taken from Table 3. Error bars represent ± one standard error of the mean. The line is a least squares fit to the data.

therefore, is also a feature of the bacterial individuality and is retained throughout the generation time of the bacterium.

Implications of individuality

Study of individual bacteria in various ways has established that a bacterial culture which is genetically homogeneous and grown in homogeneous nutrient conditions nevertheless produces characteristically different individuals. These individuals retain their properties throughout their life cycle, showing that the individuality is not a momentary effect of random chance bombardments by a fluctuating environment. Moreover, the individuality is not a function of position in the cell division cycle.

How could such individuality be produced? A bacterium is a small cell. In the process of division and replication of the cellular components there may well be certain molecules which are present in such low amounts that they are subject to Poissonian variation. In general, the standard deviation of a Poisson distribution is the square root of n, where n is the mean number of events. If there are 10^4 molecules of a particular type, the s.d. would be 100 molecules, giving a 1% deviation. If, on the other hand, only 100 molecules are produced, a 10% s.d. would arise. In many cellular processes less than 100 molecules participate (for example, there are only 10–20 molecules of *lac* repressor per cell[20] and enzyme cofactor concentrations are extremely low[21]). In other processes there may be more total molecules but their ultimate number may have been determined by a small number of generating molecules (for example, there are only 6–14 *trp* mRNA molecules per bacterial cell, and each mRNA molecule is translated an average of 20 times[22]). Probabilistic fluctuations in small numbers of molecules have been discussed as possible causes of bacteriophage burst size variation by Delbrück[1] and bacterial β-galactosidase concentration variation by several investigators[5–7].

In the case of chemotaxis, it has been postulated that the tumble regulator is produced and destroyed according to scheme 2, implying that some enzymes or structural molecules control the velocities of the steps represented by v_f and v_d. If a small number of mRNA molecules code for the enzyme which, for example, controls the step v_d, Poissonian fluctuation in the mRNA concentration would generate quite different total numbers of molecules of this enzyme in different individuals. If this affects not only the steady-state tumbling pattern, but also the rate of recovery from a stimulus[12], both properties would be different from individual to individual over the lifespan of the cells. Conversely, if a particular cellular component were produced in a much larger number of copies

$$W \xrightarrow{v_f} X \xrightarrow{v_d} Y \qquad (2)$$

where X = tumble regulator over a much longer interval, Poissonian variation would be relatively small and one would not expect much variation in this property from cell to cell. The number of copies of an individual cellular component, at some crucial period in the life of the cell, would therefore determine whether or not that component would contribute to the non-genetic variability of the population.

The existence of such variability leads one to ask whether it has some advantage to the organism or whether it is a disadvantage which must be surmounted in the development of the species. Although there may be no significant selective pressure against non-genetic variability, one can certainly make an argument that non-genetic variability aids in the survival of a population subjected to widely varying conditions during its lifetime. If the bacterium has a single or monolithic reaction to a particular chemical gradient, it might migrate as a colony into a toxic situation or fail as a colony to be sufficiently sensitive to an essential new nutrient. If there were individual bacterial variation in a genetically homogeneous population, a few fractions of the bacteria might either be supersensitive or insensitive. These bacteria would normally not survive as effectively as the bulk of the more average optimised population. They would then have lower survival probabilities in most circumstances, an unimportant loss if the main body of the colony survived. If, on the other hand, the toxic and lethal situations described above arose, a small fraction, on the wings of the probability distribution, might constitute the only bacteria to survive and would then reproduce the species for future generations. Genetic variation would not accomplish the same purpose, since selection in a rare toxic situation would produce a mutant poorly adapted to the more common conditions of the environment. The population, however, was selected over evolutionary time for survival in all of the widely varying conditions of the environment. Thus non-genetic variability would be a preferred mechanism for accommodation to random fluctuations in the environment and genetic variability the preferred mechanism for accommodation to long lasting environmental changes. Induction and repression of enzyme synthesis reflect intermediate accommodations to fluctuations of a lengthy but impermanent type.

It would be intriguing if certain properties were found to be insulated against chance by the large number of copies in the cell at all crucial stages and other properties deliberately to originate in a small number of starting molecules, to create non-genetic diversity. An interesting example may arise in the differentiation of individual *Dictyostelium* amoebae into multicellular fruiting bodies. This development depends on the existence of a small number of early cyclic AMP-emitting founder cells which are believed to be genetically identical to the other cells in the population which are not early emitters[23]. The difference between a founder cell and other cells in the culture seems to be the result of molecular accidents in the cell's individual history and this could be explained by a Poissonian distribution of properties deriving from small numbers of a cellular component as discussed here. Possibly over evolutionary time, larger cells and larger individuals were selected for decreased non-genetic variability; for example, identical human twins are morphologically much more similar than twin bacteria, and in higher species the genetic variability carries the main load of ensuring the survival of the species. Poissonian variation at early stages in differentiation may be an advantage for the species even though ultimately chance is eliminated because of large numbers of cells developed in the individual.

Poissonian variation may be the reason for the rapid asynchronisation of synchronised prokaryotic[24] and eukaryotic[25] cell cultures. If one or more steps leading to growth and cell division are controlled by a small number of molecules, then a Poissonian distribution should exist and cell cycles would quickly get out of phase. In fact there is evidence for individuality in bacterial division times[2] of the type we observe in chemotactic behaviour. Also in eukaryotic cells synchrony is not maintained even in populations selected for genetic homogeneity[25]. To explain this, Smith and Martin[26] have proposed that growth of cultured cells is dependent on a random event occurring with a probability which is constant for all individual cells in postulated "indeterminate" phase in G_1 (the "A-state"). As evidence for this hypothesis they present generation time distributions which are exponential over most of their range. A chance external event could explain the probabilistic transition out of the A-state, if the Smith and Martin model is correct. Alternatively, as suggested here, the number of generating molecules for an enzyme required for passage through G_1 could be so small that Poissonian fluctuations result in a broad distribution of concentrations of this enzyme among the cells. Such a non-genetic individuality would be consistent with rapid asynchronisation, correlation of sibling generation times[2,27,28] (if the enzyme half life is longer than one generation time), and the exponential character of the distributions of Smith and Martin. If Poissonian variation determines rates of passage through G_1, or any stage in the cell cycle, cell synchrony over extended periods will be difficult to attain. If our explanation is correct, a possible approach to obtaining a synchronous cell line would be genetic manipulation, for example by episomes, to increase significantly the concentrations of the rate limiting enzymes.

Biological systems therefore can produce individual non-genetic diversity through a few generating molecules which determine a property at some key stages of development or can ensure against such chance diversity by increasing the number of generating molecules to a size which eliminates significant internal variation.

letters to nature

Observations of X-ray and γ bursts

We report on some bursts of hard X rays seen in March 1976 by the Ariel-V scintillation telescope (ST). The timescale of a few seconds, the correlation with low energy events seen by a proportional counter on the same satellite (ref. 1 and S. J. Bell-Burnell, private communication) and a photon energy > 50 keV, are factors which suggest a connection in origin between the gamma bursts of Klebesadel *et al.*[2] and the X-ray events noticed by Grindlay *et al.*[3]. A delayed arrival at high energies seems to be an important feature of our observations.

The Ariel-V scintillation telescope (area 8 cm^2, 11° effective FWHM field of view) observed in a direction centred on RA 17 h 27 min, dec. $-33.5°$ (1950) during March 8–11 with a broad energy channel extending from 50 to 190 keV. Counts from 0.5-s intervals were stored sequentially in sets (bins) of 16 locations which were scanned four times before proceeding to the next set. Each bin thus contained the superposition of 4 time profiles, 8 s long. An identical data mode was used for the 2–7-keV collimated proportional counter (CPC) of ref. 1. Burst sources MXB 1730–335, MXB1728−34, MXB1743−293 and MXB1742−297 were in the field of view of the ST but only the first two could be seen by the CPC. MXB1730−335 is the repetitive burster with small events as close as 7 s apart, while the others give at the most ~5 bursts d^{-1} (ref. 4).

Four very important proportional counter bursts were selected corresponding to those times when the ST data was expected to be free of all spurious events (events A, C, E, F Table 1), two of which (E, F) are plotted in Fig. 1, together with data from the ST. Absolute time is known to ±30 s and this is shown at the beginning of each 32-s bin. In two cases the CPC data showed a pulse at least 8 s long; the double peaks probably arise from two successive scans. In at least 3 cases, the ST increase appeared delayed with respect to the CPC data. Because of the superposition of scans the delay cannot be determined uniquely. Table 1 lists the limits within which the delays lie, the significance in s. d. (σ) of the ST events, the pulse durations and the total energy in erg cm^{-2} assuming all high energy photons were at 50 keV.

In the case of events A and F, the larger of the two figures for minimum delay is more likely; the smaller figure results from taking smaller, secondary peaks in the CPC data as the associated events. Note the tendency for the high energy channel to carry at least as much energy as the low energy channel. Suggestions have been made for 1.39- and 1.36-h periodicities in the intervals between some bursts from this region (ref. 1 and Carpenter *et al.*, to be published). Only event A fits such a scheme (with a 1.36-h period).

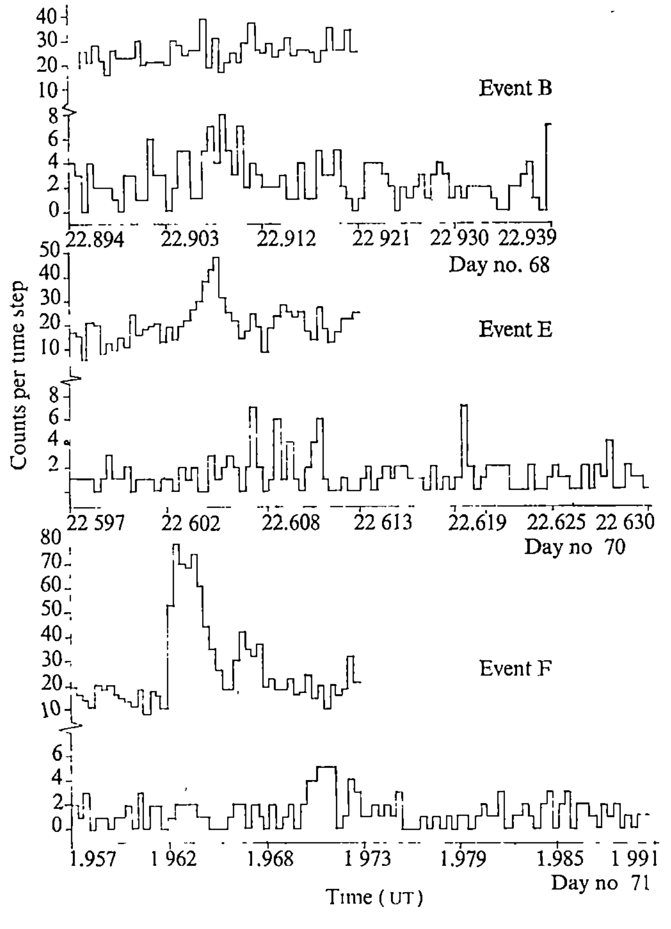
To relate our work to searches for γ bursts, a scan of all the suitable March 8–11 data was made to pick out statistically

Table 1 Data from scintillation telescope and collimated proportional counter on Ariel V

Event	Time at start of bin (day in 1976 March)	2–7-keV channel Width (s)	2–7-keV channel erg cm^{-2}	50–190-keV channel Width (s)	50–190-keV channel erg cm^{-2}	Significance (σ)	Delay (s) Min	Delay (s) Max
A	8.7765	8–32	2×10^{-7}	2.5	2.4×10^{-7}	3.7	11.5 or 1.5	59.5
B	8.9544	4	2.3×10^{-8}	3.5	4.1×10^{-7}	5.4	2.5	26.5
C	9.1656	8–32	1.8×10^{-7}	3.0	2.2×10^{-7}	3.3	0	28.0
D	9.4869	3	2.5×10^{-8}	6.5	4.3×10^{-7}	6	3.5	27.5
E	10.9419	4.5	5.2×10^{-8}	2.5	2.7×10^{-7}	5	3–4	34.3
F	11.0819	3.2	1.4×10^{-7}	1.6	2.9×10^{-7}	6.5	7.2 or 3.8	37.2

significant increases in 32-s intervals. Five such events were identified, corresponding to a rate of one every two hours with a significance such that the total chance probability of getting such increases in the data set was 10^{-6}. Two were events previously selected (A, F) and a further two, B and D, are added to Table 1 (B is also shown in Fig. 1) with correlated CPC data where any increase can only be in the 3–4σ region. To compare with previous γ-burst measurements we assume the typical burst spectrum of ref. 5, integrate all the energy > 25 keV and correct the rate for the telescope solid angle by assuming (*a*) the sources are isotropic and (*b*) the sources are distributed according to the density of mean galactic matter. These two rates are shown in Fig. 2, along with Vela, Imp-7 and the balloon data of Bewick *et al.*[6]. The balloon search only included the galactic disk between longitudes 70°–230° within its field of view. It is clear that at some times at least, 'X-ray' bursts, which could equally well be classified as small 'γ bursts' in the 10^{-7}–10^{-6} erg cm^{-2} energy range, are far more likely to be seen from the certain regions in the galactic disk than from elsewhere, a conclusion already suggested by Bewick *et al.*[6] We have insufficient data at present, however, to compare the results with the prediction of a globular cluster origin (compare with ref. 3). Although we cannot measure the energy spectrum with Ariel V, one notes that Grindlay *et al.*[3] found an exponential fit to their data with kT hardening from 5–20 keV. Thus it is possible to regard γ bursts as being particularly 'hot' X-ray bursts. Since, however, Lewin *et al.* saw no apparent hardening with time of bursts from MXB1730-335, it is clear that there is more than one source mechanism, or variant of the mechanism, at work. Also our events may not arise from this repetitive burster.

Fig. 1 Time profiles of three events showing scintillation telescope (ST) (top) data (50–190 keV) and collimated proportional counter (CPC) (bottom) data (2–7 keV) plotted on same timescale.



The importance of the spectral hardening with time has already been discussed by Grindlay *et al.*[3] who saw kT increase to 20 keV, but we have shown that at late times and for some events, the energy can reside almost entirely in > 7-keV photons. Their suggested mechanism, involving Inverse Compton acceleration of an initial low energy pulse, requires an optical depth > 1 and is unlikely to fit the acceleration (by a factor > 10) required by our observations, which consequently greatly increases the optical depth necessary. Let us instead think in terms of variants of a mechanism in which gravitational energy is transformed by a shock to an optically thick plasma emitting by a thermal process. Suppose at first that the shock is travelling between a companion star and a compact object, mass M, by near free fall in the gravitational field in a comparatively rarified medium, from an initial position $R_{9,0}$ (units of 10^9 cm). Individual particles behind the strong shock can reach a thermal energy $E \leqslant (1/4)^2\frac{1}{2}m_pU^2$ if the relative downstream velocity is randomised, for shock velocity U in the rest frame, position R_9, away from the compact object

Then

$$E = \frac{8.7\times10^3}{R_9}\left[\frac{M}{M_\odot}\right]\text{(eV)} \qquad (1)$$

and

$$t = 1.3\,(R_{9,0}{}^{3/2} - R_9{}^{3/2})\left[\frac{M}{M_\odot}\right]^{-\frac{1}{2}}\text{(s)} \qquad (2)$$

is the time travel between $R_{9,0}$ and R_9. If the object is a neutron star with magnetopause $\sim$ 0.2 R_9, it is possible by free fall to get temperatures $\sim$ 50 keV outside the magnetosphere. Equation (2) yields, however, a minimum delay between attaining 7 keV and 50 keV of $1.7(M/M_\odot)$ s, while the delay between 2 keV and 7 keV is $9.9(M/M_\odot)$ s. Thus it is difficult to explain observations where the low and high energy pulses are of comparable width unless a dramatic slowing of the shock by accreting material can be invoked. Increased energy in the higher channel does follow naturally from this mechanism, however.

Another possibility is to suppose that penetration of the magnetosphere by a large mass of transferring material occurs by some convection process (see ref. 4). Then this is followed by gravitational fall on to the neutron star atmosphere where the shock occurs to thermalise the energy. One must further suppose that deeper penetration at later times connects the material to different atmospheric conditions where the energy gets shared among fewer particles and hence a higher temperature results. Any short term periodicity (tens of seconds) can perhaps be related to the magnetosphere spin while long term periodicities

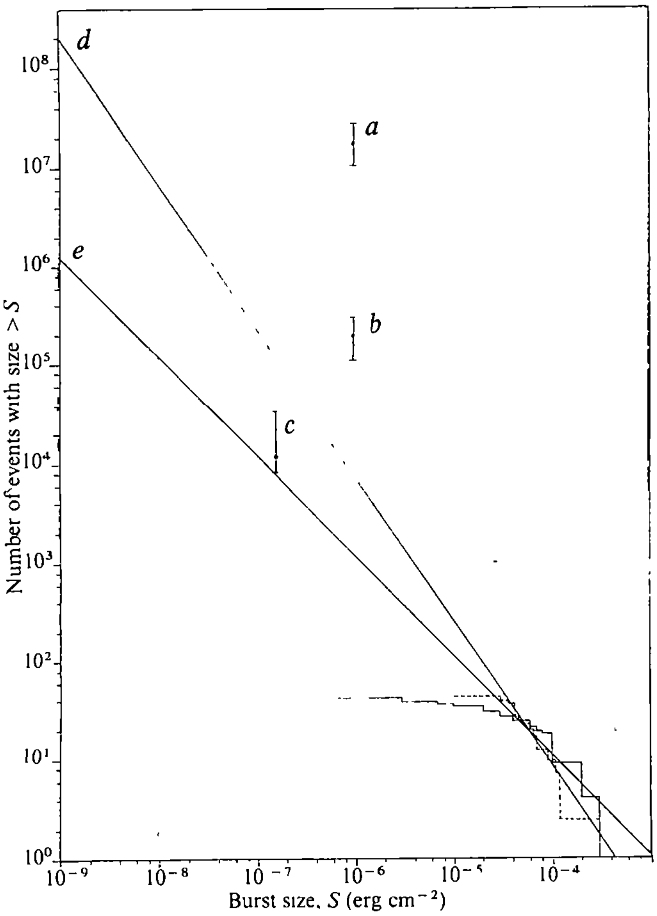


Fig. 2 Burst occurrence rates derived from our experimental results, for two source distributions; *a*, isotropic and *b*, galactic. Also illustrated for reference are the Vela (——) and Imp-7 (----) size spectra. *c*, From Imperial College balloon data. The two straight lines are extrapolations of the Vela/Imp-7 data assuming either *d*, $I^{-3/2}$ law or *e*, I^{-1} law. All rates have been normalised to Vela observation period July 3, 1969–December 23, 1973.

(~ hours) could depend on the orbital period of the companion ~ 4×10^{10} cm away.

Positions and evidence for a steady component for X-ray burst sources

DURING observations of the galactic centre region with the Ariel V RMC experiment we have observed X-ray flux from two sources within the error boxes for the burst sources MXB 1730−335 and MXB 1728−34. The observations were made in RMC mode and represent integrations over periods of about one satellite orbit (100 min). This is distinct from the time mode used for the observations described in a companian paper (to be published) in which the time resolution is 32 s but with which no spatial resolution is possible.

The two sources were each observed at various times during the period 1976, 28 February to 8 March. The positions of these sources are

(1) $\alpha_{1950} = 17$ h 30 min 14 s $\delta_{1950} = -33° 21'$
(2) $\alpha_{1950} = 17$ h 28 min 29 s $\delta_{1950} = -33° 48'$

each with an error circle radius of 2′. Position (1) lies wholly within the original error box[1] for the burst source MXB 1730−335 and overlaps the improved error circle given by Hearn[2] (Fig. 1). MXB 1730−335 is known to produce a rapid succession of bursts with an integrated intensity[3] of 1.7×10^{-9} erg cm^{-2} s^{-1} (1.5–20 keV). Lewin *et al.* place an upper limit of twice this level on any non-burst activity from the source[3]. The intensity of the source which we observe corresponds to an energy of ~3×10^{-9} erg cm^{-2} s^{-1} over the range 1.5–20 keV, although this represents an extrapolation from the 2.9–7.6 keV range in which our observations were made. Thus the observed intensity is consistent with the reported burst activity, probably together with a steady non-burst component of about one half of the level of the upper limit found by Lewin *et al.* Thus the position quoted above almost certainly represents an improved determination of the position of MXB1730−335. We note that the star cluster observed by Liller[4] lies close to the centre of our error circle.

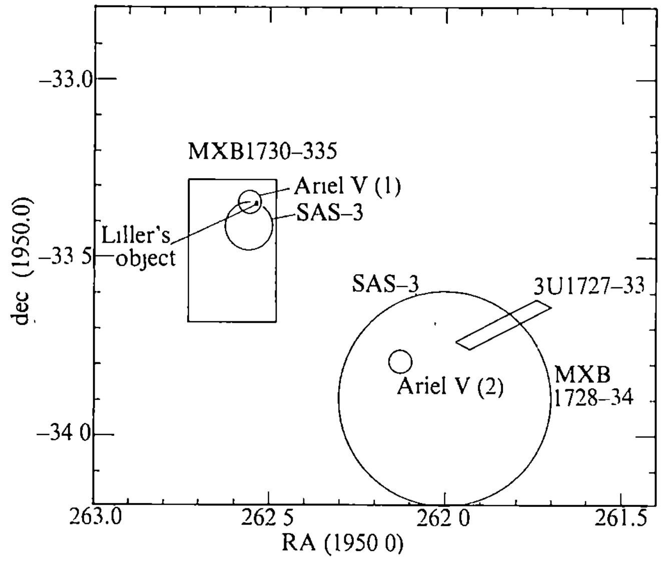

Fig. 1 90 per cent confidence error circles for the two sources reported here shown relative to the SAS-3 burst sources. The error circles should be shown as ellipses extended by 15% in the E–W direction.

The position of source (2) lies within the 18′ radius error circle of MXB1728−34 (unpublished). Only four bursts have been reported from this source, with a probable time between bursts of ~5 h. Each burst lasted only for a few seconds and the mean integrated flux associated with the bursts is at least two orders of magnitude lower than in MXB1730−335. The intensity of source (2) integrated over one orbit was typically similar to that of source (1) although it was rather more variable. Thus there is no question of the observed flux being the integral of bursts of the type which have been reported for this source. If the source (2) represents flux from MXB1728−34 then it must be due to a non-burst background emission.

We note that the position of source (2) lies close to the error box of the Uhuru source 3U1727−33. There is evidence for a source at position (2) in data collected in February–March, 1975, but we have found no evidence for flux from within the error box of 3U1727−33. Thus it is likely that 3U1727−33 lies outside its error box at position (2).

If 3U1727−33 and MXB1728−34 and our source (2) prove to be the same object then it will provide a useful clue to the nature of burst sources as 3U1727−33 has been shown to exhibit a periodicity indicating a 'slow rotator' type of source[5].

Observations of X-ray bursts from the vicinity of 3U1727−33

Ariel V experiment C observed the region of sky near 3U1727−33 between March 8 and 10, 1976 and again between March 24 and 25. The experiment[1] consists of a multiwire collimated proportional counter with a field of view of 3.5° FWHM. The experiment is, however, offset from the spin axis of the satellite by 1.75°, so the effective field of view per spin cycle (4–5 s) is a Gaussian-like curve of 5.0° FWHM centred on the spin axis. The field of view during the present observations included the positions of 3U1727−33 (ref. 2), MX1716−30 (ref. 3) and two recently discovered burst sources, MXB1730−335 and MXB1728−34 (ref. 4).

Table 1 Data accumulated by experiment C on the Ariel V satellite

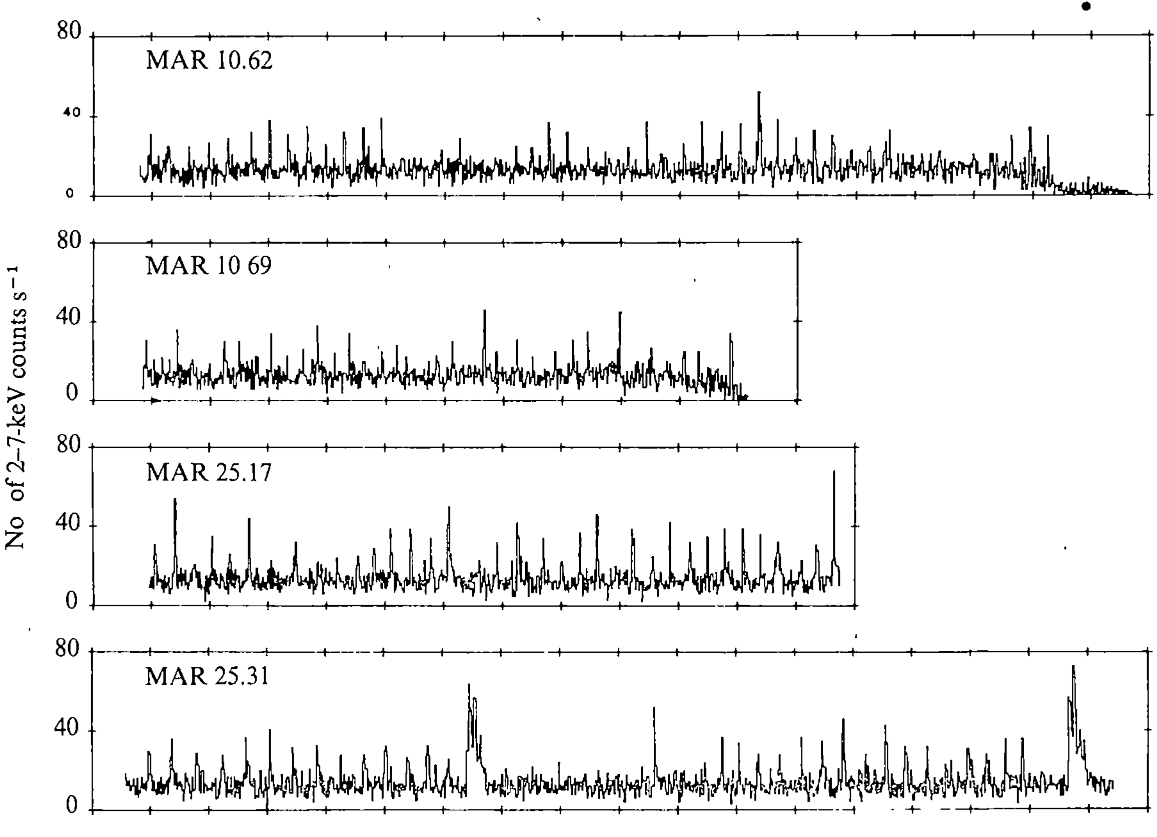
Time of burst (March 1976) (d)	Intensity ($\times 10^{-8}$ erg cm^{-2})	Time resolution (s)	Notes
(1) 8.7764	20.0	32	
(2) 8.8910	5.2	32	Probably two pulses but maybe one.
8.8914	14.0	32	
(3) 9.1655	18.0	32	
(4) 10.3487	13.6	20	One long pulse or two close together.
(5) 10.6251	4.0	0.5	
(6) 10.9420	5.2	20	
(7) 11.0820	14.4	20	
(8) 24.7959	8.0	20	
(9) 24.8462	6.4	20	
(10) 24.8513	4.4	20	
(11) 24.8539	18.0	20	
(12) 24.9885	12.4	20	
(13) 25.2432	6.4	0.5	
(14) 25.2494	11.2	0.5	
(15) 25.3097	16.4	0.5	
(16) 25.3170	18.8	0.5	
(17) 25.3774	8.8	0.5	

Bursts listed above with 0.5-s time resolution are included because they are sufficiently strong to have exceeded the threshold set for detection with a 32 or 20 s accumulation interval. Numbers 15 and 16 can be seen in the lowest panel of Fig 1.

Observations were made with a time resolution of 32 s, 20 s and 0.5 s in the 2–7 keV energy band. The mean counting rate from all the sources in the field of view, plus background, was ~ 12 counts s^{-1} (the detector records ~ 100 counts s^{-1} from the Crab Nebula in the same energy band).

The X-ray bursts seen by the ANS (ref. 5) and SAS-3 (refs. 4, 6) satellites generally last for of the order of a few

Fig. 1 Four orbits of experiment C data accumulated in 1-s intervals. The time of the beginning of each data record is given in days from the beginning of March 1976. The abscissae are graduated in 1-min intervals. The flux is plotted as experiment C 2–7 keV counts s^{-1} with no aspect correction. On the same scale the Crab Nebula would register 100 counts s^{-1} when aligned with the satellite spin axis. The field of view is occulted by the Earth towards the end of the records marked MAR 10.62 and MAR 10.69.



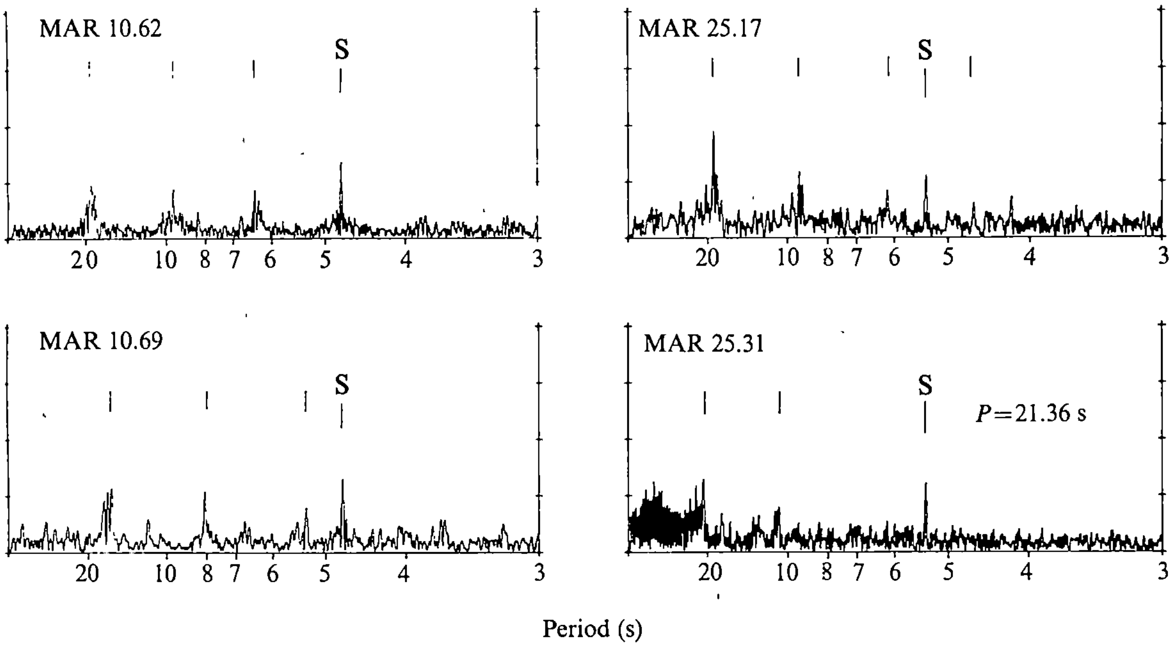


Fig. 2 Power spectra of the data shown in Fig. 1. Peaks near 20 s, plus their harmonics, are marked with vertical bars. The peak caused by the spin modulation is marked by a vertical bar with the symbol 'S' above

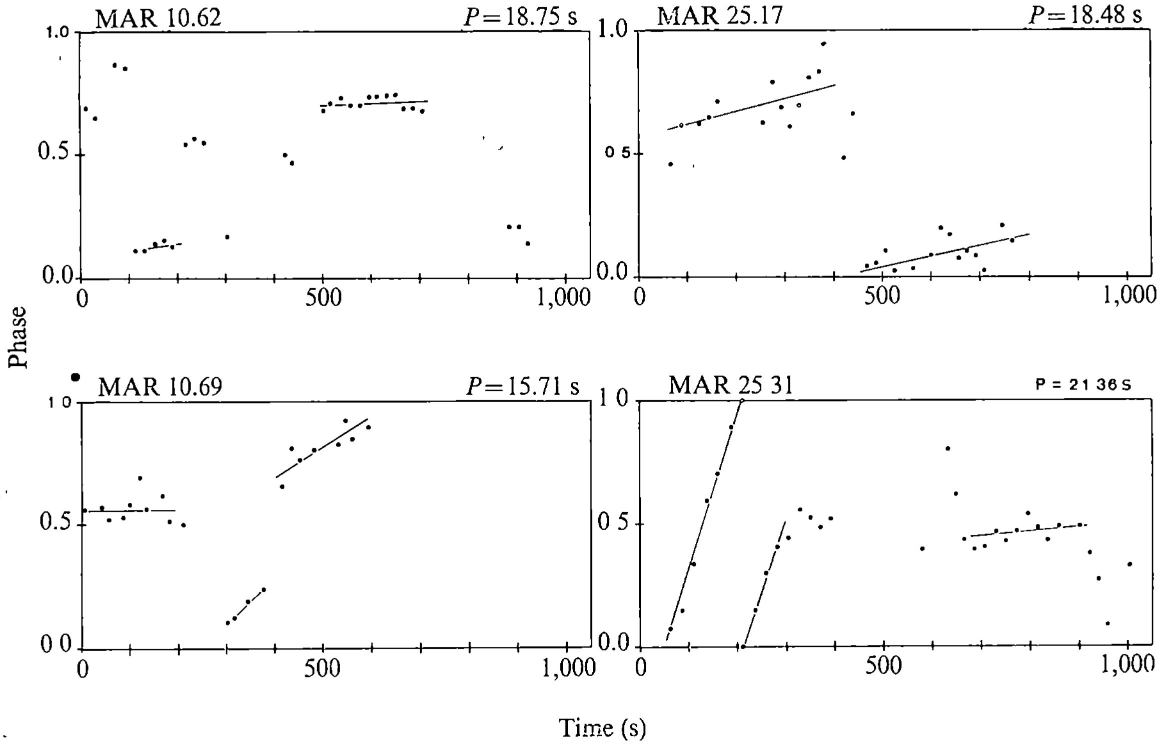

Fig. 3 The phase of bursts with respect to the folding period, P, is plotted against their arrival times (see text) Well defined burst trains are marked with straight lines.

seconds only, shorter than the 20 and 32 s accumulation intervals. The Ariel V data taken at these time resolutions can therefore only distinguish relatively intense or long lasting bursts. A threshold of 8 counts s^{-1} above the mean count rate was set as a criterion for identifying accumulation intervals containing such bursts. During a total of 17 h actual observing time, 17 of these events were recorded The strength of each burst and the start time of the accumulation interval in which it was seen are listed in Table 1. Carpenter *et al.*[7] have found a series of bursts originating from within the 17 ° FWHM field of view of experiment A which recur every 1.39 h. Using their epoch and period (G. K. Skinner, personal communication) we have computed the expected arrival times of bursts in the sequence for the experiment C observing intervals. None of the events listed in Table 1 coincides with the times predicted by the sequence, whereas we should have observed 11 of these. The nearest, event 12 in Table 1, occurred 5 min later than the time predicted by the experiment A data, well outside the jitter observed by Carpenter *et al.*[7]. We note, however, that the first five events recorded by experiment C, which span an interval of 1.9 d, can be fitted by a period of 1.35 h with a jitter of ±5%. One other event in the sequence should have been seen during the above interval and was not. Experiment A cannot collect data when experiment C is in a high time resolution mode, because of limits on spacecraft data storage, so two interpretations of the observations are possible: either the periodic bursting source seen by Carpenter *et al.*[7] changed its mode of behaviour during the experiment C observing periods or, more likely, the source lies outside the field of view of experiment C.

Examples of the data taken by experiment C at a time resolution of 0.5 s are shown in Fig. 1, accumulated in 1-s bins. The data show many significant bursts (> 3 s.d.) superimposed on the d.c. level of ~ 12 counts s^{-1} Most of the bursts last only a few seconds, but some persist for up to ~ 20 s. The longer lasting bursts show clear evidence for spin modulation (period 4–5 s) indicating that they originate from a source which is offset from the spin axis of the satellite (RA 17 h 28 min, dec. −33.5°). The depth (~ 25% peak to mean) and phase of the modulation are consistent with the position of MXB1730−335 (refs 3,7). On the other hand, the d.c. count rate shows no evidence of spin modulation and must originate primarily from a source close to the spin axis, probably 3U1727−33. The level of burst activity clearly diminishes following the longest bursts (for example the data beginning on March 25.31). This behaviour is reminiscent of the correlation between the size of bursts and their separation reported by Lewin[4]. It also suggests that both large and small bursts originate from the same source.

The spacing between many of the bursts in Fig. 1 is similar. This is confirmed by the power spectrum of each of the four data sets. These are shown in Fig. 2. In each case there is a well defined peak at a frequency corresponding to a period ~ 15–20 s, with further peaks at the harmonics of this frequency. Note, however, that the primary peaks come at a different frequency in each of the four data sets. A peak is also seen at the spin period of the satellite and is marked by the symbol 'S'. This corresponds to the spin modulation noted earlier.

To further investigate this behaviour we have folded the arrival times of the bursts on a period close to that given by the power spectra in Fig. 2. We then plot the phase of the burst against its arrival time as shown in Fig. 3. On these diagrams, bursts which recur at the folding period lie on a horizontal line. Bursts which recur at a period slightly different from the folding period will lie on diagonal lines. It is evident that the bursts observed come in groups within which the separation of pulses remains approximately constant, the typical r.m.s. jitter being ~ 5%. Transitions from one group to another, at a different phase and/or period, occur on a time scale short compared with the length of pulse trains.

In summary, therefore, we have observed, probably from MXB1730−335, sequences of periodic bursts which maintain their phase and period for several cycles and then may change abruptly in either phase or period. Longer lasting bursts (of the order of the separation of small bursts) are followed by relatively quiescent intervals. The abrupt changes in phase and period suggest that the burst trains are not produced by a rigid dynamical system such as a rotating star or orbiting stars; rather that they represent a characteristic oscillation period in the X-ray production mechanism or orbital motion in some non-rigid system such as an accretion disk. With regard to the latter possibility, and in view of the suggested identification of MXB1730−335 with a globular cluster[8,9] we note that a time scale of ~ 20 s is the inner orbital period of a ~ $10^5 M_\odot$ black hole ($t \simeq 0.1 M_{\mathrm{BH}}/10^3 M_\odot$(s)).

The radio tail galaxies in Abell 1314

THE study of radio tail objects is important to our understanding of extragalactic radio sources because the tail morphology allows inference of the temporal evolution of ejected radio components. Furthermore, with increased understanding of these objects, it may be possible to use radio tails as probes of extragalactic space in clusters of galaxies. All published models of radio tails require some form of streamlining resulting from the relative motion of the parent galaxy and the medium producing the tail shape. Therefore, to constrain the relevant dynamical quantities, we have obtained radial velocity measurements for 18 galaxies in the vicinity of A1314, including the two radio tail objects, IC708 and IC711.

The data were obtained with the Cassegrain spectrograph and RCA 33063 image tube camera mounted on the Steward Observatory 90″ telescope. The dispersion used was ~240 Å mm^{-1}, which allowed redshift measurements using the H and K lines of calcium, as well as, in some cases, the 3,727 Å and 5,007 Å lines in emission. The results of these measurements, using the one-dimensional Grant Measuring Engine at the Kitt Peak National Observatory, are listed in Table 1.

Assuming all galaxies observed are cluster members except number 3 and number 19, we derive a mean cluster velocity of 10,160 km s^{-1} and, assuming $H_0 = 50\ \mathrm{km\ s^{-1}\ Mpc^{-1}}$, a distance of 200 Mpc.

The radial velocity dispersion of the cluster, σ, is 708 km s^{-1} and the total dispersion, σ_{T}, is 1,226 km s^{-1}.

Both radio tail galaxies, IC708 and IC711, have radial velocities fairly near the cluster mean

$$(\langle v\rangle - v_{\mathrm{r}})_{\mathrm{IC708}} \simeq 1/3\ \sigma$$

$$(\langle v\rangle - v_{\mathrm{r}})_{\mathrm{IC711}} \simeq 1/2\ \sigma$$

and, considering their proximity to the cluster centre, we therefore conclude that both galaxies are cluster members.

Confirmation of the cluster membership of IC711 strongly implies that *in situ* acceleration must be important in its radio components, as suggested by Vallee and Wilson[1]. A model predicting such acceleration was suggested by Pacholczyk and Scott[2]. Using the radial velocity data we may place strict constraints on the amount of acceleration necessary in IC711 and IC708, and, therefore, test the available radio tail models.

Table 1 Spectrographic measurements (see text)

Galaxy	α (1950) (h	min	s)	δ (1950) (°	′	″)	Heliocentric velocity (km s^{-1})
1	11	29	26	+49	17	10	9,363
2	11	29	51	+49	23	08	10,097
3	11	30	46	+49	30	54	318
4 IC708	11	31	16	+49	20	17	9,613
5 IC709	11	31	31	+49	19	09	9,549
6 IC711	11	32	03	+49	13	57	9,724
7 IC712	11	32	06	+49	21	14	10,054
8	11	33	01	+50	00	52	9,727
9	11	33	22	+49	43	38	9,467
10	11	33	49	+49	24	29	11,223
11	11	33	54	+49	20	23	9,641
12	11	32	59	+49	04	49	11,179
13	11	33	04	+49	25	39	9,870
14	11	32	47	+49	23	00	11,307
15	11	33	01	+49	26	34	10,454
16	11	29	26	+49	16	13	9,863
17	11	30	06	+49	22	34	11,251
18	11	30	34	+49	33	38	3,180

Assuming that the space velocity of IC711 relative to the cluster medium is σ_T, the angle between the velocity vector of this galaxy and our line of sight is 70°. In this case the radio tail is ~ 900 kpc long. Using these values for the galaxy velocity and tail length with Vallee and Wilson's estimate of the magnetic field ($H = 4\times10^{-6}$ gauss) we may estimate the importance of *in situ* acceleration for this radio tail.

From the equations for energy loss due to inverse Compton and synchrotron emission[3] we calculate the e-folding decay time, t, for the energy of particles in the tail. Dividing the tail's length by the estimated velocity of the galaxies with respect to the centre of the cluster gives T, the length of time that particles emit detectable energy[4]. Then the ratio $N = T/t$ is a measure of the effect of *in situ* particle acceleration in the radio tail. For IC711 we find $N \simeq 20$, a typical value from the Pacholczyk and Scott[2] theory. For IC708 a similar calculation yields $N \simeq 4$.

From our spectroscopic study of galaxies in Abell 1314 we conclude that both reported radio tail galaxies are cluster members, and that *in situ* acceleration (with a magnitude consistent with Pacholczyk and Scott's[2] model) is an important effect in their radio components.

White dwarfs, the Galaxy and Dirac's cosmology

AN apparent absence, or deficiency, of white dwarfs fainter than $\sim 10^{-4} L_\odot$ has been noticed for a long time[1]. Often attributed to incomplete statistics for the coolest, faintest objects[2,3], this deficiency has nevertheless not been removed even after the most persistent spectroscopic surveys by Greenstein[4,5] (see also Liebert[6]). Moreover, Jones's[7] analysis of reduced proper motions for the very faint proper-motion stars observed by Eggen and by Luyten tends only to confirm the deficiency. If real, the lack of very faint white dwarfs may have its origin in a rapid drop of the internal heat content of the white dwarf as a result of ion crystallisation and of envelope convection when the star becomes sufficiently cool (see Greenstein[4] and Van Horn[8] and references therein). But perhaps it will eventually prove to be difficult, as Lamb and Van Horn[9] have already found, to increase the cooling rate by a sufficiently large amount to account for all the deficiency. Another explanation is proposed here on the basis of Dirac's[10–12] cosmological hypothesis that the gravitational constant, G, varies with the elapsed time since the beginning of the expansion of the Universe as t^{-1} and the number of particles in the Universe increases as t^2 (if the measurements are made in atomic units). For a white dwarf, the Chandrasekhar mass limit is a collection of fundamental constants proportional to $G^{-3/2}$, and therefore increases with time as $t^{3/2}$. In the 'additive' version of Dirac's theory, the actual mass, M, of a relatively small object like a star remains essentially unchanged by the creation of new matter in the Universe, and so a white dwarf becomes 'more stable' as time goes on. But, in the 'multiplicative' version of his theory, M increases as t^2 and may eventually exceed the Chandrasekhar limit. If so, gravitational collapse of the white dwarf into an invisible black hole or neutron star will quickly ensue. Since some possible empirical support has already been adduced for the multiplicative theory, although not for the additive theory[13–17], it is interesting to determine whether the multiplicative theory may also have something to do with the apparent deficiency of faint white dwarfs and whether there are any possible consequences for galactic evolution.

First it is necessary to evaluate what would be the luminosity of a white dwarf (assumed to be in hydrostatic equilibrium) if the formal change of internal energy and gravitational potential energy of the star arising from the creation of new matter is available as free energy partly to raise the heat content of the star and partly to be radiated away at the surface, and is the sole source of visible luminosity. The changes of G and M are assumed to be given by

$$G(t) = G_0[t/t_0]^{-1} \tag{1}$$

and

$$M(t) = M_0[t/t_0]^2 \tag{2}$$

where the subscript 0 refers to the present epoch. Although these expressions give an undesirable zero mass and infinite G at $t = 0$, they are only needed at comparatively large fractions of t_0, at which times they may serve as suitable approximations for the present purpose (Van Flandern's[16] observed value for the residual secular acceleration of the Moon, interpreted as being carried by a decrease of G, is consistent with equation (1) for $t_0 = 12\times10^9$ yr). The mass–radius relationship[18] relevant to most of the appropriate range of white-dwarf masses is approximately

$$\left[\frac{G}{G_0}\right]^2 \frac{R}{R_0} \simeq \left[\frac{M}{M_0}\right]^{-1} \tag{3}$$

The luminosity follows from evaluating the rate of change of total (internal plus potential) energy

$$L = \frac{d}{dt}\left[\beta \frac{GM^2}{R}\right] \tag{4}$$

where β extends from 3/7 to 0, for masses ranging from very low values to values close to the Chandrasekhar limit, respectively; β may, however, be held constant here. The result is, at the present epoch

$$L = 3\beta GM^2/Rt_0 \tag{5}$$

For a typical white dwarf with $M = 0.8\,M_\odot$, $R = 10^{-2} R_\odot$, and $\beta = 0.4$, and for an approximate age for the Universe of $t_0 = 12\times10^9$ yr (refs 16, 19), the expected luminosity is $L = 0.2\,L_\odot$. (An analogous derivation for main-sequence stars shows that the 'extra' luminosity is insignificant, except for the faintest main-sequence stars; in general, it will be negligible for any star whose Helmholtz–Kelvin time, GM^2/RL, is short compared with t_0.)

Since so high a white-dwarf luminosity is in serious conflict with observations[2], it may be concluded either that Dirac's theory is untenable, or that the radiation (and 'heating') is of an unknown type, or that the process of creation of new matter requires a corresponding supply of energy. For lack of a better alternative, I shall simply assume that the 'extra' energy somehow goes into work done creating the new matter and that the ordinary rates of stellar energy generation should be used to determine stellar temperatures and luminosities. Therefore, at least in its macroscopic effect, the process of creation is assumed to be a collective phenomenon involving the whole mass of the star; but this may be an unavoidable requirement of the multiplicative theory anyway, since Dirac[12] has already pointed out that, in the case of the Earth, new atoms may have to form at the surfaces, rather than in the interiors, of rock crystals. In the case of gaseous stars, I shall follow Dirac in assuming that new atoms emerge with the same basic properties, that is, species, state, and general location, as the existing atoms.

To proceed further, simple physical assumptions about the structure and luminosity source of white dwarfs will be adopted here: (1) Chandrasekhar's[18] classic mass limit of $1.44 M_\odot$ for a white dwarf at the present epoch; (2) Mestel's[20] simplified cooling theory of white dwarfs, as presented by Schwarzschild[21]; and (3) an average mass of $0.8 M_\odot$ for young (recently formed) white dwarfs. How this average mass has varied in the past is not easy to determine, but a good assumption is that it has been proportional to $G^{-3/2}$, since most critical stellar masses in astrophysics, such as the approximate upper and lower mass limits of ordinary stars[22,23], have this proportionality.

Schwarzschild's[21] standard relationship between the luminosity, L, of a white dwarf and its isothermal core temperature, T, is

$$L = KGMT^{3.5} \tag{6}$$

where K is a constant depending on the chemical composition of the radiative envelope. The luminosity of the white dwarf is supposed to be supplied solely by thermal cooling of the non-degenerate ions; the basic equation of thermal equilibrium is given by

$$\frac{\mathrm{d}L(r)}{\mathrm{d}M(r)} = -\frac{\mathrm{d}}{\mathrm{d}t}\left[\frac{3}{2}\mathscr{R}T\right] \tag{7}$$

whose correct integrated form is

$$L = -\frac{\mathrm{d}}{\mathrm{d}t}\left[\frac{3}{2}\mathscr{R}T\right]M \tag{8}$$

Solution of equations (1), (2), (6) and (8) for the core temperature can be simplified by assuming that the initial temperature is 'infinitely' hotter than the present temperature Then the time, t_f, at which the white dwarf actually formed is found to be given by

$$t_f/t_0 = \exp(-t_{cl}/t_0) \tag{9}$$

where

$$t_{cl} = \left[\frac{3}{2}\mathscr{R}T\right]/(2.5\,L) \tag{10}$$

and all quantities in parentheses are evaluated at the present epoch. Note that t_{cl} is simply the classical cooling time that would apply if G and M remained constant in time. For the brighter luminosities characteristic of most of the observed white dwarfs, the revised cooling times are not much different from the classical cooling times and therefore do not destroy the approximate agreement with observations already achieved[2].

The most recent period at which a white dwarf with mass typical of its epoch could have formed to reach the Chandrasekhar mass limit at the present epoch follows from $0.8(t_f/t_0)^{3/2} = 1.44(t_f/t_0)^2$ and is $t_f = 0.31 t_0$. Substitution of this result into equation (9) yields $t_{cl} = 1.2 t_0$, which may be directly entered into Schwarzschild's[21] Table 27.1 for the classical cooling times of white dwarfs as a function of their luminosities, if his cooling times are multiplied by a factor 1.3 to correspond to a mass of $1.44\ M_\odot$ and by another factor 0.3 to convert from a predominantly helium core composition to a more probable carbon core composition. With $t_0 = 12 \times 10^9$ yr, a value of $L = 2 \times 10^{-5} L_\odot$ is found for the present luminosity of an 'average' white dwarf that has cooled for $t_0 - t_f = 8 \times 10^9$ yr. Older white dwarfs would long ago have faded into invisibility through gravitational collapse. (Some older white dwarfs of smaller-than-average initial mass would still be visible, of course) Most younger white dwarfs would not yet have collapsed. It is interesting to note that most of the old white dwarfs with high space velocities[1,24] have large photometrically implied masses. Could some of these objects be on the verge of gravitational collapse? Accurate measurements of the surface gravities of the oldest white dwarfs will be necessary to determine whether these stars are, on the average, heavier than the brighter objects. Noticeable differences are expected to occur only for $L < 10^{-3} L_\odot$.

Allowance for a probable initial spectrum of white-dwarf masses, for the uncertainty of the adopted chemical composition, for known corrections to the classical white-dwarf mass limit, for various inadequacies of the white-dwarf cooling theory used here, and for the uncertainty of the adopted age of the Universe leads only to a general order of magnitude of 10^{-5} to $10^{-4} L_\odot$ as the predicted cutoff luminosity for most white dwarfs. This prediction seems to be in as good agreement with the available observations as could be expected.

The earliest generation of stars in the Galaxy probably formed within one galactic rotation period after the onset of collapse of the protogalaxy[25]. At the present time, this period in the outer galactic regions near the Sun is 2×10^8 yr, but, in Dirac's theory, it must be scaled down as t, since the rotational velocity stays at the same fraction of the speed of light while the radius of the Galaxy changes as t. The first white dwarfs could have originated about one main-sequence lifetime (which also scales as t—see below) after that era. Since the collapse of the protogalaxy could have begun as late as $0.25 t_0$ (ref. 19) the foregoing stellar formation time scales are seen to be relatively short in comparison, and the first-generation white dwarfs can therefore be expected to be, at the present time, invisible black holes or neutron stars with typical masses of $> 1.6\ M_\odot$. Consequently, simple counts of observed stars in the solar neighbourhood will, if uncorrected for cosmological effects, lead to errors in the extrapolated numbers and masses of dead stars formed since the collapse of the protogalaxy. (The present discussion will ignore the probably small contribution to the mass of the Galaxy from black holes and neutron stars that have formed as direct end-products of normal stellar evolution.)

At first sight, it may seem that a gross underestimate must have been made in the standard extrapolation for dead stars[21]. That this is not so can be seen upon the following reflection. Consider the average properties of typical bright main-sequence stars that give rise to white dwarfs. Their average main-sequence lifetime, t_{MS}, at any epoch t may be regarded as short compared to t (since it is known to be short at the present epoch and it will be shown that t_{MS}/t remains approximately constant in time). Then their birthrate follows simply as $\mathrm{d}N_{MS}/\mathrm{d}t = N_{MS}/t_{MS}$, where N_{MS} is the number of such stars present in the Galaxy at time t. The next task is to evaluate $t_{MS} = qEM/L$ by noting that q, the mass fraction of hydrogen eventually consumed in the star[26], and E, the energy released per gram of material, are independent of t, while the average mass, M, of these bright main-sequence stars at the time of their formation (like all critical stellar masses) probably varies as $G^{-3/2} \propto t^{3/2}$ and their luminosity, L, scales as $G^4 M^3$ (electron-scattering opacity) or as $G^7 M^5$ (Kramers opacity). In either case $L \propto t^{1/2}$. Certainly the evolutionary change in L/M can be neglected, both because $t_{MS} \ll t$ and because this change will in any case be small ($G \propto t^{-1}$, $M \propto t^2$, and hence $L/M \simeq$ constant). It then follows that $t_{MS} \propto t$. Next, the crude assumption is made that the ratio of the total mass in the form of bright main-sequence stars to that of interstellar gas in the Galaxy remains approximately constant after the collapse of the protogalaxy (anticipating the final result that the permanent loss of gas now tied up in dead stars is small). It then follows that $N_{MS} \propto t^{1/2}$, since the mass of the average bright star when it forms varies with the epoch as $t^{3/2}$ whereas the total mass of interstellar gas in the Galaxy increases as t^2. The birthrate of bright stars becomes $\mathrm{d}N_{MS}/\mathrm{d}t \propto t^{-1/2}$.

The deathrate of these stars may be assumed to be equal to their birthrate, so that the rate of addition of mass in the form of new white dwarfs to the Galaxy is $0.8 M_\odot (t/t_0)^{3/2}$ times

$(\mathrm{d}N_{\mathrm{MS}}/\mathrm{d}t)_0(t/t_0)^{-1/2}$. The rate of growth of the masses of dead stars that have already formed follows from equation (2) as $2M_{\mathrm{dead}}(t)/t$. The sum of these two terms yields the total rate

$$\frac{\mathrm{d}M_{\mathrm{dead}}(t)}{\mathrm{d}t} = \frac{2M_{\mathrm{dead}}(t)}{t} + 0.8M_\odot\left[\frac{\mathrm{d}N_{\mathrm{MS}}}{\mathrm{d}t}\right]_0\frac{t}{t_0} \tag{11}$$

By setting $M_{\mathrm{dead}}(t) = 0$ at $t = t_i$ (corresponding to the end of the collapse of the protogalaxy) and by noting that the quantity

$$M_{\mathrm{dead}}{}^* = 0.8M_\odot(\mathrm{d}N_{\mathrm{MS}}/\mathrm{d}t)_0 t_0 \tag{12}$$

is the result of the standard extrapolation for dead stars, the solution of equation (11) is

$$M_{\mathrm{dead}}(t) = M_{\mathrm{dead}}{}^*[t/t_0]^2\ln(t/t_i) \tag{13}$$

At the present time, $M_{\mathrm{dead}} = M_{\mathrm{dead}}{}^* \ln(t_0/t_i)$. Dead stars that formed at any time earlier than $t_f = 0.31t_0$ will now, however, be invisible objects rather than white dwarfs. If the total mass of dead stars at time t_f is multiplied by $(t_0/t_f)^2$, it follows that the present total mass of collapsed objects alone is $M_{\mathrm{collapsed}} = M_{\mathrm{dead}} \ln(t_f/t_i)$. Further, the present total mass of white dwarfs alone is found to be $M_{\mathrm{WD}} = M_{\mathrm{dead}}{}^* \ln(t_0/t_f)$, which is not significantly different from $M_{\mathrm{dead}}{}^*$!

With reasonable choices for the collapse epoch, say $t_i/t_0 = 0.25-0.01$, the sought-for result is finally obtained: $M_{\mathrm{dead}}/M_{\mathrm{dead}}{}^* = 2$–5 and $M_{\mathrm{collapsed}}/M_{\mathrm{WD}} = 0.2$–3. These are modest values. Therefore, in the framework of Dirac's multiplicative theory, there is no special mechanism to produce the vast numbers of black holes or other dead stars that are sometimes suggested to compose the 'missing matter' in the solar neighbourhood and in the galactic halo.

The predicted paucity of stars during the past history of the Galaxy arises from the smaller galactic mass then, and implies that the Milky Way must have been considerably dimmer than it is at present. Most of the luminosity may be assumed to have come then (as now) from the few brightest stars. Assuming that these stars form with masses in proportion to $G^{-3/2}$ leads, as above, to $L \propto t^{1/2}$ and $N_{\mathrm{brightest}} \propto t^{1/2}$, so that the total luminosity of the Galaxy, $N_{\mathrm{brightest}}\, L$, is found to rise as t (but its colour probably changes relatively little with time). Thus, at the end of the original collapse phase of the Galaxy, after the initial metals abundance had been produced and supermassive stars were no longer being formed, the Milky Way would have been only 0.01–0.25 times as bright as it is today *ceteris paribus*. It could have been even fainter if the upper end of the allowable range of stellar masses were underpopulated when the galactic mass was small (an effect observed today in external galaxies of small mass). But, if the mass of the Galaxy had not been varying along with G, the Milky Way would have been brighter in proportion to t^{-1} in the past than it is today. Observations of distant spiral galaxies may eventually be able to discriminate between these various evolutionary models.

I thank V. Canuto and C.-w. Chin for discussions.

Extraction of metals from basalt by humic acids

In many studies, the activity of humic acid in weathering and other geological processes has been considered negligible. Only simple, low molecular weight organic acids are usually considered effective in mineral degradation[1]. Those acids, however, frequently constitute only a minor fraction of the soil organic matter, particularly in semi-arid and arid areas. In Israel, fulvic acid/humic acid ratios in the organic matter of major soil types range, with one exception, from 1.5 to 6 (ref. 2). Humic acids are also well represented in the organic matter of many sediments[3,4]. The effect of these high molecular weight compounds on mineral decomposition and metal dissolution is therefore of great interest in the earth sciences. The results presented here suggest that humic acids also may have a significant role in rock solubilisation and weathering, because of their capacity to extract considerable amounts of metals, particularly copper and zinc, from basalt rock.

Though the part played by fulvic acids and other low molecular weight organic acids in weathering has been widely documented, the action of humic acids in these processes has been examined in only a few cases. Schalscha *et al.*[5] extracted considerable amounts of Fe from minerals treated with humic acids. The solubilisation of major elements from alumosilicates has been shown to be considerably speeded up by treatments with humic acids or organic acid components of humic acid[6–8].

Baker[9] has reported on the strong solvent activity of humic acid from a podzolic soil in Tasmania, towards a number of minerals and metals. In his studies, separate mineral species were exposed to the action of humic acids. Here the effect of humic acids on basalt rock has been examined with the purpose of evaluating their role in the supply of soluble metals to soils.

Figure 1 shows that after a rapid initial rise, the dissolution rate of nearly all elements decreases rapidly. The dissolution capacity of the three humic acids is fairly similar. Ca, Mg, Co and Ni came to near equilibrium after 6–12 h, Al and Zn after 36 h. Fe, Mn, Cr and, to a lesser extent, Cu continue to be dissolved, though at a slow rate, after 108 h. Fe was the most extracted metal, followed by Al, Ca and Mg (Table 1). The transition metals were extracted in trace amounts. Relative to their contents in the basalt, Cu was the most extracted metal, followed by Zn. Next came Co, Cr and Mn, then Ni. Less than 0.5% of Fe, Al, Mg and Ca were extracted by the humic acids. Arranged according to the relative amounts extracted, the following sequence is obtained: Cu > Zn > Mn > Cr > Co > Ni > Al > Fe > Mg > Ca. The large amounts of metals extracted by the humic acids indicate the significant role these organic compounds may have in weathering and soil formation. An even more important aspect of that capacity is the role humic acids may play making micronutrients available (particularly copper and zinc) to plants growing on basalt-derived soils.

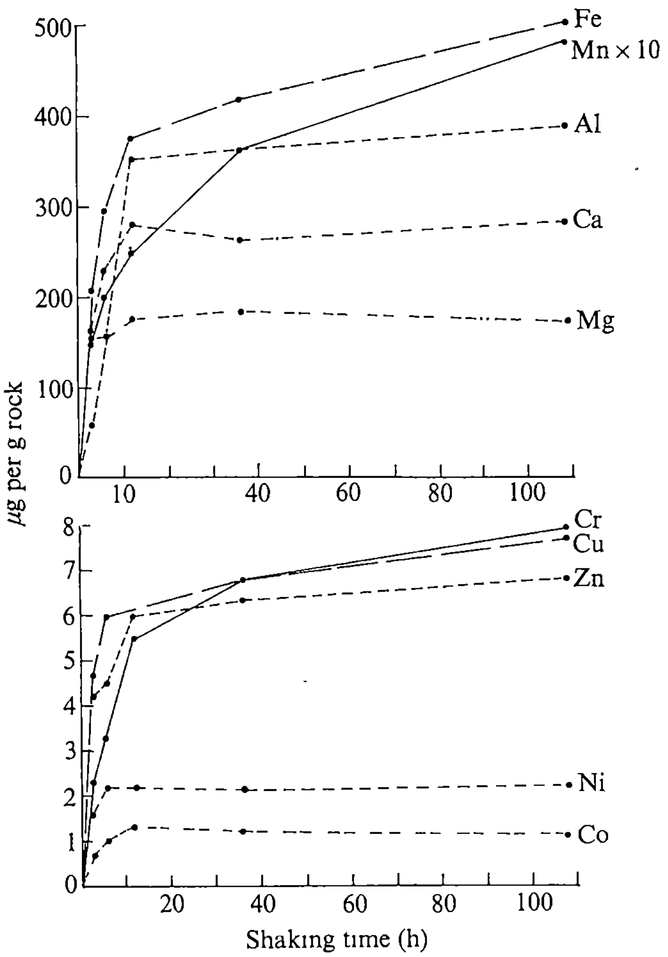
The capacity of humic acids to dissolve metals has been given as up to 682 mg g^{-1} (ref. 4). Thus, the total amounts

Table 1 Extraction of alkaline earths and metals from 1 g basalt after 108 h treatment with three humic acids

	Basalt (mg)	Humic acid 1 µg	Humic acid 1 %	Humic acid 2 µg	Humic acid 2 %	Humic acid 3 µg	Humic acid 3 %
Al	63.7	387	0.61	402	0.63	366	0.57
Fe	110.1	550	0.50	491	0.44	499	0.45
Ca	71.4	297	0.42	265	0.37	281	0.39
Mg	34.7	175	0.50	169	0.49	153	0.44
Co	41×10^{-3}	1.1	2.7	1.3	3.2	1.9	4.6
Cr	221×10^{-3}	7.9	3.6	7.6	3.4	7.2	3.3
Cu	59×10^{-3}	7.7	13.1	6.5	11.0	6.4	10.9
Mn	141×10^{-2}	48	3.4	53	3.8	47	3.3
Ni	211×10^{-3}	2.3	1.1	2.2	1.0	3.4	1.6
Zn	118×10^{-3}	5.5	4.7	6.8	5.8	6.7	5.7

dissolved in this experiment—10–15 mg g^{-1} humic acid—are far below the dissolving capacity of the acid. Incongruent dissolution of components from various alumosilicates by organic acids has been shown by Huang and Keller[7]. From most of the minerals, alkalis were removed preferentially so that the mineral surfaces remained enriched in Si–Al relative to the inner core. Further dissolution proceeds probably by diffusion through the residual envelope and is consequently slowed down considerably, or stopped altogether, as is the case with Ca and Mg in the experiment reported here. Fe and Mn, and to a lesser extent some of the other transition metals, particularly Cr, remain in basalt partly in the free oxide minerals magnetite and ilmenite, from which they continue to be dissolved, though at a slow rate.

Fig. 1 Extraction of alkaline earths and metals from basalt shaken for up to 108 h with humic acid. The humic acids were extracted from three Mediterranean soils: protogrumosol derived from basalt, under *Eucalyptus rostrata*; Mediterranean Brown Forest Soil derived from hard chalk, under annual grasses; and Rendzina, derived from soft chalk, under *Pinus halepensis*. Extraction, isolation and purification of the humic acids were similar to the methods described by Khan[10]. Alkaline olivine basalt, chemical composition given in Table 1, was pulverised in a Fritsch agate ball mill and then sieved through a 200 mesh Spex nylon sieve. The humic acid was redissolved in a NaCl solution to give a 0.1% w/v humic acid in 0.01 M NaCl final solution, and adjusted to pH 6.5 One gram of rock powder was shaken for 3, 6, 12, 36 and 108 h with the humic acid solutions at 25 °C, and the soluble elements were determined by atomic absorption. Controls of rock shaken with 0.01 M NaCl alone were run separately. Also determined was the metal content of the humic acids alone.



Incongruent dissolution is probably also related to the relative affinity of the cations for the ligands of the humic acid. Though the relative stabilities of metal–fulvic acid complexes have been studied extensively, only fragmentary data are available on metals–humic acids complexes. Courpron[11] has given stability constants of log $K = 7.00$ and log $K = 2.87$ for complexes of soil-derived humic acid with Cu and Zn, respectively. The following order of complex stability at pH 7 for soil humic acids and metals has been established by Verloo and Cottenie[12]: Zn > Cu > Pb > Fe > Mn. If the coagulation capacity of metals for humic acid is an indicator of their affinity for humic acid, the following series obtains[4]: Al > Fe > Cu > Co > Ni. The effectiveness of added metals in coagulating humic acids derived from soils follows the order[10]: Al > Fe > Cu > Zn > Ni > Co; and a similar sequence obtains in the order of magnitude of the pH drop of humic acids on addition of metallic cations. The relatively strong extraction of Cu and, to a lesser degree, of Zn from the basalt may therefore be explained by the strong affinity of those metals for humic acid.

Fe and Al were less extracted than may have been anticipated from their relative affinities for humic acid; it is very likely that the nature of the solid phase also influences the rate of dissolution. Complexes which may be theoretically possible on the basis of strictly chemical considerations may in fact not form because of geometric hindrance or bond strength[5]. Thus, in strongly complexing organic acids, the dissolution of Al progresses differently in labradorite and augite: in labradorite Al is retained, whereas in augite it is removed, though less readily than other cations[7].

Differences in the degrees of decomposition of minerals by organic acids have been explained by Ginzburg *et al.*[6] as consequent upon different relative stabilities. The relatively low extraction of iron is probably related to the relatively high Gibbs energies of formation of magnetite and ilmenite (two important host minerals of Fe in basalt) compared with the much lower formation energies of the alumosilicates, olivine, pyroxene, in which most of the transition metals are contained.

Climatic information from $^{18}O/^{16}O$ ratios of cellulose in tree rings

THE high precision of dendrochronology makes possible the construction of short (~ 9,000 yr), detailed records of past climates. This paper explores the possibility of using the oxygen isotopic composition of cellulose from tree rings as a 'thermometer' to measure past temperatures. Using meteorological data from Edmonton we have shown that temperatures can be measured with a precision of ~ ±0.15 °C when averaged over a 5-yr period.

To investigate the variation of the ^{18}O-content of cellulose with temperature, we have studied a white spruce (*Picea glauca*) which grew in Edmonton, Alberta from 1882 to 1969. Detailed climate records for this location have been kept since 1880. Samples were taken from a 5-cm thick transverse section of the trunk cut ~ 1.5 m above ground. A 1-cm wide slice was cut from the section, divided into 5-yr groups of rings and the α-cellulose from each group extracted by standard chemical procedures[1]. After washing and drying in a vacuum oven (50 °C for 5 d), the cellulose was burnt in an evacuated nickel reaction vessel at 1,100 °C for 60 min. The water–gas reaction occurs producing a mixture of CO, CO_2 and H_2 The hydrogen produced diffuses through the walls of the reaction vessel forcing the reaction to completion. (This technique was developed at the California Institute of Technology by P.T and S. Epstein). The CO was converted to CO_2 and C in a high voltage discharge produced between platinum electrodes. Yields of CO_2 were normally 98–100% of the theoretical predictions. All samples were run as consecutive replicates and no significant memory effects were observed.

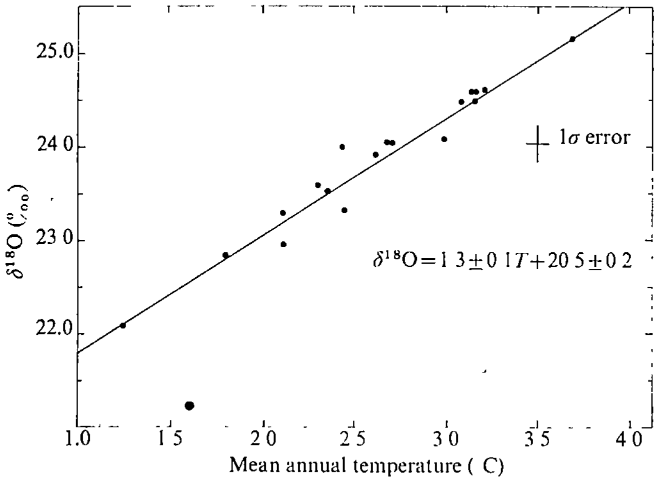

Fig. 1 The variation of $\delta^{18}O$ (SMOW) with September to August mean annual temperature for 5-yr periods. The equation of the line was obtained by a least-squares fit to the data points.

The isotopic composition of the CO_2 was measured using a 12" radius, double collecting isotope ratio mass spectrometer. Results are expressed as a δ value $^0/_{00}$ with respect to standard mean ocean water (SMOW)[2] ($\delta^{18}O_x = [(^{18}O/^{16}O)_x/(^{18}O/^{16}O)_{SMOW} - 1] \times 1{,}000\ ^0/_{00}$). The precision of the replicate analyses was generally better than ±0.20 $^0/_{00}$.

The results show a good correlation between the $^{18}O/^{16}O$ ratio and mean annual temperature calculated on the assumption that growth in any given year stops in September (Figs 1 and 2).

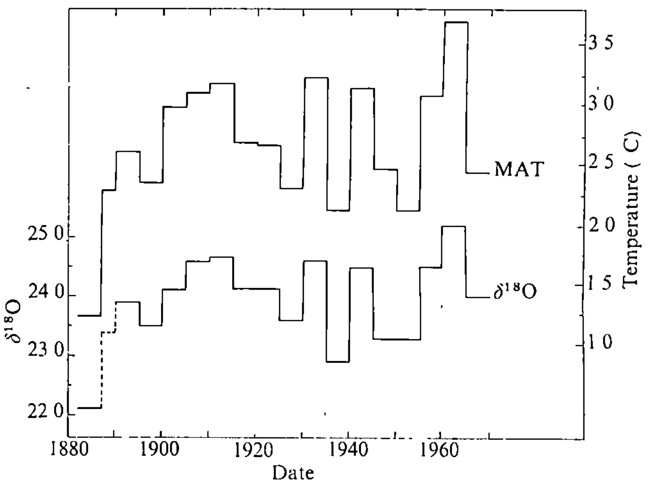

Fig. 2 A comparison between the mean annual temperature (MAT) curve obtained from the meteorological data and that obtained from $^{18}O/^{16}O$ ratios of cellulose. (The broken part of the isotope curve is calculated for some out-of-sequence rings that were not analysed.)

The $\delta^{18}O$ values range from 22.1 $^0/_{00}$ (1.23 °C) to 25.2 $^0/_{00}$ (3.64 °C). The temperature coefficient is 1.3 ± 0 1 $^0/_{00}$ per °C in reasonable agreement with the value of 2.2 ± 1.0 $^0/_{00}$ per °C obtained for algae[3]. The precision of the $^{18}O/^{16}O$ measurements corresponds to an uncertainty of ±0.15 °C in mean annual temperature.

The choice of growing period over which the temperatures are averaged is somewhat arbitrary but the September to August and January to December 5-yr means differ on average by only 0.1 °C. Table 1 shows the correlation between $\delta^{18}O$ and mean temperatures calculated for different growth periods. It is apparent that the best correlation occurs with mean annual temperatures for September to August. The correlation with mean summer temperatures is poor.

There are two possible explanations for this. First, in addition to the temperature effect on the fractionation factor, there is also variation in the isotopic composition of the source water being used to produce cellulose. This is also climate dependent[4]. Ruben[5] has shown that oxygen transpired during photosynthesis is derived only from water. It thus seems fair to assume that the cellulose oxygen is derived from CO_2. It is possible, however, that isotope exchange can occur between CO_2 and H_2O before photosynthesis occurs so that the isotopic composition of the CO_2 will reflect that of the source water ($\alpha_{CO_2-H_2O} = 1.0407$ at 25 °C (ref. 6)). Thus it is possible that winter precipitation stored as soil water after melting may have a significant role in the production of cellulose during the growing season. The results shown here suggest that the contribution from variation in source water is relatively small, however, since the temperature dependence of the fractionation factor is approximately four times as large as the observed variation in the Edmonton area (0.3$^0/_{00}$ per °C, calculated from data in the International Atomic Energy–World Meteorological

Table 1 Correlation between $\delta^{18}O$ and mean temperatures calculated for different growth periods

Temperature (5-yr mean)	Correlation coefficient $\delta^{18}O$ against temperature
Mean summer (May, June, July, August)	0.24
Mean winter (1) (January, February, March)	0.82
Mean winter (2) (December, January, February, March)	0.86
Mean annual (1) (January–December)	0.94
Mean annual (2) (September of previous year to August of final year)	0.97

Organization survey 1969, 1970, 1971 (ref. 7)). Second, it has been shown that net photosynthesis and growth in coniferous trees depends markedly on the production of stored foods (sugars from photosynthesis) during the winter[8], so that winter temperatures may have a direct bearing on the isotopic composition of the cellulose produced the following year.

It is apparent that much work remains to be done to understand fully the isotopic processes involved in the production of cellulose. The empirical results presented here, however, show that the temperature dependence of the isotopic fractionation can be measured and that the climate record in the cellulose is not destroyed by subsequent exchange over a period of up to 90 yr. Measurements of D/H ratios of cellulose are under way in this laboratory to provide an independent cross check with the oxygen data.

We thank the meteorological office of Edmonton for providing temperature records and Dr K. D. Hage for help with the acquisition of tree samples. We would also like to acknowledge the assistance of Professor S. Epstein in the early stages of the project. We thank the NRC of Canada for support.

Geometry of river meanders

THERE are many factors affecting the geometry of rivers. Width, depth, slope, flow velocity and plan shape are all influenced by discharge, sediment load, sediment types, and valley slope through the operation of the continuity, flow resistance, bed load, bank competence and meander equations. If each of these equations could be determined accurately then their simultaneous solution would define the three-dimensional geometry of alluvial channels[1,2]. Although the equations cannot be specified accurately the basic mechanical principles underlying most of the relevant processes are understood. The one exception is the process responsible for plan geometry. Indeed, many theories have been presented to explain the development and maintenance of these patterns, with varying degrees of success. I show here that meander arc length may be a unique function of channel width.

Yalin[3] has proposed that the occurrence of meanders could be attributed to the law governing the spatial correlation among perturbations in turbulent flow. He demonstrated that the behaviour of the largest macroturbulent eddies would be systematically affected by a permanent discontinuity, and that this would result in the same and reverse kind of disturbance occurring alternately at equal length intervals along the direction of flow. On the basis of his theoretical analysis the wavelength of meanders, λ, in fully developed turbulent flow was related to the width of the channel, w, through

$$\lambda = 2\pi w$$

If turbulence were not fully developed, he has argued, the wavelength would be dependent on the Reynolds number and the relative roughness of the section. For width/median bed material grain size values greater or equal to a thousand, he has argued that

$$\lambda = 20w$$

Leopold and Wolman's[4] field data plot within these limits, which seems to substantiate Yalin's hypothesis. But as turbulent flow is normally fully developed at bankfull stage—the channel-forming discharge—the coefficient in Leopold and Wolman's best-fit relationship of

$$\lambda = 10.9w^{1.01} \text{ feet}$$

seems rather high.

This discrepancy between theory and practice could be explained by the fact that the repeating distance between discontinuities should be measured along the channel and not as a straight line distance. To check this hypothesis I have compared data from the rivers Wye and Tweed with Leopold and Wolman's data.

First, their equations linking wavelength with channel width and radius of curvature, r, were solved to obtain the relationship between radius of curvature and width

$$r = 2.37w^{1.03} \text{ feet}$$

As the exponent of this equation was not significantly different from unity, a linear relationship was assumed and the slope adjusted accordingly

$$r = 2.40w \text{ feet or m}$$

Most of the data for the Wye and Tweed plot above this line (Fig. 1) immediately indicating that Leopold and Wolman's curve is not a general one. This scatter was rationalised when information on meander arc angle, θ, measured between inflexion points was included. Leopold and Wolman's curve seems to relate to well developed meanders (150°) because points further above the line have progressively smaller arc angles. On the assumption that the arc angle for their curve is 150°, the relationship between arc length, z, measured between inflexion points, and channel width can be obtained

$$\begin{aligned} z &= 6.28w \text{ m} \\ &= 2\pi w \end{aligned}$$

If this is a general relationship for all channels it would explain the plotting positions of the Wye and Tweed data on the graph of radius of curvature against channel width. Substituting z for w allows a family of curves to be constructed for different arc angles (Fig. 1). Field data corroborate this substitution,

Table 1 Relationships between wavelength, radius of curvature and bankfull channel width for various arc angles*

Arc angle ($\theta°$)	Value of k in $r = kw$	Value of m in $\lambda = mr$	Value of n in $\lambda = nw$
270	1.33	2.83	3.77

so the relationship between meander arc length and channel width seems to be general. Other research workers have noted that the spacing of riffles in straight and meandering channels is between five and seven channel widths[5] and that skew shoals in flumes have been found to be 6.5 channel widths apart[6].

This analysis indicates that the repeating distance measured down channel is $4\pi w$ which contrasts with Yalin's value for wavelength of $2\pi w$. Given that it would be more appropriate to use channel distance rather than plan distance in the calculation of repeating length, Yalin's model underestimates the repeating length by a factor of two.

How can this be explained? Closer inspection of Yalin's model indicates that he calculated repeating lengths by assuming that the largest macroturbulent eddy was equivalent to the width of the channel. Physically, this eddy must be interpreted as a helicoidal flow cell, and, as it systematically changes polarity, it influences the local pattern of accelerations and retardations. Approaching a pool (meander apex) the strength of the secondary circulation increases to a maximum with surface flows directed towards the eroding bank. Immediately downstream the polarity of the cell is reversed and the process repeated (Fig. 2*a*).

This pattern of secondary flows is probably incorrect, however. At high flow stages two cells, exhibiting surface flow convergences, have been identified at the pool (meander apex); whereas at the riffle (inflexion point) two cells, with surface flow divergence, have been observed[7] (Fig. 2*b*). On the assumption that the average size of this macroturbulent eddy is half the channel width, recalculation gives a repeating length of $4\pi w$.

As theory and practice indicate a general relationship between meander arc length and channel width it is possible to define the relationships between wavelength, radius of curvature and channel width for different arc angles (Table 1). This explains why empirical equations are specific to a given set of data unless meander arc angle is invariant.

Although this model helps to explain the regularity of channel patterns it does not successfully explain the initiation of meanders. A local increase in bank roughness is required to produce the asymmetry of flow but it does not explain how this can be achieved in homogeneous material. This approach merits further research however, particularly on the generation and effect of secondary flows on natural channels.

Even though it is not possible at present to explain meander mechanism, it is necessary to define the plan geometry of river channels for design purposes. Sinuosity, defined as the ratio of channel length to valley length or valley slope to channel slope, is probably the best measure because it is related to

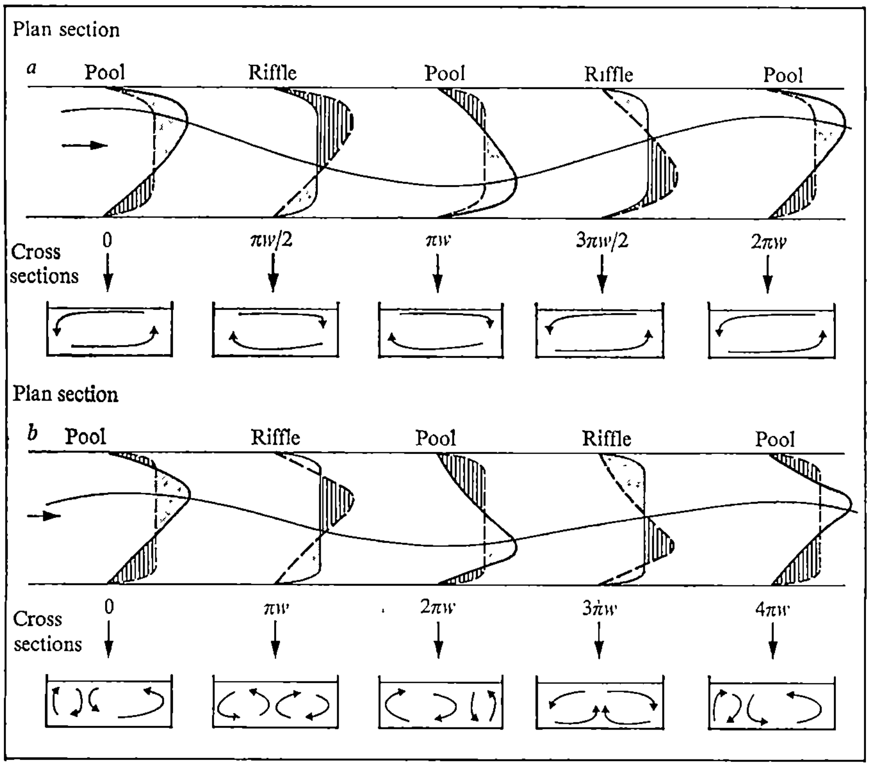

Fig. 2 Size of macroturbulent eddies in natural channels. *a*, Single secondary cell (after Yalin[3]); *b*, twin secondary cells (after Hey and Thorne[7]); —, surface velocity profile at section; - - - surface velocity profile at neighbouring upstream section; stippling, accelerated surface flow; vertical lines, retarded surface flow.

meander processes. Any change in channel slope, through erosion or deposition, to a value defined by the bed load transport equation will result in a new plan form because valley slope can be considered invariant for channel design purposes. Unfortunately, for a given value of sinuosity an almost infinite number of patterns are possible (Fig. 3). If the meander geometry is to be specified accurately then it will be necessary to determine the size of each meander arc. As arc length is a unique function of channel width, which in turn is defined by the bank competence equations, a determinate solution is possible.

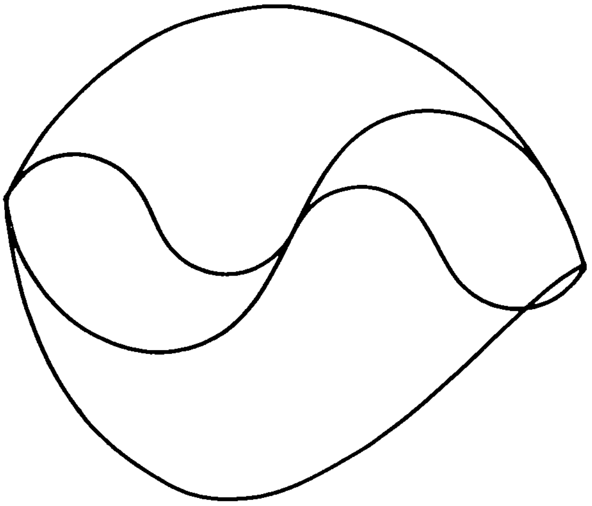

Fig. 3 Multivalued plan geometry for a given sinuosity (1.5 in case illustrated).

New hominid from Lake Ndutu, Tanzania

THIS report describes the stratigraphical and archaeological position of an hominid skull discovered in Pleistocene deposits around Lake Ndutu, on the Serengeti Plains (3°00′S; 35°00′E). The skull itself is described elsewhere[1]. Lake Ndutu, together with the adjacent Lake Masek, is geomorphologically a continuation of the Olduvai Pleistocene deposits. The names of both lakes have been used to designate the upper parts of the Olduvai Sequence—the Ndutu and Masek Beds (formerly bed V and bed IVB, respectively); both are soda lakes.

Lake Ndutu is the smaller of the two (Lake Masek had enough water during the dry season of 1974—September–November—to support a resident population of hippopotami), and shows very marked fluctuations in water level between the wet and dry seasons. During the wet season the whole lake shore is under water, whereas during the dry season the water recedes mostly southwards and eastwards to expose the larger part of the western and northern shores of the lake The exposed western flats are littered with lithic and faunal materials

The site was first visited during September 1972, when a one-week preliminary survey was undertaken. This work included random surface collections in seven areas, each 2 m in radius, and the excavation of 2 m×2 m trial trench with the objective of elucidating the stratigraphy of the site. During September and October 1973, the Tanzanian Department of Antiquities undertook the initial excavation of the site. These excavations, apart from exposing occupational floors with *in situ* lithic and faunal materials, also exposed a hominid skull[1].

The Ndutu deposits comprise a claystone member which can be subdivided into a greenish sandy clay unit, 15–45 cm thick, underlain by about 60 cm of sand-free, green clay with chert nodules in the lowest levels (R. Hay, California

Univ., Berkeley, private communication). The sandy clay unit can be further subdivided into sandy clay and silty clay subunits. To the north, along the shore, a hard, reworked tuff, 10–12 cm thick, overlies the claystone. The occupational floor containing the skull rested on the silty clay subunit, and below it, resting on sand-free, green clay, were *in situ* lithic and faunal materials of what has been tentatively designated the second occupational floor.

The surface of the western margin flats are littered with lithic and faunal material but one problem concerns its provenance Although the water level fluctuates at present it is not at all clear whether a similar situation obtained during the period when early man used either the lake or its vicinity as camping and hunting grounds. Did early man camp at the site seasonally during lacustrine recessions, or did he camp in the area when the lake was either nonexistent or had dried up during such climatic oscillations as are known to have occurred elsewhere in the Pleistocene epoch? Or has the lithic and faunal material been brought into the area from elsewhere?

During the excavations it was found that there is a noticeable discomformity between the sand-free, green clay unit, and the overlying greenish, sandy-clay unit. Several small channels were cut into the green clay, in some cases to a depth of approximately 30 cm. Lithic and faunal materials were found at the bottom of the channels. It is, therefore, possible that early man camped or hunted at the lake shore when there was a minor climatic change which either resulted in the lake temporarily drying up or the level of the lake receding. This hypothesis is supported by the fact that it is only the sandy clay unit which is fossiliferous and contains implements Although some of the artefacts are rolled it is nonetheless possible that both the lithic and faunal materials are archaeologically *in situ*; the rolling could be a consequence of the constant seasonal movements of lake currents.

During September and October 1973, an area of approximately 140 m² was excavated. The excavated deposits were situated in an area containing considerable amounts of surface lithic and faunal material. An area of approximately 80 m² included a high density of *in situ* lithic and faunal materials. It was in this area that the first and second occupational floors were exposed.

The *in situ* lithic materials are characterised by a very low percentage of finished tools. In the first floor, among the 270 plotted lithic and faunal materials only 20 are definitive tools (about 7.7%) Among the tools, spheroids and hammerstones predominate. There are six flakes in all, three of which are regular—two triangular and one rectangular. The remaining three are irregular. The cores are amorphous. Quartz and quartzite are the predominant raw material. The loose finds from within the sandy clay subunit overlying the first floor confirms this analysis They include five cores, four regular flakes (one with retouched edges), three irregular flakes, one core scraper, two quartz pebbles probably used as hammerstones, and twenty-two waste flakes.

The tools represented in this collection are rather nondescript and of an indeterminate industry. Although hand axes and cleavers occur in the surface material, they are few, and even among the surface collections spheroids seem to be the predominant tool type, with cores also well represented The absence of hand axes and cleavers among the *in situ* artefacts raises the question of the type of industry represented. The type of hominid represented by the skull is generally thought to be associated with the Acheulean industrial complex. The tentative date of the site as well as the mineralogical contents of the deposits also place the site within the chronological boundaries of the Acheulean industrial complex in the Olduvai Gorge and other sites in Tanzania and eastern Africa Two possible hypotheses can be used to explain the absence of the tool types widely found in the Acheulean industrial complex. Either the assemblage belongs to a different cultural and technological continuum and belongs to an industry post-dating, or contemporaneous with, later phases of the Acheulean industrial complex, or it belongs to the Acheulean, and the area excavated is only an indication of activity patterning. The latter hypothesis seems to be the most likely, and is supported by the fact that hand axes and cleavers, though few, are represented in the surface materials; moreover, excavation of a small trench on the site revealed an *in situ* hand axe (M. D. Leakey and R. Hay, private communication). The presence of a very high percentage of faunal materials in the collection—about 94 out of the 270 plotted *in situ* materials of the first floor are splinters and sizeable bone pieces including horns and antlers—seems to suggest that the area was probably a butchering site, though the presence of a hominid skull among the collection in such a context would be rather enigmatic.

The tuff overlying the claystone probably represents the Norkilili Member of the Masek Beds of Olduvai, though the possibility that it represents the lower unit of the Ndutu Beds cannot be ruled out (R. Hay, private communication). One preliminary chronometric date has been obtained from bone found in the first occupational floor, and preliminary racemisation measurements suggest a general age of ~500,000–600,000 yr (J. L. Bada, private communication). A sample of bone from the Masek Beds of Olduvai has given similar results.

I thank Mr F. T. Masao, the Curator of the National Museum, who participated in the 1972 preliminary survey, and the staff of the Department of Antiquities, who assisted in the excavations. I also thank M. D. Leakey for help, advice and encouragement.

New cranium of *Homo erectus* from Lake Ndutu, Tanzania

I DESCRIBE here the humanoid cranium recovered by Mturi[1] during excavations at Lake Ndutu in northern Tanzania. A fuller description will be published elsewhere.

The cranium is remarkable in that it seems to form an evolutionary link between *Homo erectus pekinensis* and *Homo sapiens*, having features in common with both. It cannot, however, be classified as *Homo sapiens*, and in spite of its strong resemblance to *H.e. pekinensis* its more advanced characteristics and its occurrence in Africa rather than Asia may eventually warrant the creation of a new subspecies of *H erectus* to accommodate it. This will be determined following full comparative studies.

The specimen is similar to *H.e. pekinensis* in the following features·

- The form and contour of the occipital, which has a markedly thickened nuchal torus.
- The form of the mastoid region.
- The almost vertical forehead.
- The inferred supraorbital torus.
- The great thickness of the vault.
- The outline, as seen in norma verticalis.

The cranium differs from *H.e. pekinensis* and is similar to *H. sapiens* in the following features:

SCIENCE COLLEGE

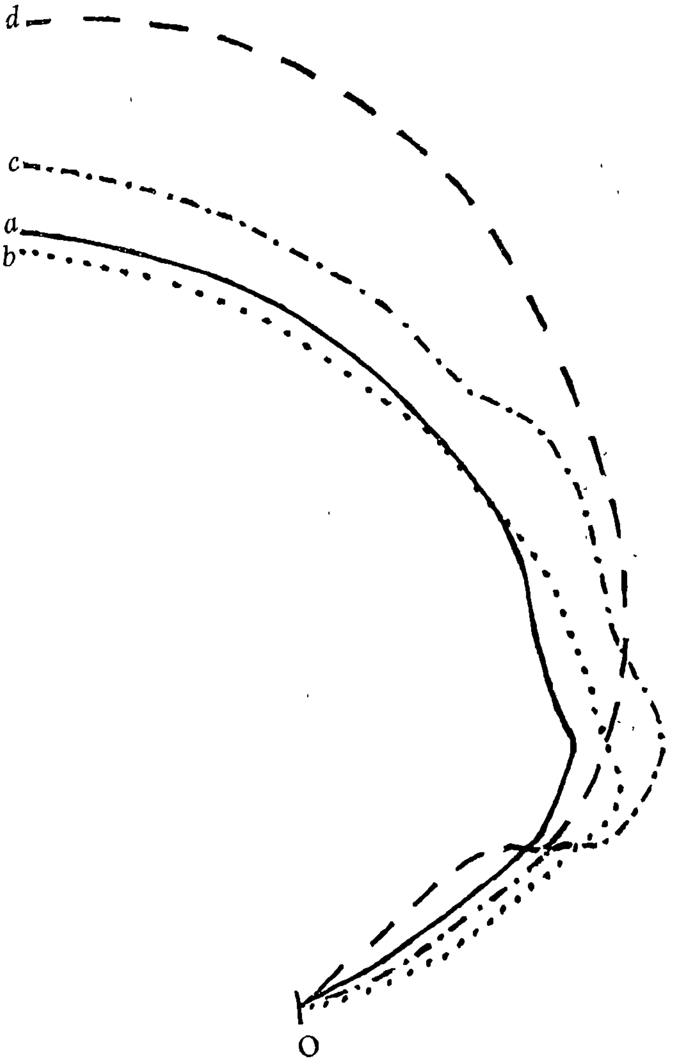

Fig. 1 Mid-sagittal craniograms of the occipital region: *a*, Ndutu cranium; *b*, *H.e. pekinensis* (Skull III from locus L); *c*, Ngandong (Solo), Skull V; *d*, Australian aborigine; O, opisthion. Adapted from Weidenreich[2].

- The presence in the adult of pronounced parietal bosses.
- The more vertical sides of the vault as viewed in norma occipitalis.
- The presence of an ossified styloid process.
- The apparent absence of a sagittal torus.
- The supramastoid crest does not extend over the external acoustic meatus.

The Ndutu cranium is housed at the National Museum of Tanzania in Dar es Salaam. The specimen includes the virtually complete occipital and left temporal; the right temporal lacks the glenoid fossa, parts of both parietals and part of the right side of the frontal, parts of the sphenoid, and the fragmentary central region of the face which is attached to a fragment of the left maxilla. In addition, there are isolated right tympanic plates and both isolated petrous temporals.

Before reconstruction the parts of the cranium were very much broken and separated, but were retained in their approximate anatomical position by a matrix of sand and clay which was impregnated with a hardener (Bedacryl) before the cranium was removed from the site. Much of the parietals had suffered badly from cracking and fragmentation, and also from a displacement of inner and outer tables. In parts the inner table only was present and in others only the outer table in the form of a thin shell with the diploë missing. In other places the inner and outer tables had been pushed apart from the diploë, and the spaces between were filled by the sandy matrix, thus giving an artificial, exaggerated thickness to the vault.

The occipital is nearly complete, lacking only the left occipital condyle and some small areas near the foramen magnum. The foramen magnum measures 37.5 mm in anteroposterior length and 28.7 mm in breadth. The apex of the occipital is represented by a sutural bone. There is also a sutural bone to the right of this along the lambdoid suture. On each side there are two small sutural bones at asterion, but one of those on the right had fallen out and was not recovered during the excavation.

There is a well developed nuchal torus as in *H.e. pekinensis*, giving the bone a markedly angulated lateral contour (Fig. 1). The bone is fairly thick, particularly at asterion.

The left of the temporals is the more complete. Its mastoid process is small and of a triangular horizontal cross section. The posterior part of the mastoid is flattened and lies in the nuchal plane. The mastoid is thus similar to that of *H.e. pekinensis*, and is particularly similar to that of Olduvai hominids 9 and 12. There is a well defined mastoid notch which is divided along its length by a central ridge.

An ossified styloid process is present and can be seen particularly well under cover of the isolated right tympanic plate.

The lower margin of the external acoustic meatus preserved on the left is thick and elongated in a downward direction.

A supramastoid crest can be seen, but it does not extend over the external acoustic meatus as in *H.e. pekinensis*.

The left glenoid fossa is deep, relatively small and short anteroposteriorly. The articular tubercle lacks its lateral margin.

The bone at asterion is very thick as is the case in *H. erectus pekinensis*.

The right parietal is missing large areas around its centre and anteromedially, but it has contact laterally at the coronal suture with a frontal fragment. The conformation of the bone around the centre of the parietal indicates that it had a pronounced parietal boss. The parietal thickness at a point anterior to the boss is 11.5 mm. This is well within the upper range of parietal thickness given by Weidenreich[2] for *H.e. pekinensis*, and much thicker than the range he quotes for *H. sapiens*.

The left parietal is represented mainly by the posteromedial portion externally and the posterolateral portion internally. The anterior part is missing but an anterolateral fragment adjoins the squamous part of the temporal. The left parietal is in articulation with the occipital and left temporal at asterion.

The temporal line is seen only very faintly on the right parietal and, from the contour of the surface of the parietals near the sagittal suture, there was apparently no sagittal torus, such as occurs in *H.e. pekinensis*.

The preserved right frontal fragment is 8.6 mm thick and thus well within the range of 7.0–13 mm given by Weidenreich[2] for *H.e. pekinensis*, and is at the same time greater than the maximum of 6.3 mm he quotes for *H. sapiens*.

The anterolateral corner of this frontal fragment curves forward and outward, indicating that there must have been a supra orbital torus in order for that fragment to meet with the glabellar fragment attached to the face. The glabella together with the face, could not be placed further back because it is restricted by other anatomical features such as the cribriform plate of the ethmoid bone, and by the necessity for room for the anterior fibres of the temporalis muscle. In reconstruction, allowance was made for only the smallest supraorbital torus permitted by the preserved anatomy, but it is possible that a larger torus could have been present.

The frontal bone rises in a high curve of the forehead as in *H.e. pekinensis* but unlike the frontals of *H. erectus erectus*, the Ngandong crania or the Broken Hill cranium.

The middle portion of the face is preserved, including much of the nasal aperture, the upper part of the left nasal bone, the lower medial parts of the orbital rims together with the lacrimal grooves, and much of the superior part of the right orbital plate. The crista galli is present and is attached to the cribriform plate behind the nasal bones.

On the right, the medial part of the face is preserved as far down as the infraorbital foramen, and on the left there is continuous bone contact from the nasal bone to the palate. The

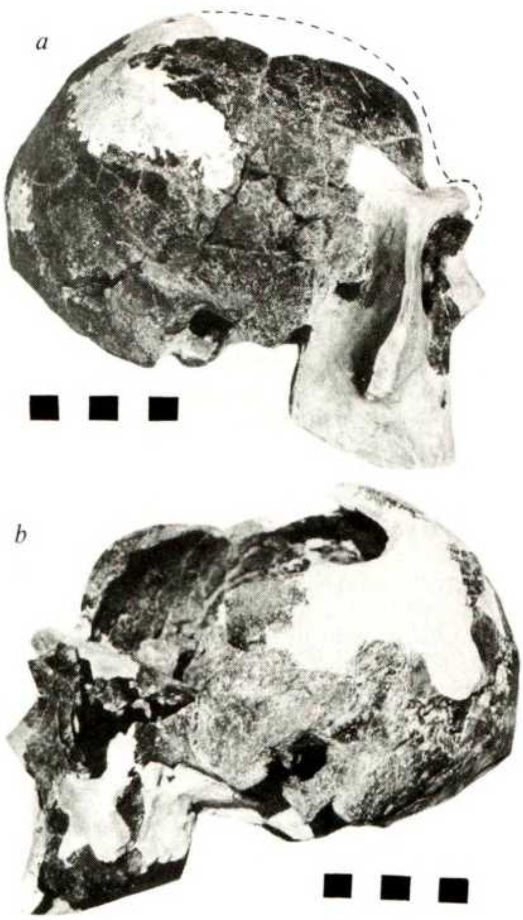

Fig. 2 *a*, Right norma lateralis of the Ndutu cranium; *b*, left norma lateralis of the Ndutu cranium.

conformation of the bone around the nasal aperture, and the angle between the nasal bones indicate that the nose was very prominent.

The left portion of the palate contains fragments of the roots of the canine, P^3, P^4 and M^1 and the mesiobuccal socket of M^2. This palatal fragment reaches almost to the midline of the cranium.

Areas of the cranium were reconstructed with plaster of paris both to strengthen the parietal region, where either inner or outer tables only were preserved, and to attach the face to the rest of the cranium. This reconstruction was minimal and preliminary. The reconstruction suggests that slight adjustments can be made to the position of the face, but this will not affect the conclusion that a supraorbital torus must have been present originally. The size and shape of the maxilla remain unknown as it is extremely fragmentary. The top of the cranium has been left open in order that the internal anatomy can be seen.

The cranium (Fig. 2) has some similarities to Olduvai hominid 12 in the thickness of the vault and the shape of the mastoid, but it is much larger. It differs from the Ngandong and Omo II crania in its outline as seen in norma verticalis. The former have a more rectangular outline whereas the Ndutu cranium and *H.e. pekinensis* have a pear-shaped outline. It differs from Ngandong and Omo II also in possessing a more vertical forehead, though it is similar to Ngandong in the morphology of the temporal. The mastoid of the Ndutu cranium differs from that of Omo II. It differs from the Broken Hill cranium in its temporal and frontal and in being much smaller. It differs from Swanscombe and Steinheim in its occipital curvature and in that the mastoid of Steinheim is sapient in form. It differs also from Skhul V in its occipital and mastoid. It bears little comparison with *H.e. erectus* except in vault thickness and in its outline seen in norma verticalis. The mastoid region is similar to that of Olduvai hominid 9, but otherwise, apart from thickness of the vault, there is little resemblance.

It would have been of interest to compare the Ndutu cranium with that of the Eyassi I cranium[3] but unfortunately the original disappeared in Berlin in 1945 according to Weinert[3], and available casts are too poor to allow comparison. Published descriptions and photographs are also not of any great help because the cranium was reconstructed from fragments, and it is difficult to ascertain what is reliable. In spite of all of these deficiencies, the Eyassi cranium does seem to have been rather similar to the Ndutu cranium. It was found not far away from Lake Ndutu in a similar deposit on the shore of the saline Lake Eyassi. It had also undergone separation of inner and outer tables of the vault bones, probably as a result of alternating crystallisation and solution of the salt within the diploë. A few broken handaxes and an early water-rolled fauna also occurred at the site, but Leakey[4,5] considered the cranium to be contemporary with an unrolled modern type of fauna, and with levalloisian artefacts that were also to be found on the surface. The possibility should not, however, be dismissed that the Eyassi cranium could have been contemporary with the hand axes and the rolled fauna. This is supported by the fact that, although Leakey[4] has described the skull as unrolled, Weinert[3] has claimed that the edges broken in antiquity were rounded and rarely fitted together.

The Eyassi II occipital fragment, which is preserved in the National Museum in Dar es Salaam has some similarity to that of the Ndutu cranium.

Finally, it is of interest to note that Dr Peter Andrews subjected the Ndutu cranium to a form of multivariate analysis described by Andrews and Williams[6]. He found that the cranium grouped with *H.e. pekinensis*, thus confirming by measurement the conclusion reached through observation.

I thank the Government of Tanzania and their Director of Antiquities, Amini Mturi, for giving me the privilege of cleaning, reconstructing and studying the Ndutu skull. I also thank Richard and Mary Leakey for providing facilities for the work, the L.S.B. Leakey Foundation for financing my study visit to Nairobi, and Professor P. V. Tobias for making the visit possible.

Antennal receptor response to sex pheromone mimics in the American cockroach

THE essential oils D-bornyl acetate, α- and β-santalol and several plant sesquiterpene hydrocarbons have been shown to induce sexual excitement in male American cockroaches[1], and thus seem to mimic the cockroach sex pheromone. Tahara *et al.*[2] have identified one of the active sesquiterpene hydrocarbon species obtained from Compositae plants as germacrene D. The contrast in structures of these various active compounds poses a serious problem as to the specificity of the sex pheromone receptor. To resolve this we have undertaken an electrophysiological study of the antennal receptors of both male and female cockroaches. The electroantennogram (EAG) responses of both sexes were examined during exposure to the compounds in question. Theoretically the sex specific receptors of the male antennae should respond singularly to natural sex-pheromone (and stereochemical mimics) whereas the female antennae should be unresponsive other than to general irritants and/or to food odours. In fact, the EAG response to the female sex attractant has been obtained in males but not in females[3,4].

EAGs were recorded from excised antennae of the adult American cockroach, *Periplaneta americana*. A tungsten electrode, whose tip has been electrolytically sharpened to about 1 μm with resistance of less than 1 MΩ, was inserted into the distal end of the antennae. The electrode was connected to the input probe of a unity gain d.c. pre-amplifier. A wider stainless steel electrode was placed in the scape of the antenna in a ground position. Germacrene D was isolated from the leaves of *Solidago juncea* Ait. by a combination of column chromatography over Florisil and silver nitrate coated Florisil. The spectral data are as follows: ultraviolet (hexane): 222(ε6590) and 257 nm (ε5020); infrared (film): 3,080, 1,670, 1,635, 1,610, 1,390, 1,375, 1,190, 987, 980 and 890 cm^{-1}; nuclear magnetic resonance (CCl_4): 0.84(3H, d., $J=6$ Hz), 0.90(3H, d., $J=6$ Hz), 1.53(3H, s.), 4.70 and 4.73(2H), 5.19(1H, q., $J=6$ and 10 Hz), and 5.72 p.p.m.(1H, d., $J=15$ Hz). A test chemical dissolved in acetone was completely absorbed on filter paper with the solvent evaporating at room temperature. The filter paper was placed on a vinyl tubing holder, which had been set in a 2-ml syringe. After 2 ml of air had been drawn into the syringe, the syringe plunger was quickly depressed to mix the odour into an airstream. The air taken from the ambient air supply, filtered through glass wool and distilled water, and passed continually at 60 ml min^{-1} through 5-mm diameter glass tubing. As a control the same procedure was carried out without a test compound.

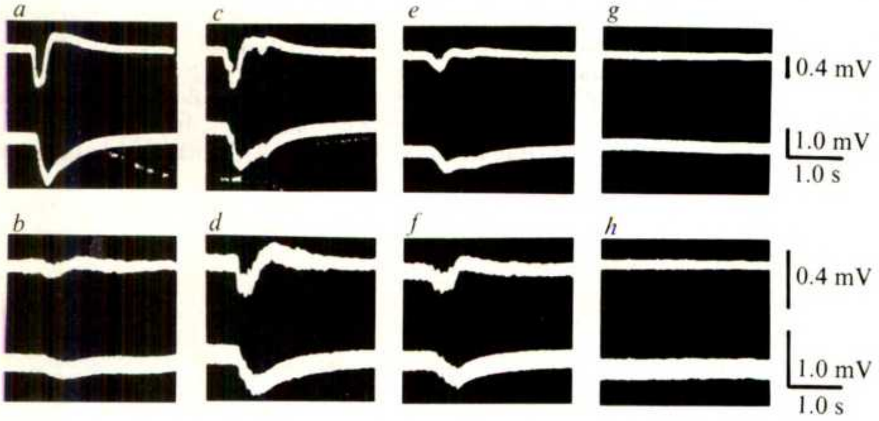

Fig. 1 EAGs recorded from a *Periplaneta americana* adult male (*a*, *c*, *e* and *g*) and female (*b*, *d*, *f* and *h*) in response to germacrene D (0.1 mg in *a* and 3 mg in *b*), D-bornyl acetate (3 mg in *c* and *d*) and L-bornyl acetate (3 mg in *e* and *f*). Controls (air without odour) are shown in *g* and *h*. In each record upper and lower traces show a.c. and d.c. recording, respectively. Note different calibrations in records of male and female antennae.

Adult male antennae showed strong EAG responses to germacrene D (Fig. 1*a*). In the female antennae, however, it caused very small negative potentials, even at much higher concentrations (Fig. 1*b*). The effect of increasing concentration of germacrene D was examined in male antennae. The amplitude of the responses increased in approximate proportion to the logarithm of the intensity of stimulus tested (Fig. 2). The threshold concentration was found to lie between 1 and 5 μg. The response approached a plateau at a concentration of 100 μg or slightly higher. In comparison with EAGs obtained to DL-bornyl acetate[4] the threshold concentration of germacrene D required to elicit the EAG response was much lower, being of the order of one-hundredth. The result of a single experiment to compare the threshold concentration of germacrene D and D-bornyl acetate showed that 5 μg of the former gave a detectable potential change, whereas 50 μg of the latter did not bring about any EAG response. Although strong EAG responses of male and female antennae to DL-bornyl acetate were obtained in agreement with earlier findings[4], we examined the effect of pure D- and L-bornyl acetate in the present work. The male antennal responses to D- and L-bornyl acetate (Fig. 1*c* and *e*) were found to be stronger than those of the female (Fig. 1*d* and *f*). Furthermore, both male and female antennae gave stronger EAG responses to D-bornyl acetate than to L-bornyl acetate. Another essential oil, santalol, was found to give very small EAG responses in both sexes.

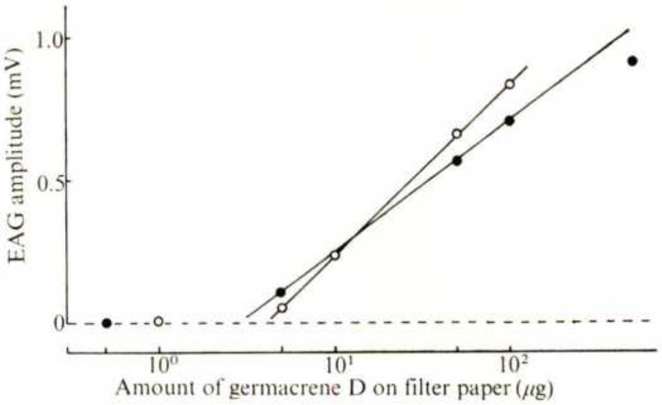

Fig. 2 Amplitude of the EAG responses of two male antennae (○, ●) as a function of the amount of germacrene D (μg) on a logarithmic scale.

It has already been shown that strong EAG responses to the female sex pheromone were obtained from the antennae of male adults but not from females[3,4]. On the other hand, bornyl acetate, which induced significant sexual excitement in the male[1], was found to give strong EAG responses with both male and female antennae. Although adult females show no change in overt behaviour when exposed to bornyl acetate, they show distinct sensitivity to bornyl acetate in EAG analysis. The response of female antennae to bornyl acetate may be due to the presence of generalised antennal receptors since it is unlikely that bornyl acetate has any natural role in female sexuality. Furthermore, in the present work it was confirmed that only the male antennae responded strongly to germacrene D, while the antennae of both sexes are stimulated by D- and L-bornyl acetate. We were unable to obtain other than minimal EAG responses from either sex with santalol.

Ritter *et al.*[5] have proposed two sesquiterpenoids for the American cockroach sex pheromone, and have suggested the germacrane skelton for one of these on the basis of spectral data. We also suggest that germacrene D is closely related to the natural sex pheromone of the cockroach since it induces strong sexual excitement[1,2], and shows a sex specific EAG response.

Cadinol, a sesquiterpenoid biogenetically related to germacrene D, has been isolated from a plant and shown to be a stimulant for both male and female cockroaches[6]. This compound together with germacrene D indicates the importance of sesquiterpenoids in the chemical communication of cockroaches. Lundgren and Bergström[7] also reported the identification of a cadinol (tentatively identified as δ-cadinol) as a constituent of a *Lepidoptera* wing scent complex, important to courtship behaviour. Thus, cadinol may be significant for other insects.

We thank Fritzsche Dodge and Olcott Inc. for analytically pure samples of D- and L-bornyl acetate, and Givaudan Inc. for α- and β-santalol. We also acknowledge technical assistance from Miss K. Tsuzuki and Miss N. Sekijima.

Ecdysone and oocyte morphogenesis in *Bombyx mori*

ECDYSONE, one of the principal hormones of insects, controls the periodic shedding and rebuilding of the cuticle during larval development. (We use "ecdysone" to designate all ecdysoids (in the sense of P. Karlson in ref. 5), or, for the radioimmunoassay, all radioimmunoassay-active ecdysteroid compounds.) It also promotes changes in gene activity observed at the initiation of metamorphosis[1] and influences morphogenetic development of the imaginal disks in pupae Some reports also indicate that ecdysone is found in adult insects[2–4]. Recent work on *Drosophila* (M.L.D.-R., M. H. Hirn and M. A. Delaage, unpublished), *Tenebrio* (P. P. Delbecque, M. H. Hirn and M.L.D.-R , unpublished), *Locusta*[5] and termites[6] has shown that a significant level of ecdysone is generally found in adult insects of both sexes and that high titres of ecdysone can be found in ovarian tissues. In *Locusta*, the ecdysone titre of the ovary increases during each cycle of oocyte maturation[7], suggesting stimulation by ecdysone, in agreement with observations on *Aedes aegypti*[8]. This reveals an unexpected aspect of the action of ecdysone. Using a radioimmunoassay to study ecdysone action in *Bombyx mori*, we have found that not only is ecdysone present in the *B. mori* ovary during egg production, but that the oocyte itself contains a high concentration of ecdysone. Moreover, this concentration changes during successive phases of oocyte morphogenesis.

In *Bombyx*, oogenesis in a well defined sequence[9] during pupal development, and is terminated when the insect ecloses. Pupae were used 6, 9 and 15 d after larval–pupal ecdysis (at 22 °C). They were quickly dissected in Ringer solution For each experiment we removed one ovariole from the right ovary; it was cleaned of adipose tissue fragments and then transferred to a small vial containing a few millilitres of Ringer solution. Oocytes were extracted from the ovarian tube by microdissection. They were collected one after the other, from the bottom to the top of the tube, rank 1 indicating the lowest and therefore the first extracted. Generally, five adjacent oocytes, that is, less than 4 mg wet weight, were sampled for each ecdysone assay. The length and width of the central oocyte of each assay were determined using a micrometer These measures enabled a good estimate of oocyte volume[10]. The samples were then frozen in liquid nitrogen and lyophilised. Dissection and sample collection did not take longer than 20 min. In these conditions, there was no noticeable loss of ecdysone during collection of oocytes as verified by replicate dissections at various intervals of time. Ecdysone titre was determined in oocytes sampled from the bottom, middle and top of the ovariole. More detailed sampling was carried out on an ovariole from a 13-d-old pupa, to measure precisely the ecdysone gradient along the ovarian tube.

Ecdysone was determined quantitatively by radioimmunoassay, as before[11]. Lyophilised samples were homogenised in 200 μl 1 N $HClO_4$ by brief sonication. The precipitated protein and the insoluble fraction were removed by centrifugation at 15,000*g* for 5 min. A sample of 150 μl supernatant was neutralised with 15 μl 6 M K_2CO_3 and the resulting salts were removed by further centrifugation. A sample of 100 μl of the second supernatant was used for radioimmunoassay, after suitable dilution in 0.1 M citrate buffer, *p*H 6.2. Results are expressed as pg β-ecdysone equivalent.

Table 1 Ecdysone content (radioimmunoassay activity) of oocytes in *B. mori* pupae*

Pupal (d)	β-ecdysone†	Position of oocytes in the ovarian tube Bottom	Middle	Top	Total ovariole content (pg β-ecdysone)
6	1	1,300	40	ND	21,000
	2	1,870	400	ND

†1, β-ecdysone equivalent content (pg per oocyte); 2, β-ecdysone equivalent concentration (pg μl^{-1}); 3, oocyte dimensions: length × width (mm).

ND, Not done because of small size of oocytes.

Oocytes were collected from the bottom, middle and top of the ovarian tube, in pupae aged 6, 9 and 15 d. Maturation of oocytes begins at the bottom of the ovariole and progresses to the top. To calculate concentration, oocyte volume was estimated by a geometric model[10].

Table 1 shows that maturing oocytes contain ecdysone at high concentrations (the highest value observed was 3,780 pg μl^{-1}, or 8×10^{-6} M). On day 6, the concentration of the hormone was 1,870 pg μl^{-1} in the lowest oocytes, which had just started to mature; whereas there was little or no ecdysone in higher oocytes Later (day 9) the morphogenetic activity in the ovariole had progressed upwards. The ecdysone titre was now at a maximum in the middle part; it had also increased in the top part of the tube, to 460 pg μl^{-1}. On day 9, the bottom oocytes had stopped growing; they contained more ecdysone than previously but less than did middle oocytes of the same ovariole. Finally, on day 15, maturing oocytes were the highest oocytes in the ovariole. They had the highest titre of ecdysone (1,340 pg μl^{-1}), whereas in those at the bottom of the ovariole, where ovulation had finished, the concentration had declined to 420 pg μl^{-1}. Table 1 also suggests that oocyte maturation leads to an increase in the ecdysone content of the entire ovariole.

Detailed ecdysone assays, on day 13, in oocytes of rank 1 to rank 70 confirm these results (Table 2) The concentration was relatively low in oocytes at the bottom and gradually increased towards the top of the ovariole; it peaked in oocyte 66, in good agreement with the data in Table 1.

Our work demonstrates that maturing oocytes of *B. mori* contain ecdysone, and that ecdysone concentration changes considerably during oocyte morphogenesis. The hormone

*Oocytes are numbered from the bottom to the top of the ovariole.
†pg β-ecdysone equivalent per oocyte.

appears at the beginning of maturation and increases during the growth phase, reaching a very high value (close to 10^{-5} M). It then decreases at the end of the process. This lowering of ecdysone concentration is noteworthy; it cannot be attributed to a dilution effect due to oocyte growth, since Table 1 shows that the ecdysone pool in the ovariole continues to increase up to 15 d This implies a gradient of hormone concentration along the ovariole, showing a maximum which moves from the bottom to the top of the ovariole as oocyte maturation progresses upward. The ecdysone titre peaks at the end of the ellipsoidal phase of oocyte morphogenesis, when the oocyte is about 1 mm wide and starts flattening to take on its final shape[9,12].

A few reports have discussed possible roles of ecdysone in ovarian development. In mosquitoes ecdysone controls vitellogenesis[13]; more precisely, it directly activates synthesis of vitellogenin[8]. In the ovary of *Tenebrio molitor,* ecdysone stimulates *in vitro* cell divisions and oocyte growth, and influences follicle organisation[14]. Our report of ecdysone in the oocyte itself raises new questions. We propose that ecdysone behaves as a metabolic symbol, that is, a specific intracellular effector molecule which accumulates when the cell is exposed to a certain environment[15]. Perhaps it has a double role—as suggested by Laverdure's[14] work *in vitro*—stimulating oocyte growth and influencing oocyte morphogenesis. The ecdysone variation we observed in the ovarian tube could reflect the organisational action mentioned by Laverdure[14]. It could also be one element of the longitudinal energy gradient proposed by Legay[12] By our hypothesis, ecdysone action on oocytes is connected to its known effects on the morphogenesis of imaginal disks *in vitro,* in *Galleria*[16] and in *Drosophila*[17].

We were intrigued by the lowering of ecdysone level during the last phase of oocyte development. Further observations indicate that the concentration of the hormone increases again in newly laid eggs of *B. mori* (M.H.H., M. Coulon and M.L.D.-R., unpublished). This shows that ecdysone does not simply accumulate in the cell as a passive component, and that specific pathways exist for ecdysone elimination from oocytes.

Covering response in sea urchins

THE tendency of many species of sea urchins to pick up particles and debris with their spines and tube feet, and to move and then hold the particles on their aboral surface is well known. Functional bases (decreasing the susceptibility to water or wave action, desiccation, light, or predation; supplying nutrients through skin digestion and absorption) have been ascribed to this "covering reaction"[1–13].

In contrast to these 'functional' explanations for the covering response of sea urchins, Dambach and Hentschel[14] concluded that the phenomenon is simply reflexive: mechanical, chemical or photic stimuli produce increased tube feet and spine activity involved in locomotion, or in a generally higher activity level, resulting in the covering of the individual. The suggestion that reflexes are involved has been made before[1,2], but Dambach and Hentschel are the first to provide experimental data to support it. The functional explanations of weight and protection from light involve stimuli (mechanical and photic) which lead to increased activity of the tube feet and spines[2,6]. Support for Dambach and Hentschel's proposal also comes from the previously unreported observation that there is a reversal of the covering response by *Lytechinus variegatus* when it is inverted; thus, material held on the aboral surface is quickly moved orally by inverted animals.

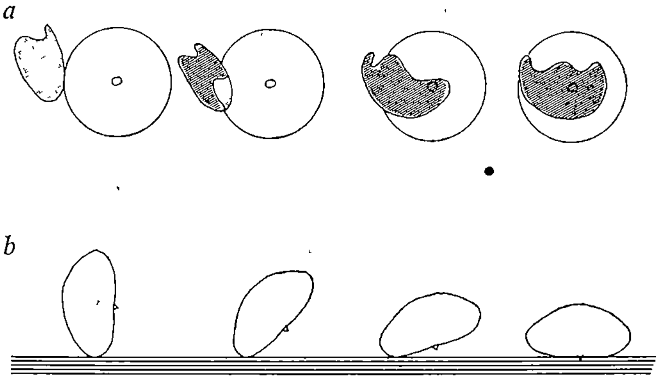

Fig. 1 *a*, Diagrammatic representation of the reversal of the covering response in *Lytechinus variegatus.* A shell, originally on the aboral surface of the animal, has been moved to the ambitus and is subsequently moved to the oral surface. (Drawn from a photographic series). *b*, Diagrammatic representation of the righting response in *Lytechinus variegatus.* The urchin has righted itself to the vertical position where the ambitus is in contact with the substratum. Subsequent positions of the animal in righting correspond to the positions involved in the reversal of the covering response indicated directly above.

Twenty individuals, which were well covered by shell and pebbles on the aboral surface, were collected. The animals were hand held in the inverted position below the surface of seawater in a large container. In each case, the material held by the sea urchin on the aboral surface was moved orally (Fig. 1*a*). This reversal of the covering response seems to be a reflex, particularly when compared with the well known righting response of sea urchins—the tendency of inverted animals to right themselves if physically possible. The activity of the tube feet and spines in the movement of particles in the reversal phenomenon cannot be distinguished from their activity in the righting response; the movement of a particle over the surface of the animal in reversal is identical to that of the animal's surface over the substratum in righting (Fig. 1*b*). A reflexive basis for the reversal of the covering reaction supports the suggestion of a reflexive basis for the covering reaction itself. The functional consequences of covering as proposed by other workers could still be valid, but would not be the casual explanations of the phenomenon.

This work was done at the Galeta Marine Laboratory of the Tropical Research Station of the Smithsonian Institution. I thank Dr G. Hendler for his assistance.

Testing the neutral mutation hypothesis by distribution of single locus heterozygosity

ONE of the most controversial issues in population genetics at present is whether the widespread protein variation in natural populations is maintained by some form of balancing selection[1–3] or merely represents the drifting polymorphism of neutral or nearly neutral mutations[4–6]. By the neutral mutation hypothesis the level of genetic variability in an equilibrium population is determined by mutation rate, v, and effective population size, N_e. If we use the infinite allele model, in which new mutations are assumed to be always different from the pre-existing alleles in the population, the average heterozygosity per locus is given by

$$H = M/(1+M) \qquad (1)$$

where $M = 4N_e v$ (ref. 7).

Whether the observed heterozygosity agrees with the above theoretical value or not is, in practice, however, very difficult to examine, since the exact values of N_e and v in a population are hardly obtainable. Recently, it was shown[8,9] that the variance of single locus heterozygosities is given by

$$V(h) = \frac{2M}{(1+M)^2(2+M)(3+M)} \qquad (2)$$

From this the neutral mutation hypothesis can be tested without knowing the values of N_e and v separately. By estimating M from the observed value of average heterozygosity, we can compute the theoretical variance by using equation (2) and then compare it with the observed variance[10] Preliminary results of the application of this method to a number of organisms have suggested that the agreement between the theoretical and observed variances is rather good[11,12], but the amount of data used was too small to make any general conclusion. We have accumulated all published data which are amenable to such a test. In this report we show that the observed variances of heterozygosity in most organisms so far studied can be reasonably explained by the neutral mutation hypothesis. The pattern of the distribution of heterozygosity also agrees with that expected from this hypothesis.

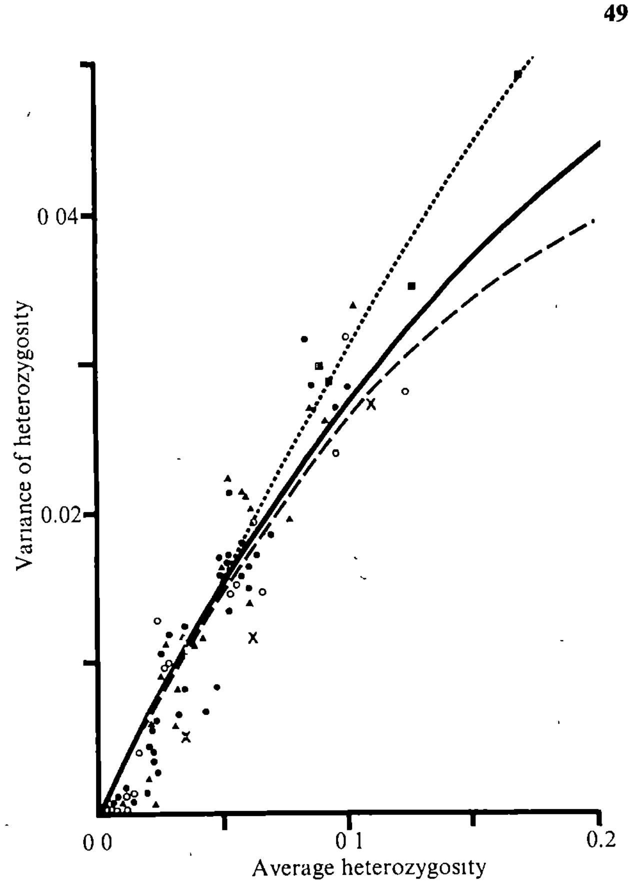

Fig. 1 Relationship between the mean and variance of heterozygosity for vertebrate species: ●, mammals (33 species); ×, birds (2 species, 1 subspecies); ○, fish (18 species, 1 subspecies); ▲, lizards (21 species); ■, amphibians (3 species, 1 subspecies). The solid and dashed lines are the theoretical relationships obtained from the infinite allele and stepwise mutation models, respectively. The dotted line is the theoretical relationship for the infinite allele model with varying mutation rate

Surveying 52 publications, we collected gene frequency data obtained by electrophoresis for 123 species and 8 subspecies, in which 15 or more loci were examined for at least 30 genomes. It is known that for estimating average heterozygosity a large number of loci should be used, whereas the sample size per locus can be rather small[10]. For each of the species and subspecies used, the mean, $\hat{H}$, and variance, $\hat{V}(h)$, of single locus heterozygosity was computed with a correction for sampling variance[10]. When a species or subspecies comprised a number of subpopulations, the average values of $\hat{H}$ and $\hat{V}(h)$ for these were used. The relationship between $\hat{H}$ and $\hat{V}(h)$ was compared with the theoretical one (solid lines in Figs 1 and 2) obtained from equations (1) and (2) It can be argued that the stepwise mutation model[13] is more appropriate for electrophoretic data than the infinite allele model. Therefore, we have also computed the theoretical curve for this model (broken line) using Ohta and Kimura's formula[13] for H and Moran's formula[14] for $V(h)$. Actually, as Figs 1 and 2 show, there is not much difference between the two models unless H is very large. Since there seems to be a significant difference in average heterozygosity between vertebrates and invertebrates[15], the two groups have been considered separately (Figs 1 and 2).

It is clear that the observed variances for vertebrates are generally in good agreement with the theoretical values, in spite of the fact that the number of loci used is relatively small and data on diverse organisms are included. A close examination of Fig. 1, however, indicates that when $\hat{H}$ is smaller than 0.05

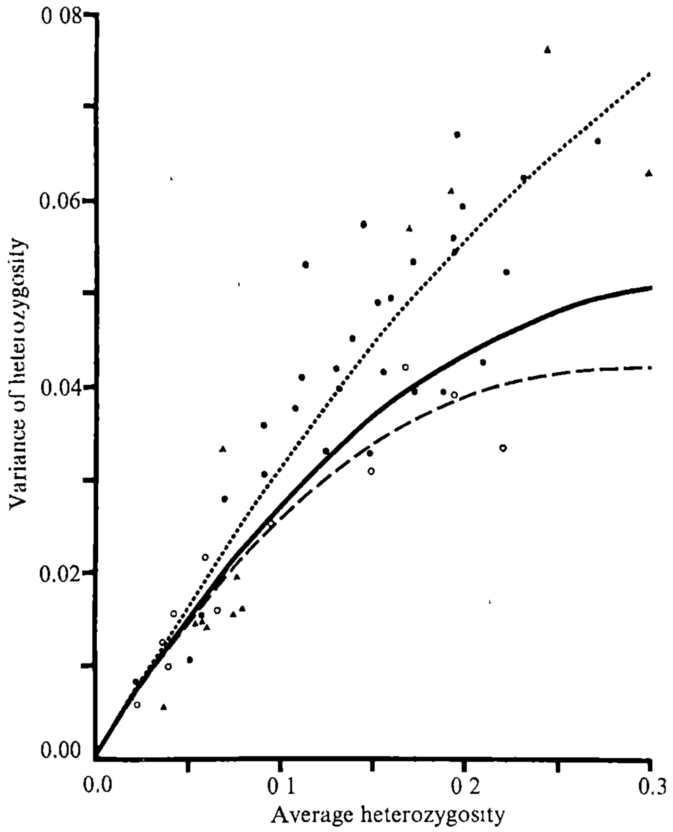

Fig. 2 Relationship between the mean and variance of heterozygosity for invertebrate species: ●, *Drosophila* (24 species, 5 subspecies); ▲, other insects (12 species); ○, other invertebrates (10 species). The solid and dashed lines are the theoretical relationships obtained from the infinite allele and stepwise mutation models, respectively. The dotted line is the theoretical relationship for the infinite allele model with varying mutation rate.

the observed variance tends to be smaller than the theoretical curve, whereas for $\hat{H} > 0.1$ it tends to be larger. The agreement between the theoretical and observed variances in invertebrates is also generally good, though the tendency for the observed variance to deviate upward is pronounced because of higher heterozygosities in this group of organisms.

The tendency for the observed variance to deviate upward for large $\hat{H}$ does not contradict the neutral mutation hypothesis and is expected to occur for the following reason. The formula for $V(h)$ is based on the assumption of identical mutation rates for all loci in both theoretical models used here. In practice, this assumption is surely incorrect, and when mutation rate varies among loci, the variance of heterozygosity is expected to inflate. To get an idea about the amount of inflation, we computed the expected variance of heterozygosity from the assumption that mutation rate varies among loci according to the gamma distribution with the coefficient of variation equal to one. The gamma distribution with this value of coefficient of variation was suggested by the examination of the rates of amino acid substitution for 19 polypeptides in evolution (Nei, Chakraborty and Fuerst, unpublished). From the assumption of neutral mutations the rate of amino acid substitution per polypeptide is equal to the mutation rate per locus, neglecting synonymous mutations[4]. At any rate, the results obtained are given by the dotted lines in Figs 1 and 2. It is clear that the agreement between the theoretical and observed variances is now very good.

The tendency for the observed variance to deviate downward for a small value of $\hat{H}$ is apparently caused by the relatively small number of loci studied (about 20) in this group of organisms. When the theoretical value of H is relatively small, the distribution of single locus heterozygosity, h, is extremely skewed towards the class of $h = 0$ (Fig. 3). Thus, whenever the sample estimate of H is small, the observed value of $V(h)$ tends to be smaller than its expected value. Our computer simulation has shown that the difference between the observed and theoretical variances for $\hat{H} \leqslant 0.05$ is of the order of magnitude that is expected to occur when the number of loci is about 20. The details of this study will be published elsewhere. Thus, the data presented in Figs 1 and 2 are consistent with the neutral mutation hypothesis.

In Fig. 3 the frequency distributions of single locus heterozygosity for three species groups in which a large number of loci have been studied are presented together with one theoretical distribution obtained by computer simulation[16]. This theoretical distribution is based on 2,000 replicate evaluations of h with the expected heterozygosity of 0.09, which is close to the observed average heterozygosities for the three species groups. All empirical distributions are L-shaped and very similar to the theoretical one. In both empirical and theoretical distributions there is a little peak around $h = 0.5$. Existence of this peak has been theoretically predicted[8,17]. In addition to those in Fig. 3, we examined the distribution of heterozygosity for all other species. The pattern of the distribution was essentially the same as that expected from the neutral mutation hypothesis for most species.

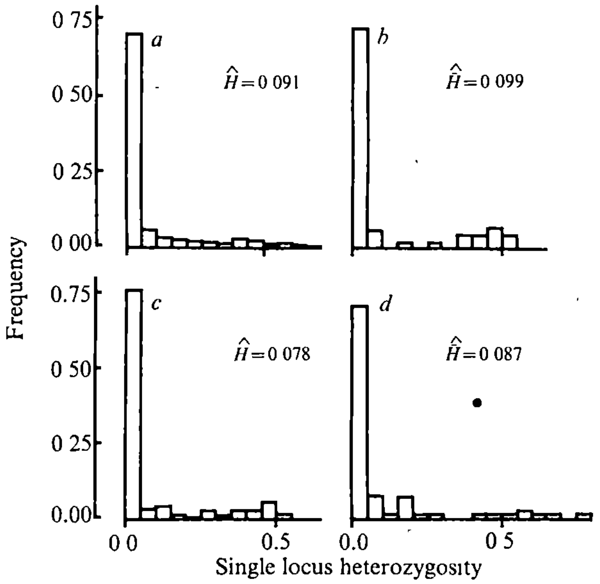

Fig. 3 Distributions of single locus heterozygosities for *b*, man (Caucasian)[11]; *c*, the house mouse[20,21] (*Mus musculus*) and *d*, the *Drosophila mulleri* species group[22]. The theoretical distribution (*a*) was obtained by computer simulation with the infinite allele model. $\hat{H}$ stands for the average heterozygosity. The distribution for the stepwise mutation model is almost identical with that for the infinite allele model when $\hat{H} = 0.09$.

We are aware that our observations about the variation and distribution of heterozygosity can be explained by some elaborate combination of different types of selection. Such an explanation is, however, strained, since we then have to assume that selection is adjusted so as to have a good agreement between the observed and theoretical variances in diverse organisms. It seems to us that the simplest and most natural explanation is the neutral mutation hypothesis. Note that this hypothesis does not exclude the existence of a small proportion of overdominant or selectively advantageous mutations. Furthermore, our analysis will not exclude the possible importance of slightly deleterious mutations[18,19], of which the contribution to heterozygosity is relatively small.

We thank Yoshio Tateno for some numerical computations involved in this study. We are also grateful to Professor P. A.

P. Moran for his unpublished formula. This work was supported by grants from the NIH.

Y chromosome visibility in quinacrine-stained human spermatozoa

THE fluorescent dye, quinacrine, binds strongly to the Y chromosome and only to a lesser extent to the other chromosomes in human metaphase cell preparations[1]. A bright fluorescent spot (F body), which is presumed to be the Y chromosome, is clearly visible in stained interphase cells from various tissues from the human male[2-5] and in mature spermatozoa[6,7]. Spermatozoa bearing one F body (about 45% of the total) are taken to be Y spermatozoa, and the staining method is now being used widely to detect physical differences, for example, in DNA content and head size[7,8] and motility[9] between X and Y spermatozoa, and for testing the efficiency of procedures designed to separate them[10-13]. Spermatozoa bearing two F bodies (about 1.3% of the total) have been interpreted as YY spermatozoa[7,8], and the relatively high number of such spermatozoa has led to speculation concerning the seemingly high non-disjunction rates during spermatogenesis[8,14,15]. We here examine the factors which affect Y chromosome visibility in sperm heads, and conclude that the F body count depends critically on observer performance, that the presence of YY spermatozoa cannot be demonstrated decisively using the quinacrine stain, and that measured physical differences between spermatozoa with and without an F body may partly reflect a dependence of the Y chromosome detection efficiency on the size of the sperm head.

When a brightly fluorescent chromosome inside a nucleus is examined under the ultraviolet microscope it appears as a bright spot against a less bright background which is produced by fluorescence from the other nuclear contents and from any unbound dye which may be present. The chromosome is detected by the observer provided that the spot intensity is more than 1 or 2% above that of the background[16], the condition for detection then being

$$(I_0 \exp(-k\bar{x})-I_B)/I_B \gtrsim 0.01\text{–}0.02 \qquad (1)$$

where $\bar{x}$ is the mean depth (weighted and averaged over all directions which lie within the acceptance cone of the objective lens) at which the chromosome is buried in the head, I_0 is the intensity of the spot which would be produced if the chromosome were located at $\bar{x} = 0$, I_B is the background intensity and k is an optical attenuation coefficient.

Almost 50% of spermatozoa are expected to carry a Y chromosome, and since only about 45% exhibit an F body it seems that about a tenth of all Y chromosomes are not detected by the staining procedure. There are two possible explanations. The first is that stain uptake among Y chromosomes from cells of any one individual may be very variable, the missing chromosomes being those which absorb so little stain as to be indiscernible above the background fluorescence. The second is that the optical attenuation coefficient is sufficiently great that chromosomes lying deep in the head are not detected[6]. This coefficient has two components. The refractive index of the DNA within the head is high (probably about 1.5 (ref. 17)) compared with that of the aqueous mounting medium (1.33) which surrounds and permeates the sperm head. If the fluorescent Y chromosome is located at the bottom of a uniform sphere of refractive index 1.5 immersed in a medium of refractive index 1.33, the average refractive deviation of light leaving the chromosome and passing through the sphere is found using Snell's law to be about 15°, sufficient to reduce the intensity of a chromosome of diameter 500 nm to about 25% of its undiminished value. If the other chromosomes each refract the light from the Y chromosome in this way the total deviation will be considerably greater than 15° across the optically inhomogeneous sperm head. In addition, the dimensions of the chromosomes are comparable with the wavelength of the fluorescent light, and diffractive scattering will occur within the sperm head, increasing background fluorescence at the expense of spot intensity. Optical attenuation may therefore be the dominant mechanism, and some support for this hypothesis is afforded by the observation that about 70% of F bodies appear at or very near the region where the background fluorescence becomes less dense[15]. We have estimated the intensities of F bodies by comparing microscope images of quinacrine-stained spermatozoa with matching images projected on to a screen in the same conditions (green light; dark-adapted vision) and measuring the screen intensities with a photometer. F body intensities varied from about 10% (the brightest) to about 1% (that is, the detection threshold) above background. Assuming that the brightest spots correspond to Y chromosomes at $\bar{x} = 0$ and that the Y chromosome is randomly distributed within the head, then $k \sim 50$ mm^{-1} would give the observed proportion of spermatozoa carrying an F body.

Other chromosomes, although fluorescing less brightly than the Y chromosome, may nevertheless be detected if they are located near the surface of the sperm head. If P_y is the probability of detecting a Y chromosome in a Y spermatozoon, and P_c is the probability of detecting any other chromosome (or other artefact such as adhering bacteria or vacuoles within the head[15]) then, assuming that X and Y spermatozoa occur in equal numbers (and, initially, that no YY spermatozoa are present) the percentages of spermatozoa exhibiting one and two F bodies, P_1 and P_2, are given by

$$P_1 = 50P_y(1-P_c)+100(1-\tfrac{1}{2}P_y)P_c$$

and

$$P_2 = 50P_y\mathrm{P}_c+100(P_c)^2 \ .$$

Solving for $P_1 = 45\%$ and $P_2 = 1.3\%$ yields $P_y \sim 0.89$ and $P_c \sim 0.0275$, this being the only solution for which both P_y and P_c lie within the range 0–1. These figures may be compared with those from buccal mucosa cells and lymphocytes where cells of known karyotype are examined[2,3]. A fluorescent spot indistinguishable from a normal Y body[2] occurs in about 5.5% of cells from 46,XX females who carry no Y chromosome, and cells from 46,XY males, carrying one Y chromosome, have one F body in about 67% of cases[2,3]. Thus $P_y \sim 0.65$ and $P_c \sim 0.055$, and the Y chromosome is clearly more difficult to detect in these cells than in spermatozoa.

Several conclusions may be drawn from this analysis. First, if the artefact rate (P_c) in spermatozoa is comparable with that in somatic cells it is clearly unnecessary to invoke the presence of any YY spermatozoa to account for those which exhibit two F bodies. It therefore seems that no estimate of the non-disjunction rate for the Y chromosome can be obtained from staining data, and similar considerations probably apply to estimates obtained using differential stains which are specific for other chromosomes[8]. If YY spermatozoa are not present in appreciable numbers then about 90% of Y spermatozoa are detected by the technique, and of those with one F body about 97% are Y spermatozoa, the rest being X spermatozoa with another fluorescing chromosome or other artefact. These figures for the efficiency may be optimistic, however, since it is assumed that the criterion for detecting an F body is the same whether one or two are present in the cell, and it seems likely that spermatozoa are only classified as bearing two F bodies when both are reasonably bright[15].

Second, equation (1) shows that the counting rate depends critically on observer performance. An observer who decreases his threshold from, say, 2% (distinct spots) to 1% (where any slight local brightening of the background is taken to be an F body) will, on the basis of the present model, increase his F body count from 40 to 50% (with only 40% of the increase coming from newly detected Y chromosomes); and the increase will be even greater if other chromosomes become visible at the new threshold level.

Finally, the present theory suggests that Y chromosome visibility depends on sperm head size, and on the basis of a constant optical attenuation coefficient of 50 mm^{-1} we estimate that P_y will increase from 0.8 to 1.0 with decreasing head size over the range of naturally occurring head volumes[18], together with a corresponding variation in P_c. This may account for the higher detection efficiency in spermatozoa compared with that in the larger somatic cell nuclei. Larger Y spermatozoa will therefore tend to be categorised as X spermatozoa, although the effect could be reduced (or even reversed) if for some reason the background fluorescence of the head itself decreased with increasing head size. Unexpectedly large differences in head area between spermatozoa with and without an F body[8] may therefore reflect variations in chromosome visibility with head size, and need not necessarily imply the occurrence of haploid gene expression in spermatozoa.

We thank the MRC for support.

Absence of axonemal arms in nasal mucosa cilia in Kartagener's syndrome

A TOTAL lack of axonemal arms in the spermatozoa of infertile men has been described[1–3] and those results included those from four men, three of whom had situs inversus of the thoracic organs while the fourth was a brother to one of the others. The total absence of axonemal arms (dynein arms) was deemed to be responsible for the complete immobility of their sperm tails. Kartagener's syndrome[4] exhibits the following symptoms: chronic sinusitis, bronchiectasis and situs inversus Sperm flagella and cilia have similar ultrastructure in principle, so it was thought possible that the respiratory tract symptoms in patients with Kartagener's syndrome might be caused, by a lack of dynein arms in the cilia. We have thus investigated the cilia of Kartagener patients at the substructural level.

The patient examined was a 25-yr-old woman, who had had daily airway symptoms from birth consisting of a cough and mucopurulent secretion from the lower, as well as from the upper, respiratory tract. She underwent surgical treatment for sinusitis, nasal polyposis and bronchiectasis. Her hearing was also impaired by chronic secretory otitis media. X-ray examination demonstrated dextrocardia. Rhinoscopy revealed small nasal polyps, but patent nasal airways. Nasal mucociliary transport function was examined on three separate occasions using the saccharine-dye method[5]. After cocaine anaesthesia, a mucosal biopsy was taken from the inferior turbinate. An additional biopsy from a polyp was taken without anaesthesia. The tissue was immediately fixed in collidine-buffered glutaraldehyde and after a short buffer rinse, postfixed in osmium tetroxide with the same buffer. After dehydration in graded concentrations of ethanol and propylene oxide the tissue was embedded in Epon. Sections stained with uranyl acetate and lead citrate were examined in a Philips 301 electron microscope. The technique was identical to that used for the examination of immobile human spermatozoa[1,2].

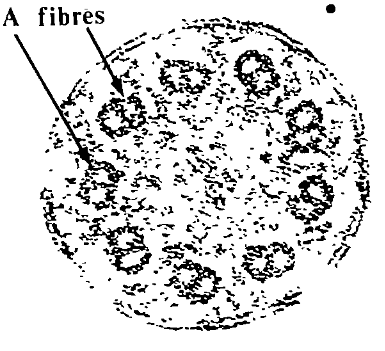

Fig. 1 Cross section of a cilium showing derangement of the axonemal matrix, but normally placed outer doublets. There is no consistent structure comparable with dynein arms on the A fibres. In this section the two central tubules are not recognisable, but in other sections they seem to be normal.

After intranasal application of the saccharine-dye particle, the patient was observed for at least 2 h, during which she did not notice any sweet taste in the mouth and no dye was observed in the throat. The normal mucociliar transport time in the nose is 10–30 min (ref. 5). Electron microscopy showed that the cilia had a uniform appearance and transverse sections revealed identical pathological findings. The microtubules were normal in position and appearance, but a common abnormal feature was an apparently total lack of dynein arms on the outer microtubules. The picture was obscured to a certain extent by complete disorganisation of the axonemal matrix (Fig. 1), so that only occasional remnants of the central sheath and spokes could be recognised. Many cross sections of cilia were examined and all showed the same abnormal features. One single cilium had structures similar to dynein arms, but whether or not these represented remnants of the C-tubule of the centriole could not be determined. All cross sections of centrioles seemed to be normal.

There is significant experimental evidence that dynein arms are essential for ciliary and flagellar motility, possibly by containing, or consisting of, protein with contractile properties (for review, see ref. 6). Spermatozoal motility is apparently not possible where there is a total lack of axonemal arms[1-3]. Our results suggest that these structures are also necessary for ciliary motility in the airways, as experiments have shown total absence of bronchial mucociliary transport in patients with Kartagener's syndrome[7]. Chronic infection, various pharmacological treatments and the preparatory procedures might, however, obscure the original basic defects and further studies, including more control measures, are needed.

If the present results and those described previously in human spermatozoa indicate the inability of such patients to produce dynein arms the same changes should be found in cilia from other sources, such as endometrium and uterine tubal mucosa. Such studies, including all the control measures mentioned above, are in progress in this laboratory. The patient described here has a long standing primary infertility of unknown origin.

Although Kartagener's syndrome simulates an immunodeficiency, immunological investigations have failed to disclose any factors of primary importance[8]. An hereditary disability to form dynein arms and the consequent lack of any mucociliary function could, however, explain the symptoms in these patients, and also why they are localised to ciliated organs.

We thank Dr Ib Andersen for supply of the saccharine-dye particles. H.P. was supported by Statens Laegevidenskabelige Forskningsraad, Denmark, and Den Laegevidenskabelige Forskningsfond for Storkøbenhavn, Faerøerne og Groenland, Copenhagen.

Separation of suppressor and killer T cells by surface phenotype

AMONG thymus-derived (T) lymphocytes of the mouse, several functionally distinct subsets may be identified (for review, see ref. 1). Early studies have shown synergy in graft-*versus*-host reactions of different populations of lymphoid cells[2], and *in vitro* studies have demonstrated interactions between cells from anti-lymphocyte serum-treated mice (T_1 cells) and adult thymectomised mice (T_2 cells)[3]. A similar synergy has been observed in the generation of T helper and T suppressor cells *in vitro*[4]. Clearer definition of the subsets of T cells interacting in the induction of immune responses has come from the use of alloantisera recognising differentiation antigens on T cells. In particular, the use of antisera to the Ly series of antigens[5] has enabled the separation of amplifying (MLR) cells from killer cells[6]. Similarly in the humoral response helper T cells can be distinguished from suppressor T cells[7]. In this report, we show that killer and suppressor T cells, both generated *in vitro* and carrying the Ly-2 and 3 antigens can also be separated using antisera to surface antigenic markers. We also present data suggesting that suppressor cells of similar phenotype may have an important function *in vivo* in the immune response.

Soluble protein antigen-specific suppressor cells and alloimmune killer cells were both generated in Marbrook culture flasks, as described previously[8,9]. Keyhole limpet haemocyanin (KLH)-specific suppressor cells were assayed in a second culture by their ability to abrogate the effect of KLH-primed helper cells[8,10]. Killer cells were assayed in a 4-h ^{51}Cr release test on P815 mastocytoma cells[11].

Anti-Ly antisera were prepared and tested as described previously[7,12]. Anti-Ia^k was prepared by repeated intraperitoneal immunisation of A.TH mice with A.TL spleen cells[13], and used unabsorbed. Rabbit serum absorbed with mouse spleen cells was the source of complement.

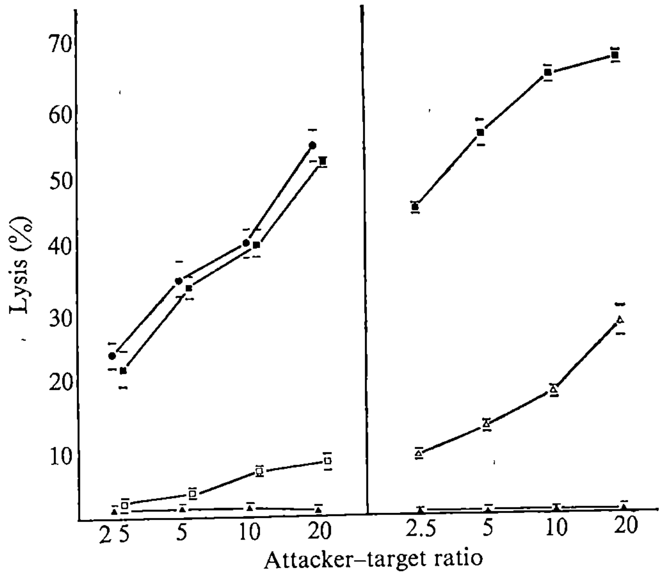

Fig. 1 Effect of anti-Ly, anti-Ia^k and anti-Thy-1 antisera and complement on alloimmune killer T cells. CBA killer cells were induced in Marbrook culture flasks by stimulation of spleen cells with 1,500 R irradiated BALB/c spleen cells[9]. Aliquots of 2×10^6 viable cells from the cultures were treated with 0.2 ml antiserum (at a concentration giving maximal lysis[7]) washed and treated with 0.2 ml absorbed rabbit complement at 1:10 dilution. After treatment cells were washed and resuspended to a fixed volume, giving a viable cell concentration in medium or complement-treated aliquots, of 2×10^6 cells ml^{-1}. Aliquots (0.1 ml) of treated cell suspensions were added to wells of round bottom microtitre plates (Linbro), containing 0.1 ml of a suspension of ^{51}Cr-labelled P815 mastocytoma cells at 10^5 cells ml^{-1}. After brief centrifugation at 150*g* (approximately 1 min) the plates were incubated for 4 h in a moist atmosphere of 10% CO_2 in air After a further centrifugation (300*g* for 1 min), 0.1 ml supernatant was collected from each well for γ counting. Low controls were incubated in medium (HEPES buffered Dulbecco's Eagles medium) alone and 100% ^{51}Cr release was taken as counts released by 5% Brij. ●, Anti-Ia^k; □, anti-Ly-2.1+3.2; ▲, anti-Thy-1.2; △, anti-Ly-1 1; ■, complement alone. Sera in absence of complement had no effect (data not shown). Four experiments with anti-Ly-1 1 and five with anti-Ia^k have been carried out using three batches of antiserum. All points are mean of triplicate cultures; bars represent standard error; % lysis calculated by the formula:
(c.p.m. killer cells – c.p.m. medium alone)/(c.p.m. detergent) × 100

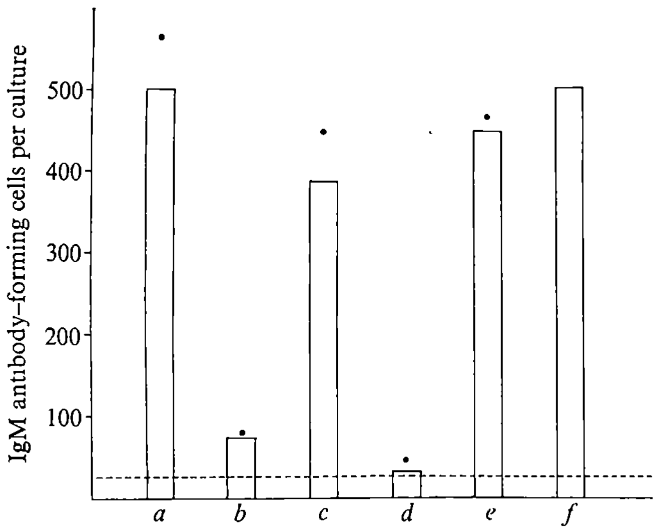

Fig. 2 Effect of anti-Ia^k and anti-Ly-3.2 sera and complement on specific suppressor cells generated *in vitro* from CBA spleen cells. Helper cells were induced as described previously[10]. In brief, spleen cells were cultured in Marbrook flasks with 0.1 µg KLH (a gift of Dr M. B. Rittenberg, Portland, Oregon) for 4 d in Eagle's MEM containing 5% foetal calf serum. Helper cells were assayed, in a second Marbrook culture, by their ability to cooperate with trinitrophenol (TNP)-reactive B cells present in normal CBA spleen in the presence of TNP–KLH. Anti-DNP or -TNP antibody-forming cells were assayed using hapten-conjugated anti-sheep red blood cell (SRBC) Fab′ fragments coupled to SRBC, using the Cunningham plaque assay. Suppressor cells were induced by culturing in similar conditions but with 100 µg KLH. Suppressors were assayed by their capacity to inhibit the helper effect of 3×10^5 helper cells. Tests for the specificity of the suppressor effect were as described previously[8]. Suppressor cells were treated with anti-Ia at 1:10 dilution or anti-Ly-3.2 at 1:20, washed and treated with absorbed rabbit complement at 1:10. After treatment cells were counted in Trypan blue and 10^4–10^5 viable cells assayed for suppressor activity. In absorption experiments sera were absorbed for 30 min at room temperature with an equal volume of packed spleen and thymus cells of appropriate mouse strain (A.TL or A.TH) and diluted to 1:10 for use. Dotted line, Number of plaques produced in presence of antigen but absence of helper cells. Dots above bars, s.e. *a*, Helper cells; *b*, helper cells+suppressor cells; *c*, complement+anti-Ia; *d*, complement+anti-Ia (absorbed using A.TL); *e*, complement+anti-Ia (absorbed using A.TH); *f*, complement +anti-Ly 3.2.

Figure 1 presents the results of two typical experiments on CBA (H–2^k, Thy-1.2, Ly-1.1, 2.1, 3.2) killer cells. In both experiments anti-Thy-1.2 completely abolished cytotoxicity, whereas anti-Ia^k had no effect. Anti-Ly-1.1 and the mixture of anti-Ly-2.1+3.2 both substantially reduce killer cell activity. In similar experiments anti-2.1 and anti-3.2 reduced but never abolished cytotoxicity, the effect of an individual serum being less than the mixture. In contrast to these results, Fig. 2 shows the effects of some of the same antisera on suppressor activity. Anti-Ia abolished suppressor activity, whereas anti-Ly-1.1 had no effect up to $1/10^7$. We have previously shown that anti-Ly-2.1 alone completely abrogates suppressor activity[7]; Fig. 2 shows that the same is true for anti-Ly-3.2.

That the effect of the anti-Ia antiserum was due to activity against antigenic determinants coded by the *I* region, was confirmed by the results of absorption experiments (Fig. 2). The anti-CBA suppressor activity could be removed by absorption with A.TL lymphocytes, which have the same H–2^k *I* region as CBA, but not by A.TH cells which are H–2^s. Note that the serum was also able to abolish the suppressor activity of C57BL/10 cells (data not shown) which share with CBA only a single known *I* region specificity[14].

Table 1 presents an *in vivo* correlate of the *in vitro* data. KLH-primed T cells, which are able to cooperate with B cells *in vivo* to give an anti-hapten response, gave a greatly increased response after treatment with anti-Ia and complement, indicating that the treatment had removed a population of suppressor cells bearing the Ia determinant.

We conclude that the antigenic phenotype of CBA killer T cells is Ly-1$^+$,2$^+$,3$^+$,Ia$^-$, whereas suppressor cells are Ly-1$^-$,2$^+$,3$^+$,Ia$^+$. The Ly phenotype for killer cells differs from that found in C57BL mice (Ly-1.2, 2.2, 3.2) in which killer cells are Ly-1$^-$,2$^+$,3$^+$ (refs 6 and 16), but agrees with the finding that in the C57BL Ly-1.1 congenic mouse, killer cells seem to be Ly-1$^+$,2$^+$,3$^+$ (ref. 16). In the same study, anti-Ly-2.1 alone had little effect on killer cells. Our data do not distinguish between the possibility that some CBA killer cells bear either 2.1 or 3.2, or alternatively that all killer cells bear low concentrations of both antigens, but it seems likely that there is heterogeneity among killer cells.

Table 2 Ly phenotype of T cell subsets

Function	Ly phenotype	Reference
Helper	1$^+$	7, 21
Suppressor	2$^+$ 3$^+$	7, 22, 23
Killer in Ly-1.1 mice	1$^+$ 2$^+$ 3$^+$	6, 16
in Ly-1.2 mice	2$^+$ 3$^+$	6, 16

It is also clear that although anti-Ly sera are useful markers for T cell subsets, antisera to the two alleles of each locus do not always have the same effect. The reason for this discrepancy is not yet clear but may reside in undetected residual genetic heterogeneity in the Ly congenic stocks or in the differences in titre of the various sera (discussed in ref. 16). Table 2 summarises current information on the Ly phenotype of T cell subsets.

Our findings confirm a previous report that suppressor

Table 1 Reduction of suppressor cell activity by treatment with anti-Ia serum and complement

DNP-primed cells	KLH-primed helper cells	Treatment	Antigen	Anti-DNP response (PFC/spleen)
10×10^6	Nil	Nil	50 µg DNP KLH	3,660±660
10×10^6	2×10^6	Nil	50 µg DNP KLH	9,240±686
10×10^6	2×10^6	C′ alone	50 µg DNP KLH	9,720±362
10×10^6	2×10^6	Anti-Ia+C′	50 µg DNP KLH	26,340±2,882
10×10^6	2×10^6	Anti-Thy-1.2+C′	50 µg DNP KLH	3,480±595

CBA mice (70–200-d old) were used. Mice were primed to dinitrophenol (DNP) by intraperitoneal immunisation, 6 weeks before use, with 100 µg alum-precipitated DNP–chicken γ globulin KLH helper cells were prepared by two intraperitoneal immunisations with 100 µg KLH absorbed to Bentonite at weekly intervals and subsequently boosted with 100 µg soluble KLH. Five days after the last injection a spleen cell suspension was prepared and passed over nylon wool columns to remove B cells[15]. Effluent cells were treated with anti-Ia^k or anti-Thy-1.2, followed by complement C′. Treated cells were mixed with DNP-primed cells and injected into 750 R irradiated CBA hosts These were boosted intraperitoneally 1 d later with 50 µg DNP–KLH. Seven days later the spleens were removed and assayed for IgG DNP plaque-forming cells.

cells bear Ia determinants[17], and provide new information that killer cells are Ia negative. The finding of Ia on suppressor cells is particularly interesting in view of recent data showing that specific suppressor factor isolated from T cells, carried similar antigens[18]. Although some workers have failed to detect Ia antigens on T cells[19], others have reported that both thymocytes and peripheral T cells carry these antigens[20]. Our data using functional assays for T cells show that at least suppressor T cells carry antigen(s) coded in the *I* region of the *H-2* complex. It is not clear whether exactly the same Ia antigen(s) was detected on B and T cells.

We thank Dr U. Hammerling (Memorial Sloan Kettering Cancer Center, New York) for anti-Ly and anti-Ia sera, and Dr H. O. McDevitt for anti-Ia.

Plasma membrane glycoprotein which mediates adhesion of fibroblasts to collagen

DEFECTS in cell behaviour associated with malignancy may be causally related to alterations in the plasma membrane of the cell on transformation[1]. Much interest has focused on a protein found on the surface of normal but not transformed cells [2–7]. This protein, designated SF (ref. 5), LETS (ref. 8), band 1 (ref. 9), Ll (ref. 3) or CSP (ref. 10), is a glycoprotein[7,9,11] with a molecular weight of 210,000–250,000 (refs 7, 8 and 12). It is present in the serum[12] and is sensitive to removal from the surface of normal fibroblasts by low levels of trypsin[2,3,9]. Several biological properties of this protein have been described. Normal fibroblasts arrested in mitosis lack this protein[8,9]. As normal cells approach confluency, there is a quantitative increase in the amount of this protein present on the cell surface[8,9], whereas confluent normal cells, stimulated by the addition of serum, have lowered levels[8]. In conflict with these results, implying a growth regulatory function, is the finding that stimulation of growth-arrested normal cells by thrombin leads to thymidine incorporation without a concomitant decrease in the levels of this protein[13]. We now present evidence which points to a functional role for the protein as a mediator of the adhesion of fibroblasts to collagen. The protein is probably identical to a serum factor previously reported to be necessary for the attachment of SV40-transformed 3T3 fibroblasts to collagen-coated dishes[14]. Based on this functional role, we propose the name cell adhesion factor (CAF) for this protein.

Table 1 Attachment of PyBHK cells to collagen in the presence of added factors

Protein addition	Concentration of added protein	% PyBHK cells attached to collagen
None	—	8
Serum (%)	1	50
	10	90
	50	96
CAF (μg ml^{-1})	0.5	3 (0–6)
	1	4 (2–7)
	5	9 (7–12)
	10	12 (10–15)
	20	29 (25–32)
	30	71 (65–77)
	40	90 (86–93)
	80	96 (94–97)
PyBHK extract (μg ml^{-1})	100	5

Assessment of cell binding to collagen-coated dishes in the presence or absence of CAF was carried out essentially as described by Klebe[14]. Plastic Petri dishes (60-mm diameter) were evenly covered with 1.5 ml 0.25% collagen (acid soluble, Type IV, Sigma) in 0.2% acetic acid plus 0.002% phenol red. Dishes were placed in plastic containers, containing open dishes filled with NH_4OH and the containers were sealed for 10 min to allow for gelation of the collagen. The dishes were air-dried overnight, washed with 8 M urea for 20 min then three times for 5 min with H_2O, and allowed to air-dry. The treatment with urea decreased attachment of cells in the absence of added protein and increased the effectiveness of CAF-mediated attachment. Coated dishes were incubated with either 0.5 ml medium, calf serum, or CAF at various concentrations for 1 h at 37 °C. All solutions contained 200 μg ml^{-1} BSA. During this incubation, cells were removed from monolayers with 0.25% trypsin–EDTA (Gibco), washed twice with medium containing 200 μg ml^{-1} BSA, and counted in a Coulter counter. Incubated dishes then received 10^6 cells in 4.5 ml E4-BSA. After incubation for 1.5 h, unattached cells were removed by decanting the medium and washing gently once with fresh medium. Attached cells were removed by treatment with trypsin–EDTA and cells counted in a Coulter counter. The percentage of cells attached to the collagen was calculated as the number of attached cells/total number of attached cells plus the number of unattached cells. Usually 80–90% of plated cells were recovered. The average of five determinations and the range of values are given. Protein was determined by the method of Lowry *et al.*[19].

The BHK 21/C13 hamster cells and a derivative transformed by polyoma virus (PyBHK) were obtained from stocks at the Imperial Cancer Research Fund, London, and were maintained in Dulbecco's modification of Eagle's medium (E4) containing 10% calf serum (Gibco) in a 5% CO_2 incubator at 37 °C. The BHK cells possess high

Table 2 Ca^{2+} and Mg^{2+} dependence of cell attachment to collagen in the presence of CAF

Cell	CAF (μg ml^{-1})	Ca^{2+}/Mg^{2+}*	% Cells attached†
PyBHK	—	—	5
PyBHK	100	—	9
PyBHK	—	+	8

†Average of two determinations.

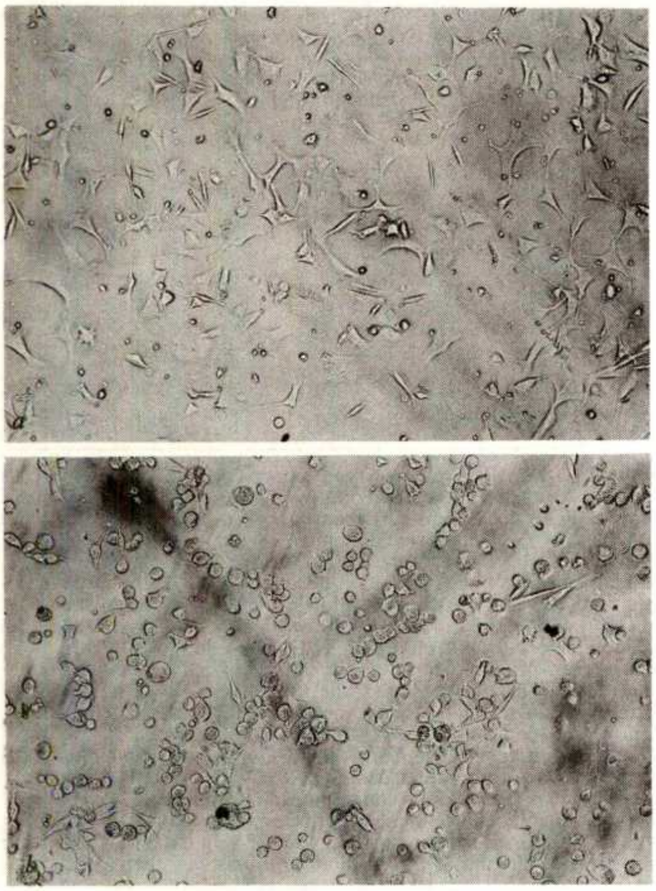

Fig. 1 Attachment of PyBHK cells to collagen-coated dishes under the influence of CAF (magnification × 65). Cells were incubated 1.5 h at 37 °C with 80 µg ml^{-1} CAF (*a*) and media containing 200 µg ml^{-1} BSA (*b*).

levels of CAF, whereas the PyBHK cells lack detectable amounts[9].

CAF was purified from BHK cells as described previously[15]. Polyacrylamide gel analysis demonstrated that the major purified protein co-migrated with the lactoperoxidase iodinated CAF obtained after surface labelling of BHK cells[9]. Immediately before use in the attachment assay, purified CAF was solubilised in medium containing 200 μg ml^{-1} BSA.

BHK-extracted CAF was effective in mediating the attachment of cells to collagen-coated dishes. The results shown in Table 1 clearly indicated a dose-dependent attachment to collagen in the presence of CAF. In agreement with others[14], no attachment was seen in medium containing only 200 μg ml^{-1} BSA. In optimal conditions, 96% of recovered cells had attached to the dishes. Table 1 shows that half-maximal attachment occurred at approximately 25 μg ml^{-1} CAF. Extracts of PyBHK at 100 μg ml^{-1} failed to enhance attachment of cells to the collagen.

The photographs of cells in Fig. 1*a* demonstrate that cells in the presence of CAF were flat and extended, morphologically identical to cells in the presence of serum. In contrast, cells plated on to collagen in medium containing 200 μg ml^{-1} BSA retained a rounded, refractile appearance (Fig. 1*b*). At concentrations of CAF which permitted half-maximal attachment of cells, a mixture of flat and rounded cells was apparent.

Attachment of cells to collagen in the presence of CAF was dependent on physiological concentrations of divalent ions, PyBHK cells failing to attach to collagen substrates in phosphate buffered saline (PBS) unless Ca^{2+} and Mg^{2+} were also present (Table 2).

When BHK cells, which contain high levels of CAF (ref. 9), were removed from confluent monolayers with trypsin–EDTA at levels of trypsin which completely remove surface CAF (ref. 9) their reattachment to collagen was also mediated by CAF with results paralleling those given for PyBHK (data not shown).

The demonstration[16] that CAF purified from chick embryo fibroblasts agglutinates formalinised erythrocytes and that agglutination could be inhibited by substances containing free amino groups, prompted our assessment of their inhibitory properties during adhesion of cells to collagen. Inhibition was determined at two stages of CAF-mediated cell-adhesion: during CAF binding to collagen and during interaction of cells with CAF–collagen complexes. The results demonstrate that when 0.1 M L-lysine was present during the first but not the second incubation, cell attachment proceeded unimpeded, but with L-lysine present during only the second incubation, the flat, extended morphology of attached cells was completely inhibited, and the cells retained a rounded morphology. They did seem, however, to be more firmly associated with collagen than they were in the presence of E4–BSA alone, as judged microscopically by shaking the dish and observing that in E4–BSA the cells floated freely, whereas in the presence of serum plus inhibitor, the cells were not freely floating but loosely associated with the collagen. Quantification of the extent of this association was difficult because the cells were readily dislodged by gentle washing.

Table 3 Inhibition of serum- or CAF-mediated adhesion of PyBHK cells to collagen

First incubation	Second incubation	Morphology
10% Serum	Media	Flat, extended
CAF	Media	Flat, extended
10% Serum + 0.1 M L-lysine	Media	Flat, extended
CAF + 0.1 M L-lysine	Media	Flat, extended
10% Serum	Media + 0.1 M L-lysine	Rounded
CAF	Media + 0.1 M L-lysine	Rounded
10% Serum + 0.1 M D-galactose	Media	Flat, extended
CAF + 0.1 M D-galactose	Media	Flat, extended
10% Serum	Media + 0.1 M D-galactose	Flat, extended
CAF	Media + 0.1 M D-galactose	Flat, extended

Final concentration of CAF 100 µg ml^{-1}. The following inhibitors also prevented adhesion of cells to collagen when added during the second incubation: D-mannosamine (0.1 M), L-arginine (0.1 M), D-glucosamine (0.1 M) and D-galactosamine (0.1 M). The following compounds failed to inhibit cell adhesion when present at either incubation: D-glucose (0.1 M), glycine (0.1 M), and α-methyl-D-mannoside (0.1 M). Substances were tested for inhibition of cell attachment to collagen in the presence of 10% calf serum or purified CAF as follows: collagen-coated 30-mm dishes were incubated 1 h at 37 °C with 0.5 ml medium with or without 0.1 M concentration of the test substances. All inhibitors were dissolved in PBS and adjusted to *p*H 7.4 before use. Dishes were then washed twice with E4–BSA (20 °C) and 1 ml E4–BSA was added containing 5×10^5 PyBHK cells with or without the test substance. After an additional 1.5 h at 37 °C, dishes were inspected microscopically to ascertain cell morphology and adhesion.

Inhibition of adhesion by L-lysine could not be attributed to cytotoxicity. When cells were exposed to 0.1 M L-lysine, washed twice with E4–BSA and plated on to collagen preincubated with serum, the cells attached and flattened. Thus, cell viability was unaffected by the inhibitor.

As an additional control, D-galactose, which was negative in agglutinating erythrocytes[16], was assayed for its ability to inhibit cell adhesion. It failed to inhibit cell attachment at either incubation step (Table 3).

Similar experiments employing CAF extracted from BHK cells (Table 3) showed that the pattern of inhibition with the purified protein was identical to that obtained in experiments with serum plus inhibitor.

It has been demonstrated[17] that transformed cells which lack surface CAF are capable of synthesising this protein and secreting it into the medium. Therefore, conditioned medium from normal and transformed cells were assayed for active CAF. The results (Table 4) demonstrate that factor secreted from either BHK or PyBHK cells was capable of mediating the adhesion of cells to collagen. L-lysine, an inhibitor of serum and CAF-mediated attachment during the second incubation step, also prevented adhesion in the presence of conditioned medium.

It seems that CAF, extracted from normal cells by urea, is active in promoting attachment of cells to collagen. The attachment is dependent on dose, with 50% attachment occurring at 25 μg ml^{-1} CAF (Table 1). Using the method of urea extraction with chick embryo fibroblasts, Yamada *et al.*[16] have extracted CAF in greater than 95% purity. With BHK cells, however, purity was never greater than approximately 60% as judged by electrophoresis in polyacrylamide gel, so that 25 μg ml^{-1} represents an overestimate of CAF added.

Table 4 Promotion of adhesion of cells to collagen by conditioned medium (CM)

Source of conditioned medium	First incubation	Second incubation	Morphology
BHK	CM	Medium	Flat, extended
BHK	CM+0.1 M L-lysine	Medium	Flat, extended
BHK	CM	Medium+0.1 M L-lysine	Rounded
PyBHK	CM	Medium	Flat, extended
PyBHK	CM+0.1 M L-lysine	Medium	Flat, extended
PyBHK	CM	Medium+0.1 M L-lysine	Rounded

Confluent monolayers of BHK and PyBHK cells on 6-cm dishes were washed three times with E4, replenished with 2 ml serum-free E4 and incubated for 24 h. The conditioned medium was removed, spun at 2,000 r.p.m. for 2 min in siliconised test tubes to pellet contaminating cells, dialysed for 48 h against distilled water, lyophilised in siliconised flasks and dissolved in E4–BSA immediately before use. Assays for cell adhesion in conditioned medium were identical to those described previously.

That a minor component of the BHK–urea extract was not responsible for promotion of adhesion is supported by the fact that: urea extracts of PyBHK cells which lack CAF failed to promote attachment; CAF and adhesion activity are both non-dialysable; and inhibition of adhesion by specific compounds exactly parallels results obtained by Yamada *et al.*[16] with pure CAF to inhibit the agglutination of erythrocytes. Production of an antibody specific for CFA, followed by inhibition experiments, would allow a direct demonstration of the role for CAF in cell attachment and spreading.

Specific inhibitors are effective in preventing firm cell adhesion and spreading when added during the second incubation (Table 3). As judged microscopically during gentle shaking of the dish, however, cells in the presence of CAF plus inhibitors were weakly adherent to the collagen when compared with cells plated solely in E4–BSA. In the presence of inhibitors, the cells retained a rounded morphology and failed to flatten and extend. It is unclear whether CAF is involved in both attachment and spreading, of which only the spreading is inhibited by the amino-containing substances; or whether another factor present in serum, urea extracts, and conditioned medium is responsible for attachment and CAF for cell spreading.

It has been demonstrated[17] that CAF is secreted by SV40-transformed human fibroblast lines although these cells do not retain membrane-bound CAF. It is also known that CAF is turned over from the surface of normal fibroblasts[9]. We have demonstrated (Table 4) that CAF released into the medium from normal or transformed cells is active in promoting attachment of cells. Therefore, CAF produced by transformed cells is a biologically functional molecule and might be absent from the plasma membrane of transformed cells because of some other defect of the transformed cell plasma membrane.

CAF is a normal constituent of serum[12], and Klebe[14] has shown that a serum factor necessary for the adhesion of cells to collagen has a molecular weight greater than 200,000, binds to DEAE, and requires physiological concentrations of Ca^{2+} and Mg^{2+} to express its function. CAF also has a molecular weight greater than 200,000 (refs 7, 8 and 12), binds to DEAE (unpublished observations) and requires Ca^{2+} and Mg^{2+} to promote adhesion (Table 2). In addition, we have found (Table 3) that whether the source of adhesion factor was serum or BHK extracts, the pattern of inhibition of adhesion by various substances was identical. Since in all these properties the serum factor corresponds to CAF it seems possible that they are identical. The activity of the serum factor was, however, resistant to 10 μg ml^{-1} trypsin[14], whereas CAF was susceptible to lower concentrations[16]. Therefore, additional work is needed to clarify the relationship between these factors.

Several types of transformed sarcoma-producing cell lines contain detectable levels of CAF (ref. 18) as determined by lactoperoxidase-catalysed iodination. Because PyBHK cells produce biologically active CAF (Table 4), it is likely that the CAF retained by some of the sarcoma-producing lines will also prove to be biologically active. Collagen is the natural substratum for fibroblasts *in vivo* and since CAF mediates the adhesion of these cells to collagen, it would be of great interest to correlate the presence or absence of CAF on transformed cells with tumour metastasis *in vivo*.

As mentioned, purified CAF can agglutinate formalinised sheep erythrocytes[16]. We believe the designation CAF to be broad enough to encompass the functions of both agglutination and adhesion.

I thank Mrs Beatrice Pyatt and Ms Marlene Chavis for assistance. Supported by a grant from the USPHS.

Temporary intestinal hypoxia induced by degradable microspheres

IN all mammalian cells and tissues studied, the adequate presence of molecular oxygen during irradiation enhances the effects of ionising radiations of low linear energy transfer (LET), such as X rays, γ rays or electrons, by a factor of 2 or 3, compared with the effects seen after irradiation in poor oxygenation conditions[1,2]. In radiotherapy, this oxygen enhancement ratio (OER) is assumed to be generally effective in all healthy tissues, whereas in poorly oxygenated tumour cells the partial radioprotection through hypoxia is believed to be efficient to an extent that the probability of tumour sterilisation may be affected critically[3,4]. It has been suggested that the relative concentration of oxygen in healthy and tumour tissues could be changed to improve the relative probability of curing the disease and of reducing clinical complications caused by radiation damage of healthy tissues. To this end, the introduction of 'high LET' radiations for which the oxygen effect is of little importance, is presently being attempted[5]. Attempts are also being made to increase the oxygen tension in poorly oxygenated areas by treatment of patients with hyperbaric oxygen during irradiation[6]. In experiments in our laboratories, we have tried various means of changing the oxygen concentrations in tissues to be irradiated by chemical removal of oxygen[7] or by mechanical obstruction of the blood flow (K.E.A., J.O.F., C. Clintenberg, B.L., B.R. and S.Ö., unpublished). We are now investigating, in experiments on pigs, the possibility of attaining temporary local hypoxia in intestinal segments by obstructing the blood flow at the level of the arterioles by intra-arterial injection of cross-linked starch microspheres, 43 μm in diameter, that are degraded by the amylase activity of the serum[8]. With a proper choice of the degree of cross linking and of particle concentration, a hypoxic period of about 5 min duration, followed by rapid normalisation, was achieved.

Three female pigs of native breed (15–20 kg) were used under Nembutal anaesthesia. A high midline abdominal laparotomy was carried out and the base of the superior mesenteric artery was freed and catheterised using an Argyle No. 5 baby feeding tube. The catheter was fixed at the base of the mesenteric artery by a purse string suture and brought, for access, through the left abdominal wall and subcutaneously to the left groin, a loop being left in the abdominal cavity. The abdominal incision was closed and a loop of the small intestine was made available for inspection and measurement through a second incision through the right flank. Oxygen tension was measured with a modified Clark platinum electrode[9] put in direct contact with the mucous membrane of the jejunum through a small incision in the intestinal wall.

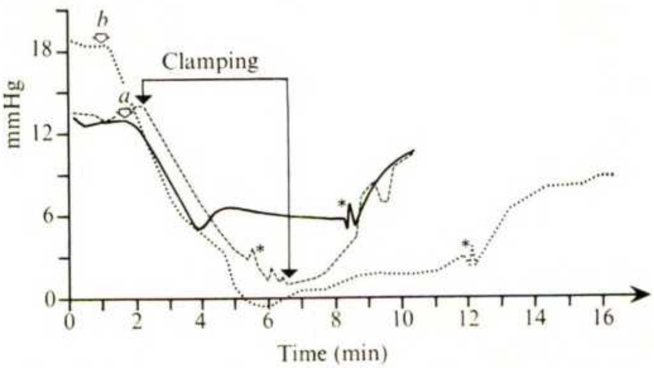

Fig. 1 Transient reduction in oxygen pressure on the jejunal mucous membrane after injection of 6×10^6 (*a*) or 30×10^6 (*b*) starch particles in the superior mesenteric artery of pigs. For comparison, the record seen after temporary mechanical 'clamping' of the vessel is also shown. *, Peristalsis.

Treatment, aimed at removal of oxygen from the intestinal segment under study, was carried out by injection of 6×10^6 (*a*) or 30×10^6 (*b*) microspheres suspended in 8 or 40 ml Ringer's solution for periods of 6 to 15 s, respectively. Alternatively, for comparison, the blood flow in the superior mesenteric artery was obstructed using a mechanical clamp.

Typical results are shown in Fig. 1. Curves *a* and *b* represent the records of the oxygen pressure during the experiments. Qualitatively, the curves are similar, showing a rapid decrease in the oxygen pressure to low values that persist for a period of 4–7 min. At the end of this phase of hypoxia a sudden peristaltic activity was apparent, initiating the phase of restoration in which the oxygen pressure rapidly returned to normal within 2–4 min (this phenomenon is also reflected in the diagram). The greater number of particles was more efficient in reducing the oxygen pressure in the intestinal mucous membrane to near zero. With the exception that restoration took place more rapidly, clamping led to similar behaviour of the recorded curves. When the oxygen pressure dropped below about 6 mmHg the intestinal segment became clearly pale. The measured and visually observed changes were well correlated in time and quite reproducible.

The results show that the intra-arterial injection of degradable starch microspheres, as described, can be used to bring about temporary intestinal hypoxia. By proper choice of the amount and concentration of particles in the injected suspension, the period of hypoxia can be programmed so as to enable experimental radiotherapy to be carried out in hypoxic conditions, seemingly without risk of damage caused by ischaemia.

The technique suggested is now subject to detailed experimental investigation in combination with irradiation. Its application to clinical radiotherapy is also being considered.

The experiments were supported by the Swedish Cancer Society.

Metabolic adaptation to pregnancy shown by increased biosynthesis of insulin in islets of Langerhans isolated from pregnant rats

MANY reports have indicated that insulin secretion is increased in pregnant women[1,2] although blood sugar levels may be unchanged, indicating an increased demand for insulin in human pregnancy. Similar findings have been reported for the effects of pregnancy on insulin secretion in pregnant rats[3,4] which begin to respond with a significantly increased insulin secretion at a lower glucose level than those found in the normal female[5]. In addition, the secretory response is considerably greater in islets of Langerhans from pregnant than in normal rats, indicating an overall increased sensitisation of the islets from pregnant rats to the effects of glucose[5]. Glucose has a major role in the metabolism of the mammalian β cell, in that at physiological concentrations it is capable of stimulating both insulin secretion and biosynthesis[6,7]. It is possible that increased insulin biosynthesis is necessary to support the increased secretory response to glucose in pregnancy, if the content of β cell insulin is to be maintained. We have therefore investigated whether the alterations in insulin secretion observed *in vivo* during pregnancy are paralleled by an enhanced insulin biosynthesis in isolated islets from pregnant rats, after exposure to increasing concentrations of glucose.

Islets of Langerhans were isolated by the method of Howell and Taylor[8], from age-matched normal female and 19-d pregnant rats. Groups of 15–20 islets were incubated in 0.5 ml bicarbonate-buffered medium *p*H 7.4[9], previously gassed with a mixture of 95% O_2 and 5% CO_2. The medium was supplemented with 1 mg ml^{-1} bovine albumin and contained various concentrations of glucose, as indicated in Fig. 1, together with 20 μCi ml^{-1} L-(4,5)-^{3}H-leucine of initial specific radioactivity 40 Ci $mmol^{-1}$. The tubes were then incubated with gentle shaking for 3 h at 37 °C. After incubation, the islets were rinsed twice in phosphate-buffered 0.9% saline, *p*H 7.4 (PBS), containing 1 mg ml^{-1} non-labelled L-leucine, and subsequently sonicated for 10 s in 150 λ μl of PBS. After a tenfold dilution, samples of the sonicate were taken for determination of protein content[10] using a crystalline bovine albumin standard. The synthesis of proinsulin and insulin in the pancreatic islets was estimated by determining the incorporation of labelled leucine into material reacting with insulin antibody (which also cross reacts with the precursor). The labelled insulin and proinsulin were separated from the rest of the islet proteins by incubation of a sample of the diluted islet sonicate with an excess of guinea pig anti-insulin serum (AIS) coupled to cyanogen bromide-activated Sepharose 4B (AIS–Sepharose)[11]. Normal guinea pig serum (NGPS) coupled to activated Sepharose (NGPS–Sepharose) served as a control for nonspecific binding of labelled proteins to the Sepharose beads. The nonspecific adsorption of proteins to the NGPS–Sepharose was examined after treatment of the beads with 2 M acetic acid. It was found that a small peak of radioactivity was eluted with the void volume on Sephadex G–50 gel chromatography, but there was virtually nothing present in the insulin or proinsulin regions. Normally the radioactivity bound to the AIS–Sepharose beads exceeded the nonspecific adsorption on NGPS–Sepharose by a factor of 2–5 in low (2 mM) and high (20 mM) glucose concentrations, respectively.

The biosynthetic response of the isolated islets to increasing glucose concentrations is shown in Fig. 1. Proinsulin–insulin biosynthesis was significantly greater ($P<0.01$) in islets from pregnant compared with non-pregnant rats, at all the glucose concentrations studied. Green and Taylor[5] have shown that there are increases in protein, DNA and insulin content of islets at day 19 of pregnancy, findings

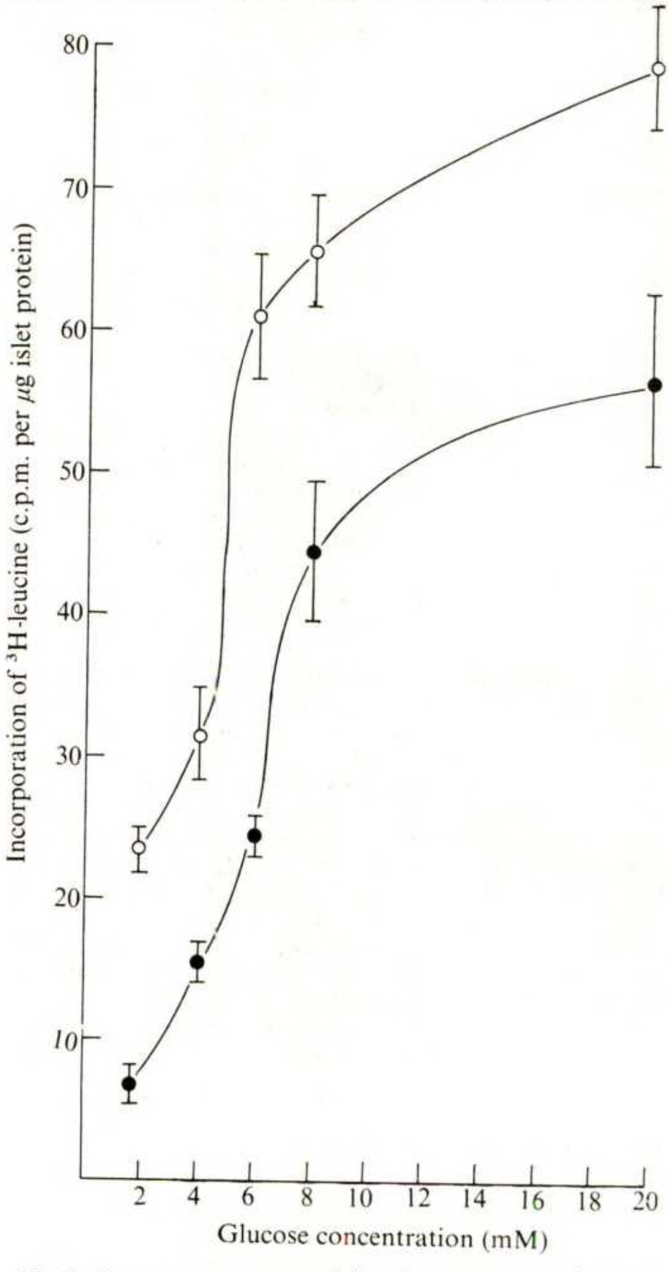

Fig. 1 Dose–response curve relating glucose concentration to the incorporation of L-4,5-^{3}H-leucine into AIS–Sepharose-bound proinsulin–insulin in islets from normal (●) and 19-d pregnant rats (○). Each point represents a mean of at least eight observations, with ±s.e.m. shown as vertical bars. Groups of 15–20 islets were incubated, washed and sonicated as described in the text; 20-μl samples of the diluted sonicates were then mixed with 1 ml PBS, supplemented with 2 mg ml^{-1} bovine albumin, and containing either 20 mg AIS–Sepharose or the same weight of NGPS–Sepharose according to the method of Berne[11]. The immune binding reaction was carried out in polythene tubes rotated end-over-end (20 r.p.m.) for 90 min at room temperature. The Sepharose beads were then washed six times with PBS and solubilised overnight in 0.8 ml Soluene 350 tissue solubiliser. Radioactivity was measured in a Beckman liquid scintillation counter after addition of 3 ml toluene-based scintillator.

confirmed by our islet protein estimations. Expressing incorporation per μg islet protein, however, we were able to nullify any differences in size and content of the isolated islets, thus enabling direct comparison of the biosynthetic response to glucose in islets from pregnant and non-pregnant rats. A sigmoidal curve is known to characterise the relationship between poinsulin–insulin biosynthesis and glucose concentration in normal islets[12]. The threshold value for the stimulant action of glucose, however, is lower in islets from pregnant rats, and in addition the rate of change of insulin biosynthesis is considerably greater than in normal islets (Fig. 1). Similar findings have been reported in the rat for the effects of pregnancy on the insulin secretory response of the islets of Langerhans[3–5]. On further examination of the sensitivity of the islets from pregnant rats to a glucose stimulus it is apparent that proinsulin–insulin biosynthesis has a lower threshold in terms of glucose stimulation than that for insulin release. Insulin biosynthesis is therefore more sensitive to glucose than is insulin release, and this will prevent the insulin stores of the β cells from becoming depleted at low glucose concentrations. This may be particularly important during pregnancy where blood sugar levels in fasted pregnant rats are significantly lower than those in fasted normal rats[5], such depressed glucose levels perhaps being associated with the increased plasma insulin levels reported in fasted rats during pregnancy[3].

The reasons for the heightened sensitivity of islets to glucose during pregnancy are at present uncertain. It has been suggested that there may be a possible involvement of increased adenylate cyclase activity or increased cyclic AMP concentrations in β cells, in controlling the altered secretory response[13]. Studies on the actions of theophylline and cyclic AMP at various glucose concentrations on biosynthesis of insulin compared with insulin secretion, prompted the suggestion by Schatz *et al.*[14], that the adenylate cyclase system besides regulating insulin secretion is involved in insulin biosynthesis. Other workers have postulated an increased sensitivity of a membrane receptor as a possible reason for changes in the sensitisation of islets to the effect of glucose[15], and changes of this type could also be operating during pregnancy. Whatever the mechanism by which it occurs, it is of great interest that at least three indices of islet activity are simultaneously increased in pregnancy. These are insulin release, insulin biosynthesis and islet glucose oxidation[16].

Further work is now in progress to elucidate more exactly the biochemical mechanisms by which the islets of Langerhans adapt to pregnancy.

Electrophysiological evidence for coupling between β cells of pancreatic islets

IT has been shown that the β cells of pancreatic islets exhibit electrical activity when stimulated with insulin releasing agents[1–3]. There is evidence that this activity is directly correlated with the insulin release and that it has an important role in the secretory process[2,4,5]. More recently it was documented that β cells within an islet are connected by gap junctions[6,7] which are considered as low resistance pathways (ref. 8 and refs therein). The question therefore arises whether the electrical activity can spread electrotonically from one cell to another within an islet. To further elucidate this question the electrical activity from two different cells was measured by simultaneous impalement with two microelectrodes.

The experiments were done on microdissected islets of the mouse pancreas as described previously[2]. The islets were continuously perifused in a small Plexiglas chamber (volume ~1 ml) with a Krebs–Henseleit solution gassed with 95% O_2 and 5% CO_2. The temperature was kept constant at 37 °C. The basal medium had the following composition (mM): glucose 2.8, NaCl 103, KCl 4.7, $CaCl_2$ 2.56, $MgCl_2$ 1.13, $NaHCO_3$ 25, NaH_2PO_4 1.15, sodium pyruvate 4.9, sodium fumarate 2.7, sodium glutamate 4.9. When the glucose concentration was increased to 11.1 or 16.6 mM, NaCl was reduced by an appropriate amount to maintain the osmolarity.

The membrane potential was measured with microelectrodes filled with 2 M potassium citrate. Because the β cells are small (diameter ~10 μm) simultaneous recording from two cells was difficult and high resistance electrodes (tip resistance >200 MΩ) were necessary to obtain stable and long lasting impalements. The electrodes were mounted on two independent micromanipulators and impaled at an angle of approximately 10°. The distance between their tips was about 50 μm before impalement. Since the β cells in mouse islets are surrounded by a layer of α cells[9] they are invisible. Therefore, they could only be identified by their characteristic electrical activity in high glucose concentrations. Membrane potentials were recorded on a double beam oscilloscope (Tektronix 565) and a double trace chart writer (W+W 1200).

The glucose-induced electrical activity is characterised by a regular burst pattern[2,5]. It consists of periodic oscillations of the membrane potential (slow waves) between a depolarised state with superimposed fast spike activity, and a polarised, silent state (Fig. 1). The burst activity appears only in glucose concentrations which also stimulate insulin release[2]. The duration of the slow waves is strongly glucose dependent; it increases as the glucose concentration is raised[2,10]. The amplitude and the duration of the superimposed spikes are unaffected by a change of the glucose concentration.

When the electrical activity was simultaneously recorded from two cells within the same islet the slow waves were highly synchronised in 6 out of 7 double impalements; only in one case were the slow waves asynchronous. The synchronisation is demonstrated in Fig. 1. It is obvious that there was a strict temporal relationship between the depolarising as well as the repolarising phases of the slow waves in the two records. This relationship was unaltered also when during the regular burst pattern a slow wave with a shorter duration was interposed (Fig. 1*b*). The

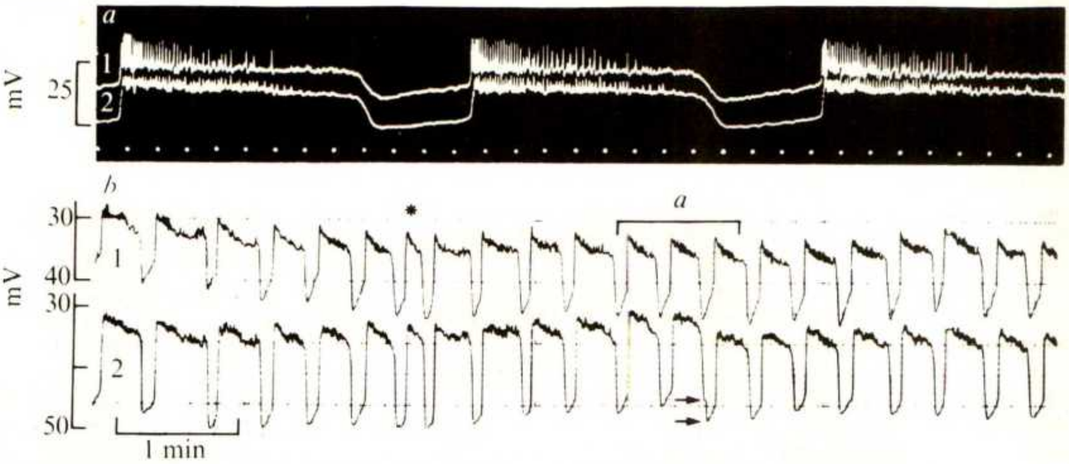

Fig. 1 Simultaneously recorded burst activity of two β cells perifused with 16.6 mM glucose. *a*, Oscilloscope record of the three bursts marked by the bar in record *b*. Distance between two subsequent points corresponds to 2 s. *b*, Train of bursts recorded with a chart writer. Trace 1 and 2 in *a* correspond to trace 1 and 2 in *b*, respectively. At the two arrows in *b* the offset was changed by about 3 mV. The asterisk in *b* denotes bursts with a short duration interposed between longer bursts. Note that the full amplitude of the spikes is not recorded in the chart recordings because of the inertia of the recording system.

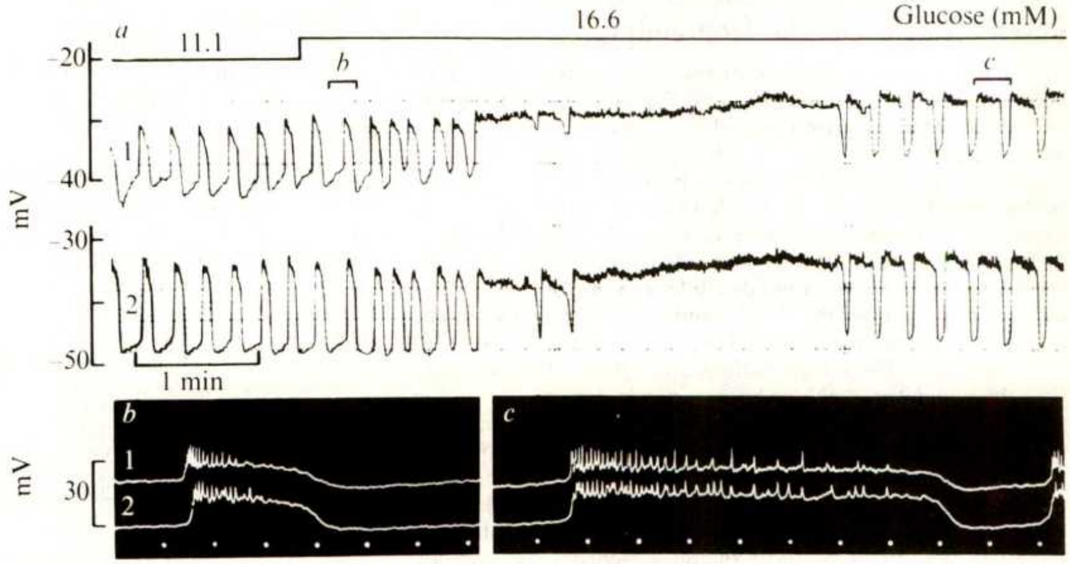

Fig. 2 Effect of changing the glucose concentration on the simultaneously recorded burst activity of two β cells. *a*, Continuous ink recording showing the time course of burst activity before and after changing the glucose concentration from 11.1 to 16.6 mM. *b* and *c*, Oscilloscope records taken at the times marked by bars in *a*. Time interval between two subsequent points in *b* corresponds to 2 s.

differences in the membrane potential values of the two cells shown in Fig. 1 are likely to be due to differences of the recording conditions and not to different properties of the impaled cells. As shown in Fig. 2, the synchronisation was also maintained when the external glucose concentration was changed, although the pattern of activity was markedly altered. It is unlikely that the synchronised activity was recorded from the same cell because the microelectrode tips were separated by distances which were several times the diameter of the β cell. This conclusion is supported by the observations shown in the oscilloscope records of Figs 1*a*, 2*b* and *c*; these records reveal that in contrast to the slow waves the superimposed spike activity was not identical at the two recording sites. From Fig. 3, which shows the spike activity on a faster time base, it becomes obvious that the spikes were well synchronised during the initial part of the burst (left half of Fig. 3) while later on, when the frequency decreased, the synchronisation was less pronounced. Thus, the spikes in the upper record of Fig. 3 appeared with an increasing delay compared with those in the lower trace (see spikes 20 to 30). Moreover, single spikes in one record were sometimes not accompanied by a corresponding spike in the other record (for example spike 30). Furthermore, if corresponding spikes were present in the two records the ratio of their amplitudes varied considerably; for instance spike 22 was larger in the lower than in the upper record, whereas for spike 29 the reverse was true.

The results show that the electrical activity is synchronised in a high percentage of β cells which are located closely together within an islet. This synchronisation concerns mainly the slow waves whereas the fast spike activity seems to be synchronised only partially. It has been established that the β cells are connected by gap junctions[6,7]; therefore it is probable that the synchronisation is due to electrical coupling. Although the ionic mechanisms producing the electrical activity in β cells so far are poorly understood it has been suggested that particularly the glucose-induced slow waves are an important link in triggering and regulating insulin release in the individual cell[2,5,10,11].

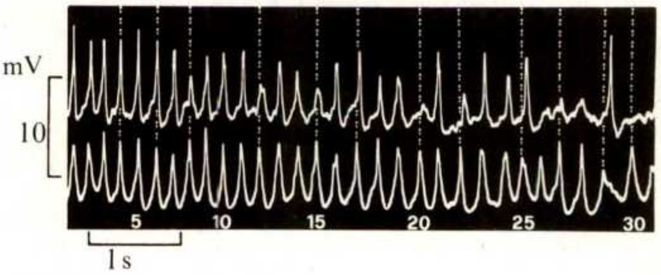

Fig. 3 Simultaneous oscilloscope records of spike activity of two β cells during the plateau phase of a slow wave. To allow comparison of the temporal relationship between spikes in the two records, the spikes have been numbered and dotted lines have been traced. Glucose concentration 16.6 mM.

Since many of these cells seem to be coupled electrically, it is possible that the slow wave originates in one cell and stimulates the coupled cells by electrotonic spread. From this point of view it is conceivable that within an islet the glucose molecule stimulates only a limited number of 'pacemaker cells' which then induce electrically the burst activity and insulin release in the coupled cells. The 'pacemaker cells' may be located in close vicinity to the blood capillaries and, therefore, be the first to come into contact with the glucose.

I thank Professor H. Schmidt for helpful comments on the manuscript. This work was supported by the Deutsche Forschungsgemeinschaft.

Decrease of Na^+ conductance during desensitisation of the frog endplate

THE membrane depolarisation of the frog endplate caused by acetylcholine (ACh), either released from the nerve terminals or applied externally, decreases when such applications of ACh are persisted or repeated[1,2]. This phenomenon, known as 'densitisation' or 'inactivation' of the receptor to ACh, was first analysed by Katz and Thesleff[1] and was suggested to be caused by a change in the receptor molecule from an effective to a refractory state. Subsequent investigations revealed that the rate of this desensitisation depends both on the extracellular concentration of Ca^{2+} ($([Ca^{2+}]_0)$)[3-5] and on membrane potential[6]; being speeded up by increasing $[Ca^{2+}]_0$ or hyperpolarisation of the membrane. These observations and others, demonstrating that the endplate membrane became permeable to Ca^{2+} during the action of ACh (ref. 7), led to the hypothesis that desensitisation was brought about by transmembrane movement of Ca^{2+} and the combination of the ions with anionic sites on the inner surface of the endplate membrane[4,5]. The question then arises of whether desensitisation is caused by molecular changes in the ACh receptor or by those of the subsequent step directly controlling the ionic conductance of the endplate membrane. This subsequent step may involve a macromolecule which has been termed "ion channel" or "ion conductance modulator"[8]. In an attempt to answer this question, we measured changes in the equilibrium potential of the endplate membrane during desensitisation, using a voltage-clamp technique[9,10].

Sciatic nerve–sartorius muscle preparations were isolated from frogs (*Rana nigromaculata*). Conventional intracellular recording techniques and a voltage clamp circuit were as used previously[11]. Ionic composition of Ringer's solution was as follows (mM): NaCl, 115; KCl, 2.0; $CaCl_2$, 1.8; NaH_2PO_4, 0.7; Na_2HPO_4, 1.3. Experiments were carried out at room temperature (20–22 °C). Electrodes for iontophoresis of ACh (2 M) had tip resistances of 100–140 MΩ and a braking current of a few nA was applied constantly.

Endplate currents (ACh-induced current) were evoked by iontophoretic applications of ACh at a rate of 0.2 Hz and at different levels of membrane potential. Thus, the endplate conductance ($G_{\rm epc}$) and its equilibrium potential ($E_{\rm epc}$) before desensitisation occurred were obtained (Fig. 2*a*). The endplate membrane was then desensitised by generating a series of ACh-induced currents at a relatively high rate (20 Hz), as demonstrated by Magazanik and Vyskocil[12] and as shown in Fig. 1. During repeated applications, the amplitude of ACh-induced currents decreased and after 20 s became 25% of the initial level. When the desensitisation had developed sufficiently, the level of membrane potential was changed from the holding potential of −50 mV up to −105 mV. Accordingly (Fig. 2*a*) changes in $G_{\rm epc}$ and $E_{\rm epc}$ during desensitisation can be compared with those before desensitisation occurred. There was a marked shift of the $E_{\rm epc}$ to a more negative value (the mean shift; -25.4 ± 5.6 mV (s.e.), $n = 9$) during desensitisation, accompanied by a decrease in the $G_{\rm epc}$ ($37.3 \pm 2.9\%$ of the control value, $n = 9$). It is unlikely that the lines, shown in Fig. 2*a*, relating the amplitude of the ACh-induced current to membrane potential before and during desensitisation will converge to the same membrane potential. In fact, in some cells, there was complete disappearance of ACh-induced currents at −50 mV during desensitisation, whereas the $E_{\rm epc}$ obtained by extrapolation before the development of densitisation was −10 mV. These results indicate that a decrease in the Na^+ conductance ($G_{\rm Na}$) of the endplate membrane would occur in these conditions.

Before this conclusion is accepted, however, the possibility should be considered that the shift in $E_{\rm epc}$ during desensitisation might be caused by a change in the equilibrium potential for Na^+ ($E_{\rm Na}$) because of an influx of Na^+ during repeated activation of the endplate membrane. To test this possibility, the $E_{\rm epc}$ was measured during repetitive generation of ACh-induced currents in low $[Ca^{2+}]_0$, where the rate of desensitisation was very slow. In this situation, if the shift of the $E_{\rm epc}$ during repetitive applications of ACh is a result of a change in the $E_{\rm Na}$, there would be a similar, or even a greater change, in the $E_{\rm epc}$ than that at normal $[Ca^{2+}]_0$, since the decrease in the amplitude of ACh-induced currents during repeated activations is smaller at low $[Ca^{2+}]_0$ (Fig. 2*b*). Even after the generation of 400 ACh-induced currents, there was only a small change in $E_{\rm epc}$ during applications of ACh at 0.45 mM $[Ca^{2+}]_0$, eliminating the possibility that the negative shift of $E_{\rm epc}$ during desensitisation seen at 1.8 mM $[Ca^{2+}]_0$ was the result of accumulation of Na^+ in the intracellular space. The change in the $E_{\rm epc}$ therefore seems to be caused by the reduction of $G_{\rm Na}$

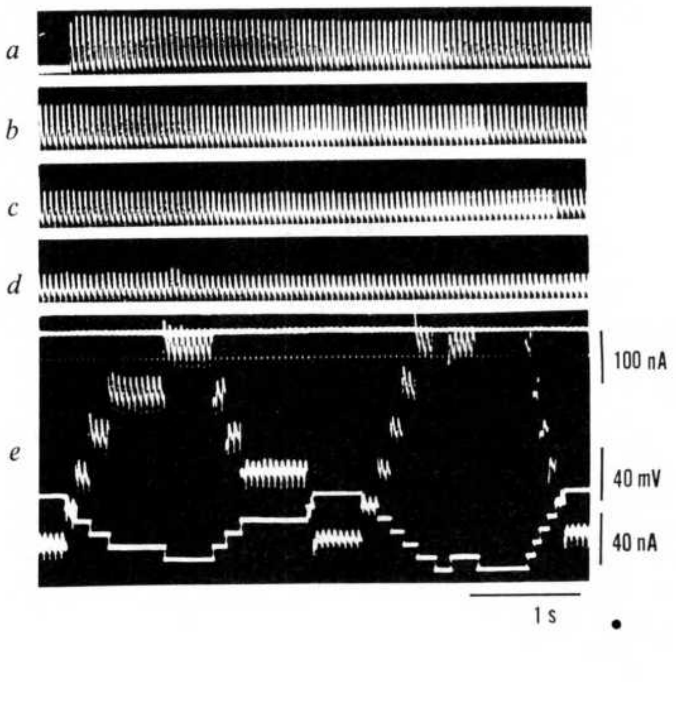

Fig. 1 ACh-induced currents evoked by repetitive applications of iontophoretic pulses (1 ms, 50 nA) at a rate of 20 Hz. Membrane potential was changed after ACh application for about 20 s, when sufficient desensitisation had occurred. *a–d*, ACh-induced currents; *e*, upper, middle (seen at the right- or left-hand margins) and lower (seen at the right- or left-hand margins) traces are the current for iontophoresis of ACh, membrane potential and ACh-induced current, respectively.

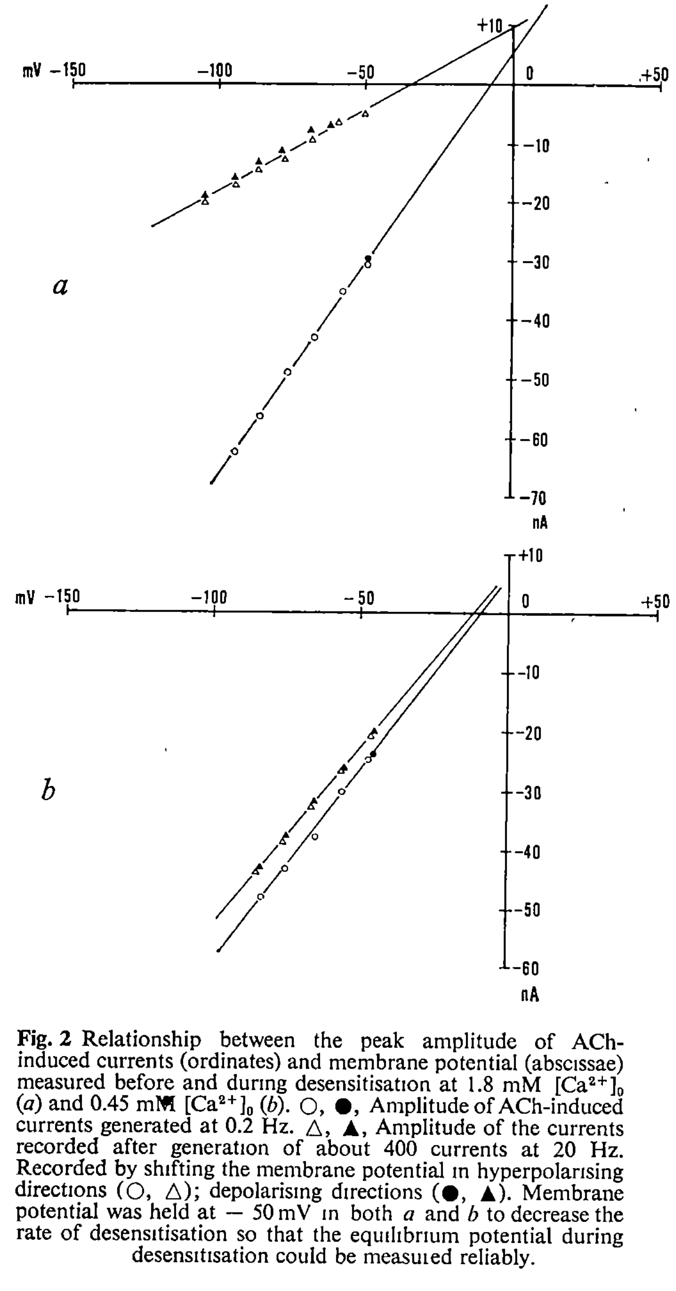

Fig. 2 Relationship between the peak amplitude of ACh-induced currents (ordinates) and membrane potential (abscissae) measured before and during desensitisation at 1.8 mM $[Ca^{2+}]_o$ (*a*) and 0.45 mM $[Ca^{2+}]_o$ (*b*). ○, ●, Amplitude of ACh-induced currents generated at 0.2 Hz. △, ▲, Amplitude of the currents recorded after generation of about 400 currents at 20 Hz. Recorded by shifting the membrane potential in hyperpolarising directions (○, △); depolarising directions (●, ▲). Membrane potential was held at − 50 mV in both *a* and *b* to decrease the rate of desensitisation so that the equilibrium potential during desensitisation could be measured reliably.

of the endplate membrane. This finding points directly to the idea that the site responsible for desensitisation is the ion channel directly controlling the conductance of the endplate membrane[6].

We also studied effects of high $[Ca^{2+}]_o$ on the ACh-induced currents which were evoked at a low rate (0.2 Hz) of ACh application, when there was no observable desensitisation. When $[Ca^{2+}]_o$ was increased from 1 8 mM to 7.2 mM, the amplitude of ACh-induced currents gradually decreased and reached a steady level. In these circumstances, there was a decrease in G_{epc} (71±6%, $n = 7$) and a negative shift of E_{epc} (−10.3±1.0 mV, $n = 7$), indicating a decrease in G_{Na}. These observations are in agreement with the original findings of Takeuchi[7]. In view of similar decreases in the G_{Na}, we suggest that two different effects of high $[Ca^{2+}]_o$—namely an increase in the rate of desensitisation and a decrease in the endplate conductance—are caused by a common mechanism, which may be explained as follows. It was proposed[4,5], that a major factor controlling the speed of desensitisation is a rise in intracellular Ca^{2+} concentration ($[Ca^{2+}]_i$) produced by activation of Ca^{2+} conductance. If this is the case, our present experimental findings indicate that an increase in $[Ca^{2+}]_i$ eventually decreases G_{Na} of the endplate membrane. When $[Ca^{2+}]_o$ is increased, $[Ca^{2+}]_i$ is also expected to rise, even at a low rate of ACh application. This leads to a similar decrease in the G_{Na}. It may thus be possible that desensitisation is caused by the acceleration of the mechanism which causes a decrease in G_{Na} of the endplate membrane by intracellular Ca^{2+}.

Elevated levels of enkephalin in morphine-dependent rats

NUMEROUS theories propose mechanisms regulating opiate dependence. Hughes[1,2] elegantly identified a morphine-like factor "enkephalin" which mimics effects of morphine on nerve plexus in smooth muscle in a fashion that can be antagonised by opiate antagonists, while a compound with the same properties has been identified in brain extracts by competition for opiate receptor binding[3–6]. Enkephalin activity has a regional and subcellular distribution similar to that of the opiate receptor[7,8] and was first shown to be a mixture of two peptides H-Tyr–Gly–Gly–Phe–Met–OH and H-Tyr–Gly–Gly–Phe–Leu–OH by Hughes *et al.*[9] with a preponderance of the methionine peptide in pig brain[9]. Independently, we identified the same two peptides in bovine brain but with four times more of the leucine than of the methionine peptide[10,11]. Brain enkephalin differs from substances in pituitary gland and hypothalamic extracts which mimic morphine[12,13].

Kosterlitz and Hughes proposed that reduced enkephalin release might explain tolerance and physical dependence to opiates[14]. Here we report enhanced enkephalin levels in brains of morphine-dependent rats, supporting the view that changes in enkephalin release account for symptoms of tolerance and physical dependence.

Enkephalin was extracted[4,6] from brains of Sprague–Dawley rats (150-175 g weight) by homogenising the brain in ten volumes of 0.32 M sucrose in a glass tube with a Teflon homogeniser. The homogenate was centrifuged at 100,000*g* for 1 h, the pellet resuspended in two volumes of 10 mM Tris-HCl buffer (*p*H 7 7 at 25 °C) and incubated in a boiling water bath for 15 min, centrifuged at 100,000*g* for 1 h and the clear supernatant lyophilised. To separate endogenous enkephalin from the administered opiates, all the lyophilised brain extracts were purified on Biogel-P_2 columns. Samples were suspended in 0 1 M ammonium-acetate buffer (*p*H 7.4) and run through Biogel P_2 columns (26×1.1 cm, 200-400 mesh) prepared in the same buffer. Fractions of 0 6 ml were collected, lyophilised, suspended in 50 mM Tris-HCl buffer (*p*H 7.7 at 25 °C) and assayed in triplicate in the opiate binding assay[4–6]. When ^3H-morphine was mixed with enkephalin, less than 1% of added ^3H-morphine emerged in the enkephalin containing fractions. The opiate binding assay was performed in 200 µl of 0 05 M Tris-HCl buffer containing membranes from Sprague–Dawley rat brains and 0 12 pmol ^3H-naloxone (5 mCi/0.04 mg). Specific opiate binding is defined as the difference

Table 1 Enkephalin activity and opiate content in morphine-dependent, withdrawn and acutely injected rats

	Enkephalin activity (Units per g wet weight)	Opiate content (ng morphine equivalents per g wet weight)
Control	3.38±0.32 (8)	
Acute morphine†, 30 min	3.42±0.43 (8)	87.5±16.2
Acute morphine, 1 h	4.20±0.51 (8)	154.4±24.0
Acute morphine, 2 h	4.05±0.37 (8)	65.4±13.3
Acute morphine, 4 h	3.78±0.40 (6)	18.3± 5.4
One day morphine pellet‡	3.65±0.44 (5)	27.7± 3.6
Five day morphine pellet§	5.96±0.72* (10)	64.1± 7.1
Five day morphine pellet plus naloxone injection (1.0 mg kg^{-1}) ‖	3.26±0.51 (8)	96.5±14.1
Naloxone injection (1.0 mg kg^{-1})¶	2.84±0.47 (5)	31.0± 4.0

For determination of enkephalin activity and opiate content, rats were decapitated and brains minus cerebella were homogenised as described in the text. Enkephalin activity was separated from opiates (morphine or naloxone) by Biogel-P_2 chromatography (see text and Fig. 1) and assayed in an opiate binding assay[4,6]. Each treatment was performed in 5–10 rats (indicated in parentheses) and enkephalin activity content quantified as described in the text. Data are means± s.e.m. with the number of rats in parentheses. For methionine and leucine enkephalins, 1 unit represents 1.25 pmol and 6.0 pmol respectively[10,11]. Thus control rat brain would contain 4.2 pmol g^{-1} or 20.3 pmol g^{-1} levels of enkephalin if it were exclusively methionine or leucine enkephalin respectively.

All samples were processed by Biogel-P_2 chromatography with assay of 50 fractions for each sample. There was no overlap between enkephalin values of 5-d pelleted rats and control rats or 5-d pelleted animals treated with naloxone.

*Significantly higher than values for control rats and morphine-dependent rats treated with naloxone, $P < 0.005$.

†Morphine sulphate (15 mg kg^{-1}) was injected intraperitoneally and animals decapitated for enkephalin extraction 30 min–4 h after injection.

‡Morphine pellets (75 mg) were inoculated subcutaneously 24 h before enkephalin extraction.

§One morphine pellet (75 mg) was inoculated. After 2 d two more morphine pellets (75 mg each) were inoculated together. Rats were decapitated and their brains extracted 5 d after inoculation of the first pellet.

‖Rats were treated as in § except that naloxone (1.0 mg kg^{-1} intraperitoneally) was injected 1 h before decapitation and brain extraction.

¶Naive animals were injected intraperitoneally with naloxone (1.0 mg kg^{-1} intraperitoneally) and the brains extracted 1 h later as in ‖.

in binding in the presence of 1 μM levallorphan from that in its absence. Enkephalin activity was quantified using a standard curve elaborated with different enkephalin concentrations. One unit of enkephalin is defined as that amount of enkephalin which yields 50% occupancy, determined according to Colquhoun[15] assuming classical binding interactions. The amount of opiate in the brain extracts that was run through Biogel-P_2 columns was also determined in the opiate binding assay and quantified by comparison with morphine. Synthetic methionine- and leucine-enkephalins emerged from these columns in the same fractions as enkephalin extracted from rat brain[10,11]. Chromatography on AG-1 columns also showed the same elution pattern for synthetic enkephalins and enkephalin activity extracted from rat brain Recovery of added methionine- and leucine-enkephalins (80-90%) was the same for control and morphine pelleted rats.

One hour after a single injection of morphine (15 mg kg^{-1} intraperitoneally) enkephalin levels increase about 25%, which attains statistical significance in some experiments (Table 1). No augmentation is detected 30 min after morphine injection and the levels of enkephalin then decline.

To evaluate the influence of tolerance and physical dependence, rats were implanted with slow-release morphine pellets and their brains assayed for enkephalin and morphine content 1 and 5 d later (Table 1; Fig. 1). At 1 d, enkephalin levels are no different from those of control animals, though brain levels of morphine at this time are only 15% of those obtained 1 h after an acute injection of morphine, consistent with the reported slow release of morphine from such pellets in rats[16,17]. Five days after initial pellet implantation and 3 d after the second pellets, when tolerance and physical dependence are maximal[16,17], enkephalin levels are increased 75% over control values; 1 h after precipitating abstinence in animals by naloxone treatment (1.0 mg kg^{-1} intraperitoneally), enkephalin levels have returned again to control values. In naive rats the same dose of naloxone produces no alteration in enkephalin levels.

Changes in enkephalin activity are not simply related to presence in the brain of the opiate administered to the animals, because naloxone injection reduces enkephalin levels in 5-d morphine pelleted rats, while it increases the opiate content of the brain (Fig. 1; Table 1). Moreover, after a single injection of morphine, enkephalin levels are substantially lower than after 5 d of morphine pellets, yet with the acute injection of morphine, the total opiate content of the brain is two- to threefold higher than after pellet implantation.

Do the elevated levels of enkephalin in morphine pelleted rats represent the same substance as that detected in control animals? One unique characteristic of enkephalin activity is its enhancement by manganese but not by calcium ions and its depression by sodium but not potassium ions[4,6]. As previously reported for crude and purified enkephalin preparations, in control rats as well as in morphine pelleted animals and rats treated with both morphine pellets and naloxone, ionic influences on enkephalin activity are essentially the same. Thus in all three cases, 15 mM and 100 mM sodium reduce enkephalin activity about 60 and

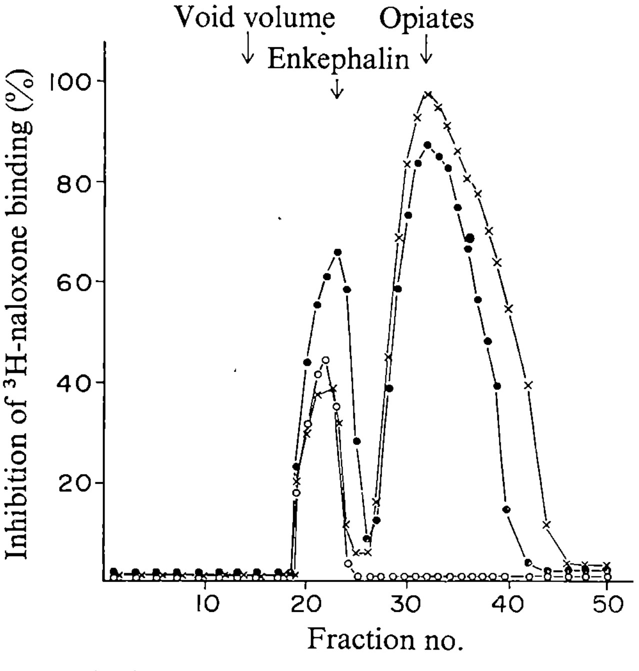

Fig. 1 Biogel-P_2 chromatography of enkephalin activity from control, morphine-dependent and morphine-dependent, naloxone-injected rats. Morphine dependence was elicited by implanting one morphine pellet (75 mg) for 2 d and then two other pellets (75 mg each) together for another 3 d before brain extraction. Abstinence was precipitated by intraperitoneal injection of 1.0 mg kg^{-1} naloxone to rats 5 d after morphine pellet implantation, and the brains were extracted 1 h after naloxone injection. Each treatment was performed with 5–8 animals. Enkephalin was extracted, run through Biogel-P_2 column and assayed in the opiate receptor binding assay as described in the text. The same Biogel-P_2 assay was calibrated with ^{3}H-morphine, synthetic methionine-enkephalin and non-radioactive insulin (molecular weight, 6,000). The negligible overlap of enkephalin and opiate profiles and their comparable magnitude ensures that enkephalin activity determinations are not affected to a great extent by opiate content of brain. ○, control; ●, morphine dependent; ×, morphine dependent+naloxone.

70% respectively, while the same concentrations of potassium have no effect. By contrast, 1 mM manganese increases enkephalin activity about 50–70% in all three groups of animals, although the same concentration of calcium has no appreciable influence. Elevated enkephalin levels in morphine-dependent rats remain apparent regardless of ionic manipulations.

How might these changes in enkephalin activity relate to opiate dependence? The jumping, wet shakes and diarrhoea associated with morphine abstinence are observable in our animals 5 min after naloxone injection, peak at about 15 min and subside by 60 min, as reported by others[16]. Coincident with the reduction in abstinence symptoms 1 h after naloxone administration, sensitivity to the analgesic effects of morphine returns almost to control levels[17], when enkephalin levels have also declined to control values. Thus the changes in enkephalin activity after chronic treatment with morphine and induction of abstinence correlate with behavioural changes associated with tolerance and physical dependence.

Brain levels of dopamine and acetylcholine reflect changes in the firing rate of cholinergic and dopaminergic neurones[18,19]. Cessation of firing is accompanied by an elevation of the levels of these transmitters. If enkephalin is a neurotransmitter or neuromodulator of analogous neuronal systems, elevations in enkephalin activity might reflect a slowing in the firing rate of "enkephalinergic" neurones. Conceivably large doses of morphine substitute for the physiological effects of enkephalin and, by a "feedback" message, cause the enkephalinergic neurones to reduce their activity as proposed by Kosterlitz and Hughes[14]. Such a mechanism could account for the behavioural manifestations of opiate tolerance and physical dependence. With acute morphine administration, opiate receptors are exposed both to morphine and enkephalin. With chronic morphine administration, enkephalin release slows or ceases, and opiate receptors, now exposed only to morphine, appear "tolerant". On abrupt cessation of opiate administration or with antagonist treatment, receptors are deprived both of the opiate and of enkephalin, resulting in "abstinence". As the firing rate of enkephalin neurones returns to normal, elevated levels of enkephalin decline to control values, and the organism is again normally responsive to opiates. Possibly, the "feedback" message to the enkephalin neurones is mediated by changes in cyclic nucleotides in postsynaptic cells containing opiate receptors[20].

Prolactin suppresses release of luteinising hormone during lactation in the monkey

STUDIES with rats have shown that during lactation there is an inhibition of luteinising hormone (LH)-dependent physiological events, such as implantation[1], and a return to oestrus cyclicity[2]. This inhibition has been shown to occur only during the intense suckling phase and it has been correlated with the high levels of prolactin present in the circulation at this time. Although exogenous prolactin could substitute for the effects of intense suckling, it could do so only under the permissive influence of minimal suckling stimulus. We have shown that there is, in these conditions, a lowering of LH levels, and that this is due to interference by prolactin with the pituitary responsiveness to LH-releasing hormone (LHRH) (K. Muralidhar, R. M. and N. R. M., unpublished). Using the lactating monkey, we have now demonstrated a similar inhibitory effect of prolactin on pituitary responsiveness to LHRH, suggesting a mechanism by which amenorrhoeic conditions are maintained during lactation.

Four female bonnet monkeys (*Macaca radiata*), in the second month of lactation, were caged individually with their babies and maintained in standard laboratory conditions[3]. Synthetic LHRH (100 µg AY-24, 031-4, given by Dr F. Labrie) in 1 ml 0.9% NaCl was administered through the femoral vein. LHRH was first injected while the mother was suckling her baby and blood was withdrawn by venepuncture 10, 20 and 40 min later. The baby was then separated from the mother for 24 h, at the end of which period a second injection of 100 µg LHRH was given, followed by blood sampling at the intervals indicated above. After a rest of 2–3 weeks the same monkeys were used for the prolactin inhibition experiment. The experimental protocol was identical to that described above, except for the intramuscular injection of 5 mg ovine prolactin (NIH-P-S5)

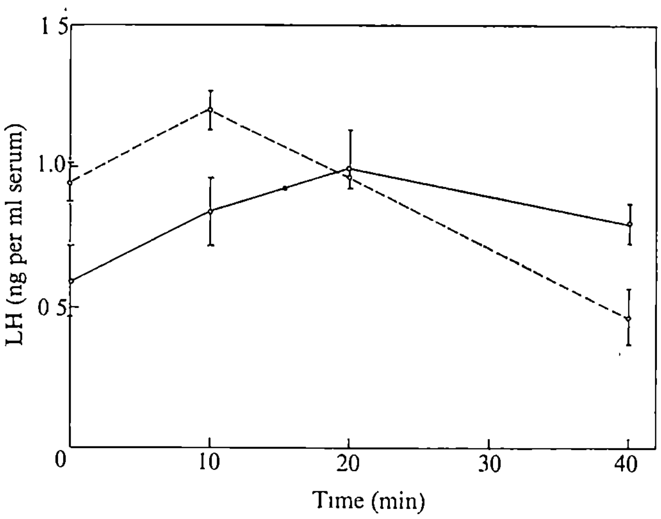

Fig. 1 Effect of suckling on pituitary response to LHRH. Four monkeys in the second month of lactation were used. LH was measured in duplicate in 0.1-ml samples by the double-antibody radioimmunoassay, using human LH (given by Dr C. H. Li), for iodination and standard and human chorionic gonadotrophin-β antiserum (NIAMDD, NIH) as a source of antibody. This assay accurately measured LH in the range of 0.1–5 ng. —, Suckling; — —, non-suckling.

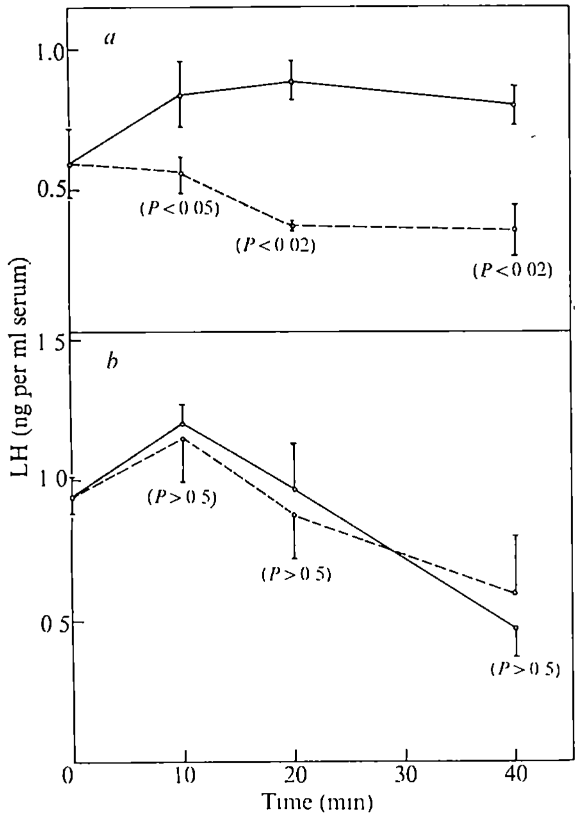
in 0.5 ml 0.9% NaCl 1 h before administration of LHRH. In all experiments a control blood sample was taken 30 min before injection of either prolactin or LHRH. Serum LH was estimated by the double-antibody radioimmunoassay at 37 °C as described previously[4–6] (details in Fig. 1).

Administration of LHRH resulted in an increase in serum of LH within 10 min, in both the suckling group and those from which the suckling stimulus was withdrawn for 24 h (Fig. 1). Whereas this increase in LH levels was maintained until 40 min in the suckling group ($P < 0.02$ between control and 40-min sample), LH reached control values in the non-suckling group by 20 min ($P > 0.5$ between control and 20-min sample). The basal level of LH was significantly increased after withdrawal of the suckling stimulus for 24 h (from 0.6±0.12 ng ml^{-1} to 0.95±0.07 ng ml^{-1}, $P < 0.001$).

Administration of 5 mg prolactin 1 h before injection of LHRH resulted in a suppression of LH release into the circulation only in the group in which the suckling stimulus was present (Fig. 2*a*). This suppression of LH continued until 40 min after injection of LHRH. At any given time interval tested, LH levels in the prolactin-treated suckling group were significantly lower than in the corresponding controls. In contrast, withdrawal of the neurogenic stimulus of suckling for 24 h resulted in an inability of prolactin to block LH release (Fig. 2*b*). Although a comparison between the lactating and the non-lactating groups provided a means of assessing the influence of suckling/endogenous prolactin on LHRH responsiveness, the model in which exogenous prolactin was used, although it is a heterologous species, clearly shows that prolactin *per se* influences pituitary responsiveness to LHRH during lactation.

Ovarian quiescence during lactation has attracted the attention of several investigators. Our study with subhuman primates demonstrates that during lactation the monkey, similar to the rat, has a decreased responsiveness to LHRH. Although the ability of LHRH to release LH from the pituitary is reduced if suckling is present, the effect is further accentuated by a single injection of prolactin. Based on our results with the rat, it can be presumed that in the monkey also the inhibitory effect of prolactin on pituitary responsiveness is direct, and not mediated by ovarian or adrenal progesterone. The mechanism and duration of this inhibition is under investigation.

Fig. 2 Effect of prolactin on pituitary response to LHRH during lactation in the presence (*a*) and absence of suckling stimulus (*b*). *P* values were calculated for values at any given time between the treated and untreated groups. All values > 0.05 were considered to be not significant. —, No prolactin; - - , plus prolactin.



Although others have shown with rats that continued application of the suckling stimulus by litter replacement[7,8] or injection of prolactin[9] can prolong lactation considerably, we have observed that a single injection of prolactin can extend the anoestrus period significantly[2]. Recent studies in humans have shown that thyrotropin-releasing hormone (TRH) extends the lactational amenorrhoeic period[10]. Whether continued use of TRH would, in addition to releasing prolactin by continuously releasing thyroid-stimulating hormone (TSH), have an adverse effect on thyroid metabolism is a point to be considered. The present study, by demonstrating the possible mechanisms whereby gonadoptrophin release is suppressed during lactation, suggests the use of human prolactin to extend the amenorrhoeic condition in lactating women.

The monkey is known to be less responsive to LHRH than the human and the rat[11]. Consequently, the increase (28–66%) in LH levels observed after administration of LHRH and the maintenance of the response for 20–40 min suggests that we observed a true increase in LH. It has been suggested that there is no apparent difference in the levels of follicle-stimulating hormone and LH between lactating and non-lactating humans[12]. With the radioimmunoassay techniques available it may be difficult to pick out differences in the levels of these hormones, particularly when looking for a suppression over the tonic levels. Our study with the monkey, as well as our earlier work with the rat, has shown that withdrawal of the suckling stimulus results in an increase in LH levels over the basal value. Similarly, the use of LHRH has enabled us to show the presence of a clear difference in LH levels of lactating and non-lactating animals.

This study, however, does not exclude the effect of suckling/prolactin directly on the ovarian responsiveness to exogenous gonadotrophins. McNatty *et al.*[13], using *in vitro* cultures of human granulosa cells, have suggested that prolactin could have an influence on the end-organ responsiveness to exogenous gonadotrophins.

Bacteria necessary to produce experimental autoimmune myasthenia gravis in acetylcholine receptor-immunised rabbits?

WE have[1-3] described previously a paralytic disease observed in rabbits immunised with small doses, in Freund's complete adjuvant, of nicotinic cholinergic receptor protein (nAChR) isolated from the electric organ of *Torpedo marmorata* Decremental muscle response after nerve stimulation and positive effects of anticholinesterase administration, decrease in miniature endplate potential amplitude and increased curare sensitivity were similar to findings in patients suffering from myasthenia gravis. Nicotinic AChR antibody titres above 2–3 mg ml^{-1} have been found, the observed muscle decrement increasing with increasing antibody titre. Occasionally, variations in electromyographic activity were observed, suggesting denervation Morphological analysis[3,4] showed severe destruction of postsynaptic motor endplate areas and reduction of toxin-binding sites, followed by changes at the presynaptic side. A second stage of the disease was characterised by high sensitivity to nAChR injections and by the presence of motor endplates lacking secondary postsynaptic foldings. Our work and that of others (for review see ref 5) suggests that an immune response to nAChR seems to be involved in the aetiology of experimental autoimmune myasthenia gravis (EAM) just as is suggested for human myasthenia gravis. The role of a humoral and/or cellular immune response and that of the thymus are under discussion[5,6]. The decremental response to repetitive nerve stimulation may be caused directly and/or indirectly by nAChR antibodies, whereas defects in electromyographic activity such as high frequency discharges and fibrillation action potentials which we have observed may have been caused by other, accompanying mechanisms. This report deals with the role of bacteria in EAM and with the relationship of the antibody titre to the electrophysiological findings.

A sterile-filtered receptor solution produced a low antibody titre, and no decremental response on repetitive stimulation or response to Tensilon was observed. The nAChR used previously[1-3] in immunisation which always resulted in animals with EAM was obtained after solubilisation with phosphate buffer containing 1% Triton X-100 and purification by affinity and ion-exchange chromatography. Sodium azide (0.02%) was added to the purified receptor to prevent further growth of bacteria. About 30 rabbits were immunised with such preparations, all of which showed typical symptoms of EAM.

We have introduced a sterile filtration step (Millipore filters, pore size 0.22 μm) after Triton X-100 solubilisation to reduce bacteria present from 4,000–12,000 to 30 ml^{-1}. The receptor obtained had chemical and physical properties similar to those of material obtained previously, except for a considerably lower antigenicity, as expressed in obtained antibody titre in otherwise identical conditions. Rabbits immunised with a 'sterile' receptor show greater variability in the onset time for the disease, but the clinical picture observed is close to those animals observed previously. The electrophysiological investigations revealed only a very small decrement, about 5–10%, which could not be responsible for the severe visible symptoms in the examined rabbits. An analysis of the receptor antibody titres (rocket immunoelectrophoresis) showed that these are rather low, below 1.2 mg ml^{-1}. A return to receptor purification without sterile filtration resulted in rabbits with high antibody titres and greater decrement. Results from ten rabbits are summarised in Table 1.

Table 1 Relationship between nAChR antibody titre and decremental muscle response after repetitive stimulation of peroneal nerve

Rabbit no	Antibody titre (mg ml^{-1})	Decrement (%)
1	2.9	56
2	4.9	25
3	6.7	62
4	3.0	37
5	3.4	40
6	0.7	5
7	1.2	8
8	0.7	6
9	0.7	6
10	0.5	7

Antibody titres and decrement in rabbits immunised with a non-sterile (1–5) and a sterile (6–10) receptor preparation.

We conclude that so called 'EAM rabbits' may suffer from at least two different kinds of defects one at the neuromuscular junction, which may be of the kind observed in myasthenia gravis (this defect seems to be clearly correlated with the titre of circulating antibody to nAChR); and one, responsible for the severe symptoms visible in rabbits immunised with receptor isolated after sterile filtration, which seems to involve denervation rather than neuromuscular deficiency, revealed in the electromyographic investigation as high frequency discharges and fibrillation action potentials'. These effects were observed also at low nAChR antibody titres.

We have found therefore that besides 'myasthenic symptoms' EAM rabbits seem to have another type of weakness, not correlated with high antibody titre. We may be dealing with a potentiation of nAChR antigenicity, but a specific effect of a bacteria—for example, due to binding to and/or transformation of nAChR—may well be the explanation. It is also possible that the filtration step removes non-bacterial material—for example, aggregated proteins. We have, however, not noticed a lower receptor yield in our final preparations.

Cyclic AMP and cyclic GMP may play opposing roles in influencing force of contraction in mammalian myocardium

CYCLIC AMP and cyclic GMP have been suggested to play opposing regulatory roles in several biological systems[1]. Supporting evidence for the yin yang hypothesis of opposing biological regulation has been obtained in sympathetic ganglia[2,3] and pyramidal neurones in the rat cerebral cortex[4]. In the mammalian heart, the role of cyclic AMP in mediating the positive inotropic response to catecholamines was advanced by the observation that the inotropic effect was preceded by an increase

SCIENCE COLLEGE

in cyclic AMP levels[5]. On the other hand, the levels of cyclic GMP were found to be increased after cholinergic stimulation[6]. In frog, oscillations of cyclic AMP[7] and cyclic changes in the levels of cyclic AMP and cyclic GMP[8] during the cardiac cycle have been reported. The importance of cyclic AMP for the inotropic effects of catecholamines was confirmed by the observation that the dibutyryl derivative of cyclic AMP exerted a positive inotropic effect in cat papillary muscles[9] and in the isolated perfused hearts from rabbits, rats and guinea pigs[10]. I now report a direct negative inotropic effect of 8-Br-cyclic GMP on force of contraction (F_c) in rat auricles and papillary muscles from cats.

Rats and cats were anaesthetised with ether and either auricles or papillary muscles were dissected from the heart and mounted in a muscle chamber for recording mechanical activity as described previously[11]. Left auricles were driven electrically at 2 Hz and cat papillary muscles at 0.2 Hz. Drugs (all cyclic nucleotides from Boehringer/Mannheim) were freshly dissolved in distilled water and 0.1 ml was injected into the muscle chamber containing 5 ml of Tyrode solution (composition in mM: NaCl, 136.9; KCl, 5.4; $MgCl_2$, 1.05; $CaCl_2$, 1.8; NaH_2PO_4, 0.42; $NaHCO_3$, 11.9; glucose, 5.5) which was gassed with 95% CO_2–5% O_2 and heated to 35 °C.

Figure 1 shows the influence of 8-Br-cyclic GMP on F_c in electrically driven left auricles and on frequency of spontaneously beating right auricles isolated from rat hearts. 8-Br-cyclic GMP exerted a concentration-dependent negative inotropic effect; when the preparation was washed three times in drug-free solution, the negative inotropic effect was partially reversible, but F_c did not return fully to its previous control value within 60 min. The frequency of spontaneously beating right auricles was not significantly affected by 8-Br-cyclic GMP within the whole concentration range. Control experiments showed that the negative inotropic effect of 8-Br-cyclic GMP was not influenced when the preparations were pretreated with 5×10^{-6} M atropine sulphate. 10^{-3} M cyclic GMP (not substituted) or 10^{-3} M NaBr did not affect F_c. Figure 2 shows the influence of 8-Br-cyclic GMP on F_c in a cat papillary muscle (mean±s.e. of four experiments: decrease of F_c to 67.7±3.7% of control values). The negative inotropic effect of 8-Br-cyclic GMP was fully reversible within 60 min when the preparation was washed three times in drug-free solution. For comparison, the effects of 8-Br-cyclic AMP were also studied. In papillary muscles from cats, 8-Br-cyclic AMP did not affect F_c; however, after pretreatment with the strong phosphodiesterase inhibitor papaverine (2×10^{-5} M) a positive inotropic effect was observed (Fig. 3; mean±s.e. of six experiments: increase of F_c to 180±22.1% of control values before addition of 8-Br-cyclic AMP).

In atrial tissue, studies with cyclic AMP and its derivatives are complicated by the fact that the breakdown products of cyclic AMP or cyclic AMP itself—if applied from outside the cell—have a strong negative inotropic effect in auricles[12]. In rat left auricles, 8-Br-cyclic AMP caused a sharp decline of F_c that was followed by a second component of a slowly developing increase in F_c (Fig. 4). This second component seems to correspond to the positive inotropic effect seen in cat papillary muscles (Fig. 3), since it was augmented after pretreatment with 2×10^{-5} M papaverine.

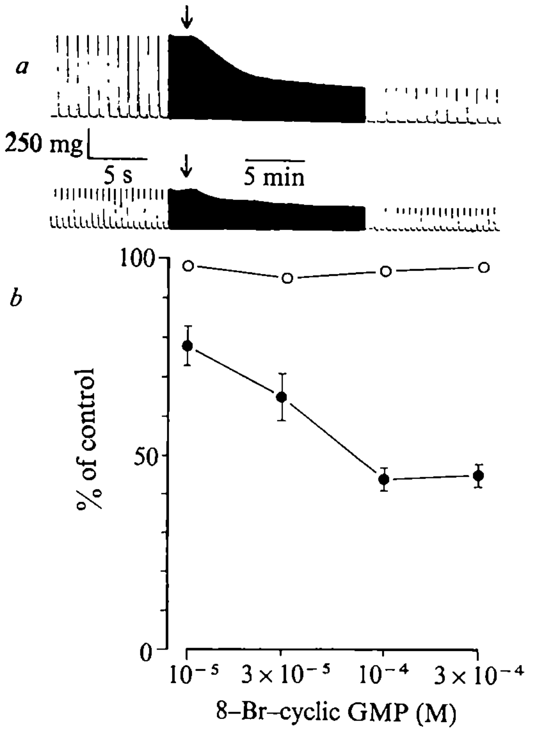

Fig. 1 Effect of 8-Br-cyclic GMP on force of contraction (F_c) and frequency in isolated auricles from rat hearts. F_c was determined in electrically driven left auricles, frequency in spontaneously beating right auricles. *a*, Original traces of a left (upper) and a right (lower) auricle in response to 3×10^{-4} M 8-Br-cyclic GMP. Addition of drug is indicated by the arrows. *b*, Concentration-response relationships. Each concentration was tested in individual preparations. Symbols represent means±s.e. of 8–16 preparations Values of s.e. for the frequency of contraction are smaller than the size of the symbols used and are therefore omitted. ○, Frequency; ●, F_c.

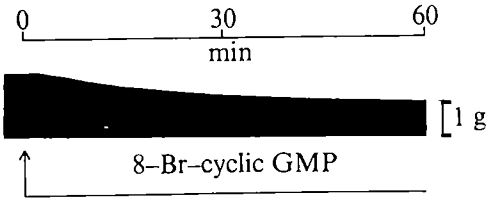

Fig. 2 Effect of 3×10^{-4} M 8-Br-cyclic GMP on F_c in a cat papillary muscle.

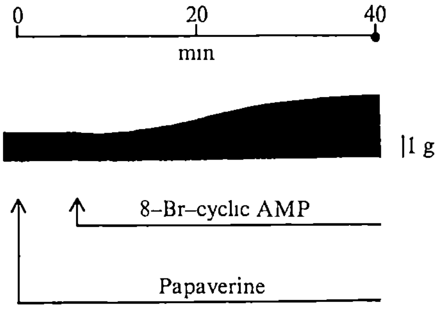

Fig. 3 Effect of 3×10^{-4} M 8-Br-cyclic AMP in a papillary muscle from a reserpinised cat (Serpasil, Ciba, 5 mg kg^{-1}, 18 h before the experiment) in the presence of 2×10^{-5} M papaverine Both papaverine and 8-Br-cyclic AMP alone did not affect F_c but only if given in combination. The same positive inotropic effect was obtained when 8-Br-cyclic AMP was added first and then papaverine. Papaverine itself (2×10^{-5} M) exerts a slight positive inotropic effect in papillary muscles from non-reserpinised cats that is accompanied by an increase in the slow inward current as measured by the voltage clamp technique (H.N., to be published). The positive inotropic effect disappears after pretreat- papaverine has a negative inotropic effect; this corresponds to the findings of Schneider *et al.*[14] who reported a depression of Ca-dependent action potentials in the guinea pig heart with 4×10^{-4} M papaverine. Papaverine (2×10^{-5} M) was given in preference to other drugs because it strongly inhibits the phosphodiesterase activity in the heart but does not affect F_c in cat papillary muscles provided that any adrenergic influences are excluded. Cats were reserpinised to exclude catecholamine effects due to either papaverine or 8-Br-cyclic AMP. This is an appropriate and widely used method to exclude any interference by noradrenaline which may be eventually released by the use of some drugs. The possibility that 8-Br-cyclic AMP releases noradrenaline is not excluded; papaverine, indeed, is able to release endogenously stored catecholamines[15].

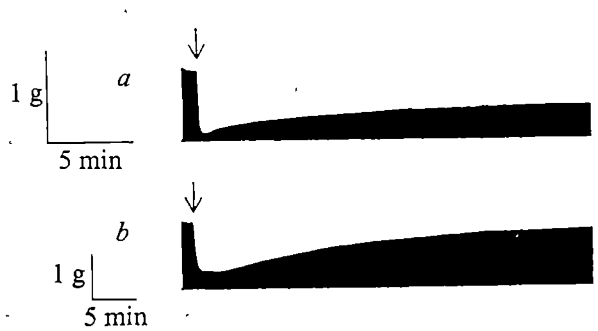

Fig. 4 Effect of 3×10^{-4} M 8-Br-cyclic AMP without (*a*) and in the presence of 2×10^{-5} M papaverine (*b*) in the same preparation (rat left auricle). Papaverine alone had a positive inotropic effect: control F_c in (*b*) before addition of 8-Br-cyclic AMP, indicated by the arrows, was about twice as big as in (*a*). The initial negative inotropic effect of 8-Br-cyclic AMP in rat atrial muscle most probably resulted from 8-Br-cyclic AMP *per se*, if applied from outside the cell, since 10^{-3} M 8-Br-5′ AMP (Schwarz/Mann)—the non-cyclic breakdown product of 8-Br-cyclic AMP—did not produce either the negative or the positive inotropic effect.

These findings indicate a positive inotropic action of 8-Br-cyclic AMP and the sum of results therefore suggests an opposite influence of cyclic GMP and cyclic AMP on F_c in atrial as well as in ventricular myocardium. In contrast to the negative inotropic action of 8-Br-cyclic GMP in rat auricles, the pacemaker activity was virtually unaffected by the drug. This points to a difference in the action of acetylcholine on rat atrial muscle. Voltage clamp experiments have shown that the negative inotropic effect of acetylcholine in mammalian atrial muscle can be explained by an increase in potassium conductance at lower doses and, additionally, by a decrease in calcium conductance at higher doses[13]. It remains open whether similar conductance changes are brought about by the action of cyclic GMP and can be related to the corresponding changes in force of contraction.

I thank Dr Wollenberger for suggesting use of the 8-Br-derivative of cyclic GMP and Mrs Gibson for technical help. This research was supported by a grant from the Deutsche Forschungsgemeinschaft.

Opposing effects of cyclic AMP and cyclic GMP on protein phosphorylation in tubulin preparations

CYCLIC AMP and cyclic GMP have been postulated to be in certain cases, antagonistic intracellular messengers of many hormones and neurotransmitters acting at the cell membrane[1]. At least part of their antagonism may be the result of their ability to affect, in opposite directions, specific protein kinases and phosphates which work on common substrates (enzymes, structural proteins). Cyclic AMP and cyclic GMP have been found to activate, and the former also to inhibit, specific protein kinases[2–5]; cyclic AMP can activate or inhibit[5–8] specific protein phosphates, and both cyclic nucleotide-sensitive protein kinases and protein phosphates have been isolated forming a complex with their substrate[5]. Some of these effects of cyclic nucleotides, however, have been found to depend on the type and concentration (not necessarily physiological) of the ion used in the assay[5] and no direct evidence exists to show that one of the cyclic nucleotides opposes the effects of the other on protein phosphorylation. We report here that physiological concentrations (10^{-7} M–10^{-9} M) of cyclic GMP oppose the cyclic AMP (10^{-6} M) dependent phosphorylation of a soluble, perhaps tubulin-related brain protein, possibly by activation of a phosphoprotein phosphatase.

The enzyme preparation we used is the eluate of the second of two sequential isodeacetylcolchicine-deacetylcolchicine (I-DAC) affinity columns used[9] to purify tubulin from 100,000*g* rat brain supernatants (see legend to Table 1). Previous studies have shown that tubulin purified by these and other methods, contains endogenous protein

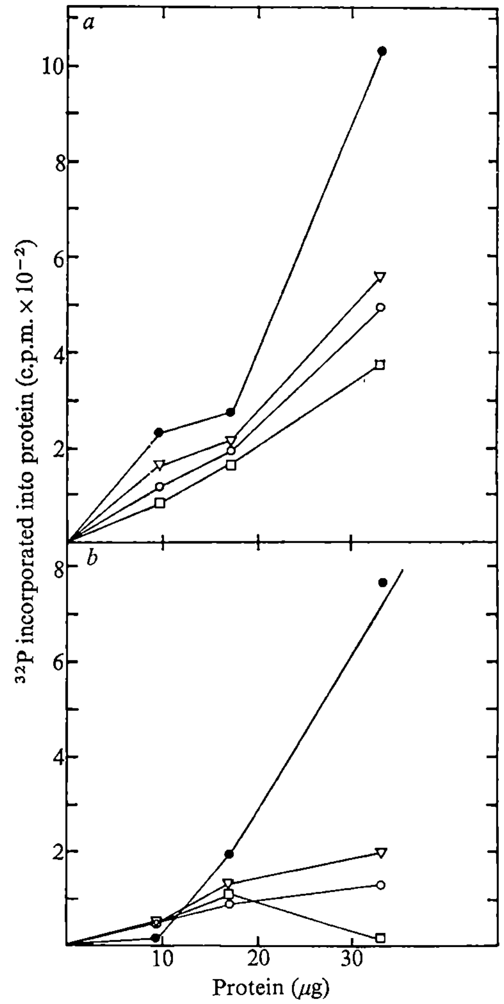

Fig. 1 Effect of cyclic GMP on endogenous protein phosphorylation as a function of the concentration of protein. Data presented correspond to the same experiment: *a*, whole protein kinase; *b*, cyclic AMP-stimulated protein kinase Preparation of the kinase and its assay (5 min, 37 °C) were as described in Tables 1 and 2. The following additions were made to the assay mixture: (●) 2.5×10^{-6} M cyclic AMP, (△) 2.5×10^{-6} M cyclic AMP plus 2.5×10^{-7} M cyclic GMP, (□) 2.5×10^{-6} M cyclic AMP plus 2.5×10^{-8} M cyclic GMP, (○) 2.5×10^{-6} M cyclic AMP plus 2.5×10^{-9} M cyclic GMP.

kinase activity[10-13] which specifically phosphorylates high molecular weight proteins closely associated with tubulin[9,14]. Furthermore, essentially all of the kinase activity in such preparations (including that observed in the absence of added cyclic AMP) is fundamentally cyclic AMP dependent since total suppression of activity occurs[9] on addition of a specific muscle protein kinase modulator[15].

Phosphorylation of endogenous protein in the various colchicine–Agarose eluate fractions is strongly opposed by very low, physiological concentrations of cyclic GMP (Table 1, fractions 3, 4 and 5). Although such inhibition is most marked when exogenous cyclic AMP is added, significant inhibition occurs reproducibly even in the absence of added cyclic AMP. The inhibition occurs at physiological *p*H (7.5) and temperature (37 °C), whether Mg^{2+} (5 mM), Mn^{2+} (5 mM), or both are used and the optimal concentrations of cyclic GMP vary between 10^{-7} and 10^{-9} M. Although there is some experimental variability, the data from many experiments indicate that cyclic GMP concentrations above or below 10^{-8} M are usually less effective (Tables 1 and 2*A*).

The inhibitory effect of cyclic GMP and the relative effectiveness of varying concentrations of this nucleotide are maintained over a relatively wide range of protein concentration in each individual experiment, although the total phosphorylation varies from preparation to preparation (for example, we have observed endogenous phosphorylation–dephosphorylation in preparations containing as little as 1 μg of protein per assay) (Fig. 1).

During the early stages of the kinase assay (for example, 1 min) the inhibitory effect of cyclic GMP is usually not apparent (Table 2*A*) As incubation progresses (from 5 to 10 min), with the concomitant increase in the quantity of

Cyclic GMP inhibition of protein kinase activity in various fractions of a rat brain tubulin preparation chromatographed on a I-DAC–Agarose affinity column. Rat brains (10 g) were homogenised in 10 ml of 10 mM sodium phosphate, *p*H 7.65, containing 5 mM $MgCl_2$ and 1 mM GTP (buffer A). The 100,000*g* (1 h, 4 °C) supernatant of the homogenate was applied (4–10 °C) on a 2 ml I-DAC–Agarose column[9] (containing 160 nmol of bound ligand) equilibrated with buffer A. The column was washed thoroughly (50 ml) with buffer A before the protein was eluted with the same buffer containing 0 1 M NaCl (4 °C). The eluate was desalted on a 40-ml Sephadex G-25 (coarse grade) column equilibrated with buffer A. The protein was then reapplied to the same I-DAC column after washing with 7 M guanidine-HCl followed by equilibration with buffer A. The 0.1 M NaCl eluate of this column was collected in sequential 0 7-ml fractions, each of which was tested for protein kinase activity using the endogenous protein present in the sample as substrate. The enzymatic assay mixture contained, in a total final volume of 200 μl, 50 μmol potassium phosphate, *p*H 7.5, 5 μmol $MnCl_2$, 2 nmol of unlabelled ATP, 2×10^6 c.p.m. of γ-^{32}P-ATP and 50 μl of sample (column eluent) which contained 5 mM $MgCl_2$, 1 mM GTP and 0.1 M NaCl. The samples were incubated for 5 min at 37 °C and the reaction was stopped by the addition of 3 ml of ice-cold 20% trichloroacetic acid plus 300 μg of serum albumin per 200 μl of assay mixture. The values have been corrected for blanks (880 c p.m.), which were determined by adding the radioactivity after stopping the reaction. The ^{32}P incorporated into protein was determined (liquid scintillation) in the second 20% trichloroacetic-acid precipitate after dissolving in 0.5 ml of 1 M NaOH. Values are averages of duplicate replications.

Effect of length of incubation on the cyclic GMP inhibition of cyclic AMP-stimulated protein kinase activity of tubulin preparations. The two independent experiments shown were carried out with protein purified on two sequential I-DAC affinity columns, as described in Table 1. The eluent samples of the second column were pooled before assay. Kinase activity was determined as described in Table 1, using the endogenous protein as the substrate (15 μg). Results essentially similar to those described here have been obtained in at least 20 separate experiments. The data have been corrected for blanks (490 c.p.m. in *A*, 1,100 c.p.m. in *B*).

phosphorylated protein, the effect of cyclic GMP becomes apparent. With progressively longer periods of incubation, however, the effects of cyclic GMP become less obvious, or are obscured by the obvious dephosphorylation which occurs spontaneously in all conditions (Table 2*B*). The kinetic data are most consistent with a cyclic GMP-induced acceleration of a protein dephosphorylation reaction. Addition of adenosine thiotriphosphate (as a carrier) together with γ-^{32}P-ATP decreases greatly the rate of spontaneous dephosphorylation, consistent with the presence of protein phosphatases[16].

Although the kinase activity in the tubulin preparation can effectively phosphorylate exogenously added proteins such as histone (lysine enriched, f1), such phosphorylation is not opposed by cyclic GMP (Table 3). On the other hand, phosphorylation of aged (24 h, −20 °C) colchicine–Agarose eluates (I-DAC), which also occurs readily in the absence of cyclic AMP, is clearly inhibited by cyclic GMP in the absence, but not presence, of cyclic AMP. This suggests that the cyclic GMP-enhanced dephosphorylation may be restricted to certain specific sites of natural protein substrates. These latter sites are probably not the only ones available for phosphorylation in the aged natural substrate when the protein kinase activity is fully expressed (that is, in the presence of cyclic AMP).

Table 3 Effect of cyclic GMP on the phosphorylation of endogenous and exogenous substrates by the eluate of I-DAC–Agarose affinity columns

Effect of cyclic GMP on the phosphorylation of endogenous and exogenous substrates by the eluate of I-DAC–Agarose affinity columns. The kinase preparation described in Table 2 was incubated for 5 min (37 °C) with no other addition (fresh I-DAC protein), with an aged, desalted eluent fraction (10 µg of protein) which had been stored at −20 °C for 24 h (aged I-DAC protein) or with 10 µg of histone. Assay conditions were as described in Table 1.

*Histone type V (Sigma), lysine-rich subgroup f1.

The effects of cyclic GMP cannot be explained on the basis of competition or direct antagonism of a cyclic AMP effect since they can occur even in the absence of cyclic AMP, they clearly follow an initial phosphorylation reaction, the inhibition is much less effective at the highest concentrations of cyclic GMP tested, and direct binding studies using ^{3}H-labelled cyclic AMP (10^{-8} M) show no competition of binding with cyclic GMP concentrations varying from 10^{-7} M to 10^{-9} M. With regard to nucleotide specificity, it is important that the cyclic GMP (10^{-7}–10^{-9} M) effect on protein phosphorylation is observed in reaction mixtures containing much higher concentrations of cyclic AMP (10^{-6} M), ATP (10^{-6} M) and GTP (10^{-4} M). In certain types of experiments it has been observed consistently that prolonged incubation of the kinase assay mixture results in a slow cyclic GMP-stimulated phosphorylation, suggesting the possible additional existence in this system of a specific cyclic GMP-dependent kinase which can complicate observations of the specific phosphatase effect described here (Table 3). For this reason, careful attention to the time course of the assay at a given protein concentration is critical for the demonstration of the cyclic GMP-enhanced dephosphorylation reaction.

These studies suggest the existence of a highly specific, cyclic GMP-sensitive phosphoprotein phosphatase which acts on specific sites of natural substrates which are themselves phosphorylated by a cyclic AMP-dependent protein kinase. We will not speculate further on the possible mechanism of this cyclic GMP effect. These observations, together with earlier studies demonstrating that the kinase activity of the tubulin preparation used here is completely cyclic AMP dependent[9], and that the proteins phosphorylated (*in vivo* as well as *in vitro*) are specific high molecular weight proteins closely associated with the 36S tubulin molecule[9,14], may be pertinent to understanding the regulation of the structure and function of tubulin and microtubules The specific cyclic GMP effect described here may also have broader significance with respect to the biochemical actions of this cyclic nucleotide. The low levels of protein phosphatase activity in preparations of tubulin obtained by two cycles of polymerisation–depolymerisation may reflect a weak association of the protein phosphatase with tubulin, or may be uniquely related to the specific method of purification. The fact, however, that certain colchicine derivatives, such as that used in the affinity adsorbent used here, inhibit bacterial and animal non-protein alkaline phosphatases as well as vegetable non-protein acid phosphatases[17] opens the possibility that the I-DAC affinity column may also retain protein phosphatases physiologically unrelated with tubulin or functionally related proteins.

Structural properties of rat serum proteins which correlate with their degradative rates *in vivo*

SERUM proteins[1,2] like intracellular proteins[3–7], are continually being degraded and replaced at characteristic rates. Although there is appreciable evidence that structural alterations can influence the half lives of serum proteins[8–11], the features of serum proteins which normally influence their degradative rates are unknown. The present experiments were undertaken to learn more about the factors influencing the degradation of serum proteins and to explore any possible relationship of this process to the catabolism of intracellular proteins.

There is now strong evidence that the degradative rates of intracellular proteins are determined to a large extent by their conformations[5,6]. For example, in both animal and bacterial cells, the catabolic rates of different proteins correlate with their relative sensitivities *in vitro* to purified endoproteases[5–7] and to lysosomal extracts[12–14]. In addition two structural features of normal proteins have been shown to correlate with their half lives in a wide variety of organisms and tissues: (1) proteins with large subunits tend to be degraded more rapidly on the average than those with small subunits[5–7,15], and (2) proteins with acidic isoelectric points tend to be degraded more rapidly than proteins with neutral or basic isoelectric points[16].

Analogous studies of the possible relationship between the degradative rates of serum proteins and these structural properties have not been reported. We now present evidence that the catabolism of serum protein shows two of the characteristics previously reported for degradation of intracellular proteins: (1) the rates of catabolism of rat serum proteins *in vivo* correlate with their relative sensitivity *in vitro* to a wide variety of endoproteases, and (2) the more acidic serum proteins turn over *in vivo* more rapidly than neutral or basic ones. In contrast to findings with intracellular proteins, no relationship was found between the molecular weights of serum proteins and their half lives *in vivo*

To test whether half lives of serum proteins are related to their sensitivity to proteolytic attack, we used the double-isotope approach of Arias *et al.*[17] to differentiate serum proteins which turn over rapidly from those which turn over slowly *in vivo*. This same technique was used previously to establish a correlation between degradative rates and protease sensitivity for intracellular proteins[7]. ^{14}C-leucine was administered to a rat 4 d before an injection of ^{3}H-leucine, and the animal was killed 4–12 h after the second injection. The ^{14}C remaining in protein after 4 d is primarily contained in the more stable proteins, while the ^{3}H is found preferentially in proteins that turn over rapidly[5,17,18].

We then compared the susceptibility to various proteases of proteins having shorter *in vivo* half lives (enriched for ^{3}H) and those that are more stable (enriched for ^{14}C). As shown in Fig. 1, serum proteins rapidly degraded *in vivo* were more susceptible to digestion at *p*H 7.2 by Pronase (*a,f*), trypsin (*b*) and chymotrypsin (*c*) and at *p*H 4.0 by the acidic proteases, pepsin (*d*) and lysosomal cathepsins from rat liver (*e*). Similar results were obtained with three separate preparations of double-labelled proteins from rat serum. These findings are analogous to those obtained earlier with intracellular proteins[5–7,12–14], although the serum proteins on the average appeared much less susceptible to trypsin and chymotrypsin than were liver proteins (J.F.D. and A.L.G., unpublished).

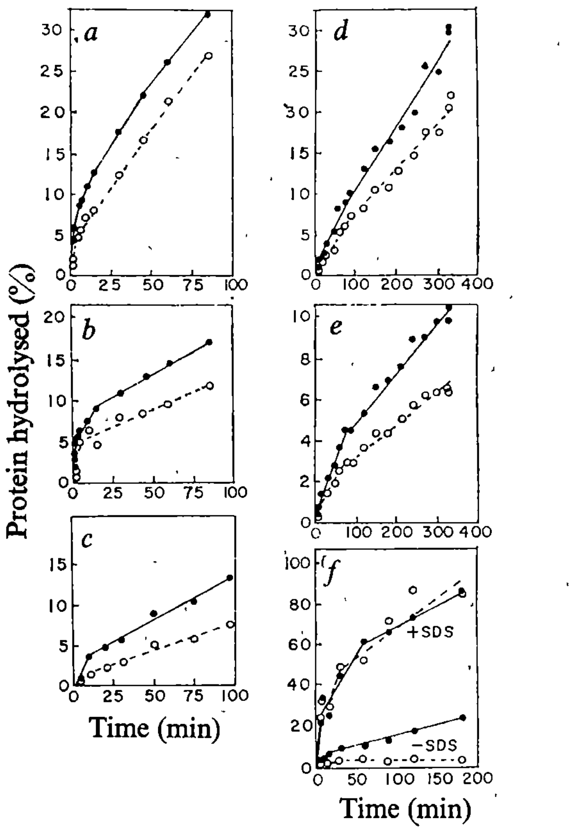

Fig. 1 Comparison of the susceptibility of stable and rapidly turning-over serum proteins to proteolytic enzymes To label these fractions preferentially, 100 µCi of ^{14}C-leucine was administered intraperitoneally to a male rat (125 g) Four days later, the same animal was injected with 500 µCi of ^{3}H-leucine and killed 4 or 12 h thereafter. Consequently, the ^{14}C is found primarily in proteins with relatively long half lives (○) while ^{3}H-proteins (●) are enriched for more labile polypeptides. To prepare the serum, the rats were anaesthetised with ether, blood (about 5 ml) was collected from the aorta into a heparinised tube, and cells were separated by centrifugation at 100*g* for 10 min. The clear supernatant containing the serum proteins was dialysed against phosphate-buffered saline (*p*H 7.2, ref. 7) (for experiments *a–c* and *f*) or 100 mM citrate buffer (*p*H 4.0) (for experiments *d* and *e*) to remove free amino acids. The procedure for incubation with proteases, and the sources for all materials have been reported previously[7]. Each incubation mixture contained approximately 5 mg of serum protein with a specific activity of about 70,000 d.p.m. ^{3}H and 5,000 d.p.m. ^{14}C per mg. Enzymes were added at the following concentrations: *a*, Pronase, 100 µg ml^{-1}; *b*, trypsin, 100 µg ml^{-1}; *c*, chymotrypsin, 1 mg ml^{-1}; *d*, pepsin, 50 µg ml^{-1}; *e*, crude lysosomal fraction (prepared as described in (31)), 10 mg ml^{-1}; *f*, Pronase, 50 µg ml^{-1}. Conformations of serum proteins were disrupted in (*f*) by addition of 1% SDS and 50 mM dithiothreitol (final concentration) and boiling for 5 min. (Pronase is at least partially active in SDS.) Protein hydrolysis is expressed as radioactivity (d.p.m.) initially in protein that is converted to a trichloroacetic-acid soluble form.

These results indicated that the rates of catabolism of serum proteins are related to their inherent susceptibility to proteolytic attack, which is presumably a function of the proteins' native conformations. In fact, the susceptibility of both rapidly and slowly turning-over proteins to digestion by Pronase increased markedly when the native conformations of the proteins were destroyed by boiling in sodium dodecyl sulphate (SDS). Following such treatment, the correlation between degradative rates *in vivo* and susceptibility to Pronase was abolished (Fig. 1*f*).

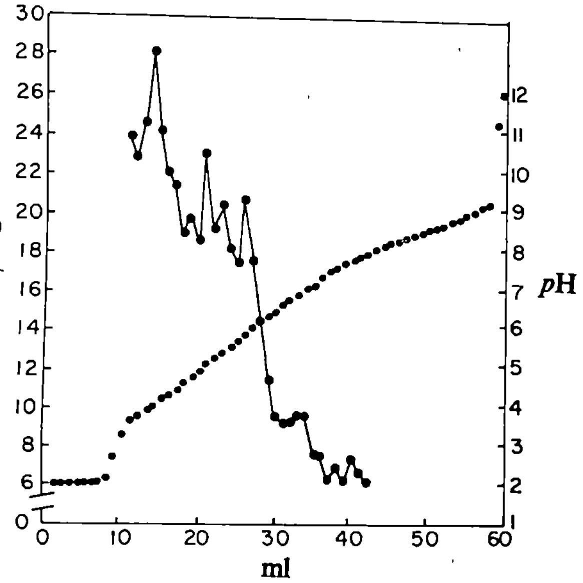

Fig. 2 Comparison of degradative rates of rat serum proteins with different isoelectric points. Double-labelled serum proteins were prepared as described in Fig. 1 and separated by isoelectric focusing as reported previously[16]. A high $^{3}H/^{14}C$ ratio indicates more rapid turnover of the fraction[17]. Radioactivity in each fraction was determined as described previously. Ratios are not plotted for fractions containing less than 200 d.p.m. for each isotope. The variation in $^{3}H/^{14}C$ ratios inherent in these experimental protocols has been reported previously[16]. Fractions from isoelectric focusing contained between 0 and 10,000 d.p.m. of ^{3}H and 0 and 500 d.p.m. of ^{14}C. The correlation between $^{3}H/^{14}C$ and *p*H is highly significant ($r = -0.957$, $P < 0.01$). *p*H, ●●●; $^{3}H/^{14}C$, ●—●.

We used the same labelling procedures to compare the degradative rates *in vivo* of serum components differing in their isoelectric points. For any protein, the amount of isotope remaining after 4 d (^{14}C) relative to the amount of isotope initially incorporated (^{3}H) reflects its rate of degradation. Thus, proteins that are synthesised and degraded rapidly will have high $^{3}H/^{14}C$ ratios, as has been discussed critically elsewhere[5,7,17,18]. The double-labelled serum proteins were then separated according to their isoelectric points by isoelectric focusing[16].

The more acidic proteins consistently had higher $^{3}H/^{14}C$ ratios ($r=0.957$, $P<0.01$). Thus on the average they are degraded more rapidly than the less acidic ones. Qualitatively similar results were obtained with three separate preparations of double-labelled proteins from rats and with two preparations from mice. Thus, a similar correlation between degradative rates and isoelectric points holds for serum proteins (Fig. 2) as for intracellular proteins, even though serum was found to contain much fewer basic proteins than most mammalian tissues (J. F. D. and A.L.G., unpublished observations).

Many earlier studies have demonstrated a correlation between degradative rates of intracellular proteins and their subunit molecular weight as determined by SDS–acrylamide gel electrophoresis[5-7,15]. But when double-labelled serum proteins were separated by SDS gel electrophoresis, no relationship was found between subunit molecular weight and degradative rates (Fig. 3). These findings differ from those obtained with all mammalian tissues tested. These negative results are complicated by the fact that most serum proteins are glycoproteins which have been shown to migrate more slowly than expected in SDS gels primarily because of a decrease in detergent binding[19,20]. Since glycoproteins should behave less anomalously during Sephadex gel filtration in the absence of SDS, we have also fractionated serum proteins according to their multimeric size by Sephadex chromatography. For intracellular proteins multimer molecular weights also correlate with half lives[1], since larger multimers tend to be composed of larger subunits[15]. On gel filtration of the serum proteins, however, no relationship was found between molecular weight and degradative rate (Fig. 4).

Thus degradative rates of serum proteins, unlike those of intracellular proteins, do not correlate with their molecular weights (Fig. 3 and 4). Larger intracellular polypeptides have been shown in general to be more sensitive to proteases *in vitro* than smaller ones, and this relationship has been suggested to be the basis for the observed correlation between molecular weight and *in vivo* degradative rates[7]. It is possible that large and small serum components do not differ in susceptibility to proteases. On the other hand, physiological processes are known that can cause the selective loss of small polypeptides from serum and may therefore obscure any general relationship that may exist between protein size and degradative rates. For instance, smaller proteins are lost especially rapidly from the circulation due to ultrafiltration in the renal glomeruli as well as in other capillary beds[22]. In addition, specific degradative mechanisms appear responsible for the rapid catabolism of small peptide hormones[7]. Thus the reasons and significance of this lack of a size correlation for serum proteins are unclear.

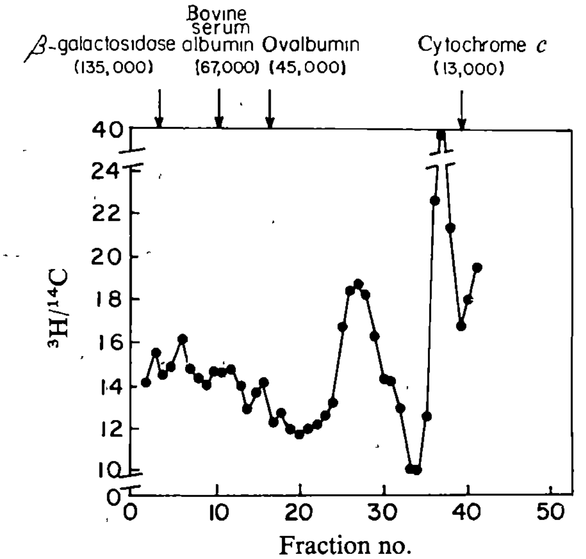

Fig. 3 Relative degradative rates of rat serum polypeptides of different molecular weights. Double-labelled serum proteins were prepared as described in Fig. 1 and separated by SDS–acrylamide gel electrophoresis. A high $^{3}H/^{14}C$ ratio indicates more rapid turnover of the fraction. The electrophoresis was performed in large diameter gels, which were sliced and counted as described earlier[7]. Electrophoretic fractions contained between 0 and 14,000 d.p.m. ^{3}H and 0 and 1,200 d.p.m. ^{14}C. Ratios are not plotted for fractions containing less than 100 d.p.m. of each isotope. The variation in $^{3}H/^{14}C$ ratios inherent in these methods has been reported previously[7].

A variety of studies have indicated that the pathway of catabolism of serum proteins involves pinocytosis and subsequent appearance of the proteins in lysosomes[8,9]. Pinocytosis has been generally assumed to be the rate-limiting step in the degradation of serum proteins. This conclusion is based primarily on studies of the fate of injected enzymes[23,24] or specific labelled serum proteins[8,25-27]. The present findings on the turnover of native serum proteins in normal conditions suggest alternative possibilities. Since the degradative rates of serum proteins *in vivo* correlate with their relative susceptibility to a variety of proteases (Fig. 1), the rate-limiting step in the catabolism of most serum proteins may be an initial proteolytic cleavage within the circulation followed by pinocytosis of the partially degraded protein. A rate-limiting proteolytic cleavage also

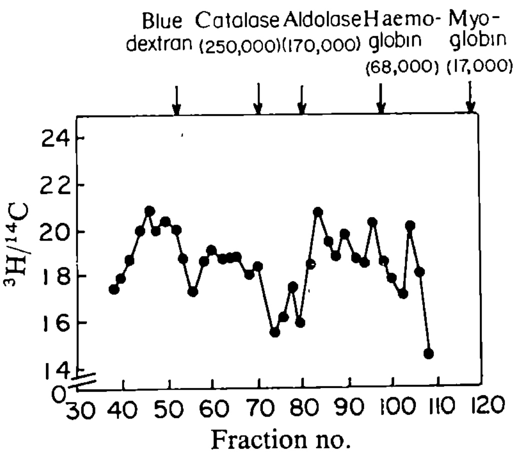

Fig. 4 Comparison of the degradative rates of serum proteins of different multimer size in the absence of SDS. Double-labelled serum proteins were prepared as in Fig. 1 and separated by Sephadex G-150. The protein fractionation and counting of radioactivity was carried out as reported earlier[7,16]. Chromatographic fractions contained between 0 and 50,000 d.p.m. ^{3}H and 0 and 2,000 d.p.m. ^{14}C. Ratios are not plotted for fractions containing less than 100 d.p.m. of each isotope.

might possibly occur within the secondary lysosome. According to this hypothesis, proteins that are relatively resistant to lysosomal proteases, might then be released and re-enter the circulation[27-29].

Alternatively, if pinocytosis of serum proteins is actually the rate-limiting step in their degradation, the structural features of the serum proteins which determine their rates of pinocytosis must correlate with their protease sensitivity (Fig. 1) and their isoelectric points (Fig. 2). For example, proteins that are more sensitive to proteases or more acidic may tend to denature more easily[5,6], and denaturation can promote pinocytosis[9,30]. Whatever the mechanism underlying the correlations with charge and proteolytic susceptibility, the fact that they apply to both intracellular and extracellular proteins suggests that degradation of these two types of proteins involves similar principles and may even share common mechanisms.

Accessibility of DNA in condensed chromatin to nuclease digestion

RECENT evidence indicates that a large portion of the DNA of higher organisms is organised in compact nucleoprotein structures. Initial studies on nuclease digestion of chromatin showed that about half the nuclear DNA is present in the form of small resistant chromatin fragments[1-3]. Subsequent studies have shown that the sites of nuclease digestion are regularly spaced, and that, at the limit of digestion, the majority of the DNA that remains is in the form of relatively homogeneous small fragments, which vary from about 120 to 200 nucleotide pairs in length[4-7]. This concept of small repeating resistant structures in chromatin is further supported by electron microscope studies on chromatin fibres spread from hypotonically treated nuclei[8] and from isolated chromatin[9]

Here we examine whether two types of 'condensed' chromatin—mitotic chromosomes and the fraction of interphase chromatin that contains satellite DNA—have the same subunit structure as 'non-condensed' chromatin. The experiments were performed on cells of *Dipodomys ordii* (kangaroo rat) because (1) mitotic cells can be shaken off monolayer cultures selectively to yield pure mitotic cell preparations and (2) this species contains 52% of its DNA in the form of satellite components[10] which are associated with a dense interphase chromatin fraction[11].

The kinetics of staphylococcal nuclease digestion of DNA in interphase nuclei or mitotic chromosomes to acid-soluble material are essentially identical At an enzyme concentration of 30 units ml^{-1} there is a rapid phase of digestion such that 65% of the DNA remains acid insoluble after 15 min, followed by a slower linear digestion until 50% remains acid insoluble after 1 h. Accessibility of DNA to the enzyme is similar in both chromatin states.

Another test for similarity in the sub-structure of interphase nuclei and mitotic chromosomes is to observe the size distribution of DNA fragments generated at various times during nuclease digestion of the chromatin Cells were uniformly labelled with ^{3}H-thymidine for two cell generations. ^{3}H-labelled chromosomes and ^{3}H-labelled interphase nuclei were prepared from these cultures and separately mixed with unlabelled interphase nuclei in the ratio of 1 : 10 in DNA amount. DNA extracted from partial nuclease digests was analysed on 1.5% Agarose gels which were photographed after staining with ethidium bromide The gels were subsequently processed for fluorography, and the sizes of unlabelled DNA fragments detected by ethidium bromide staining were compared with the sizes of ^{3}H-labelled DNA fragments detected by fluorography (Fig 1).

At all stages of nuclease digestion of the chromatin mixtures we could detect no differences in the size of the DNA fragments from single or multiple subunits derived from unlabelled interphase chromatin (Fig. 1*a* and *c*), ^{3}H-labelled interphase chromatin (Fig 1*b*), or mitotic

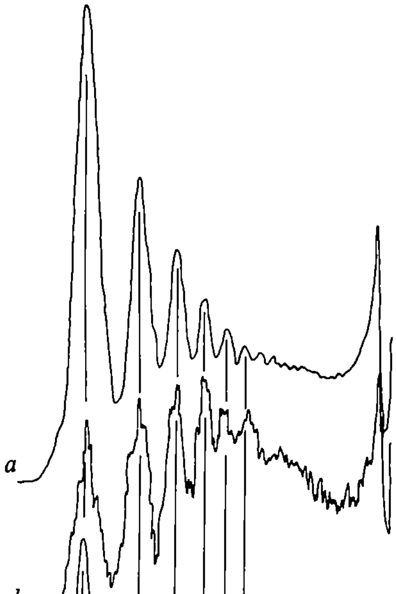

Fig. 1 Agarose gel and fluorogram analysis of DNA from interphase and mitotic chromatin digested with staphylococcal nuclease. Mitotic and interphase cells of *D. ordii*, labelled for 60 h with 0.2 µCi ^{3}H-thymidine (54 Ci mM^{-1}, Amersham) in F-12 medium lacking unlabelled thymidine, were collected separately as described elsewhere[13]. Equal quantities of each ^{3}H-labelled sample were mixed with 10 times the number of unlabelled cells. The nuclei and chromosomes were prepared by one of a number of methods[3,14,15], and resuspended in 20 mM Tris, 1 mM CaCl$_2$, 1 mM MgCl$_2$, *p*H 7.5 at a concentration equivalent to 200 µg total DNA ml^{-1}. Staphylococcal nuclease was added at 30 units ml^{-1}. At various intervals after the start of digestion, samples were removed and digestion stopped by addition of 2 ml 50 mM sodium phosphate buffer, *p*H 6.8, containing 5 mM EDTA. Sodium dodecylsarcosinate and NaCl were added to final concentrations of 0.5% and 1 M respectively, and the lysate was extracted twice with water-saturated phenol. DNA was precipitated by the addition of two volumes of absolute ethanol followed by storage overnight at −20 °C. DNA precipitates were collected by centrifugation, redissolved in 10 mM Tris, 10 mM EDTA, *p*H 8.0, and electrophoresed in 1.5% Agarose slab gels (18 cm × 18 cm × 5 mm) for 16 h at 10 mA at room temperature The electrophoresis buffer was 40 mM Tris, 20 mM sodium acetate, 1 mM EDTA, *p*H 8 2. Gels were stained with 0.5 µg ml^{-1} ethidium bromide dissolved in electrophoresis buffer, and the fluorescence photographed under light at 254 nm. Photographed gels were processed for fluorography essentially as described by Bonner and Laskey[16] except that ethoxyethanol was used as the solvent in place of dimethyl sulphoxide. Fluorograms were exposed on presensitised Kodak RP-Royal Xomat film at −75 °C and developed in Kodak D-19 developer. Photographic negatives of the stained gels and the fluorograms were scanned in a Joyce Loebl densitometer. The tracings shown are both of chromatin digested for 15 min (20% of the DNA rendered acid soluble). *a*, Ethidium bromide fluoroscence distribution; unlabelled plus ^{3}H-labelled interphase chromatin; *b*, distribution of ^{3}H-labelled DNA fragments from interphase chromatin; *c*, ethidium bromide fluorescence distribution; unlabelled interphase chromatin plus ^{3}H-labelled mitotic chromatin; *d*, distribution of ^{3}H-labelled DNA fragments from mitotic chromatin The size of the DNA fragments (in base pairs) is indicated at the bottom of the figure. These values were obtained by comparison with DNA fragments produced by *Eco*RII restriction enzyme digestion of mouse satellite DNA[17] and *Hin*dIII restriction enzyme digestion of SV40 DNA[18].

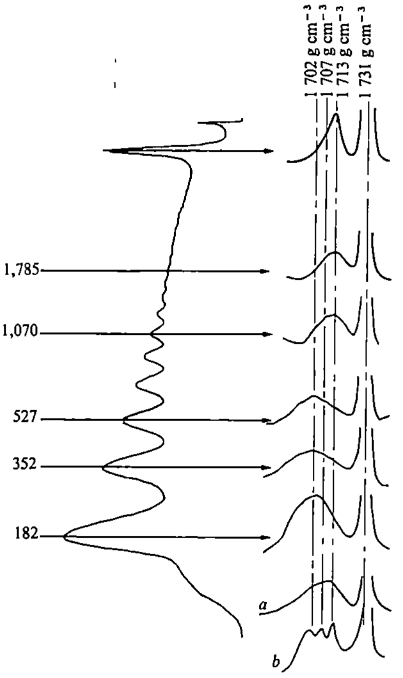

Fig. 2 Caesium chloride neutral density gradient analysis of DNA of different fragment sizes following partial digestion of nuclei by nuclease. Nuclei were isolated and digested with staphylococcal nuclease and then several slab gels were run as described in Fig. 1. The individual DNA bands were cut out, and the DNA was recovered by crushing the gel through a 24-gauge hypodermic needle and centrifuging the crushed gel at 200,000*g* for 30 min. The supernatant was removed, solid caesium chloride added to a density of 1.70 g cm^{-3} and ethidium bromide extracted with *n*-propanol. After removal of ethidium bromide, the density was adjusted to 1.710 g cm^{-3} and *Micrococcus lysodeikticus* DNA was added as a density marker. Centrifugation was at 44,700 r.p.m. at 25 °C for 24 – 48 h in the 6-place analytical rotor in an MSE Centriscan. Left, Densitometer tracing of a photographic negative of DNA from a partial digest separated on 1.5% Agarose gel as described in Fig. 1. Right, Neutral caesium chloride banding profiles of DNA isolated from the various regions of the gel as indicated. The buoyant density profiles of *a*, total DNA after partial digestion and *b*, total undigested DNA, are shown at the bottom The size of the DNA fragments (in base pairs, see Fig. 1) is indicated on the left.

chromatin (Fig. 1*d*). The distribution of the majority of nuclease-sensitive sites is thus the same in both mitotic and interphase chromatin.

We have measured the relative rates of digestion of the fractions containing satellite and non-satellite DNA in interphase chromatin. The satellite DNA component is less rapidly digested by nuclease than chromatin containing non-satellite DNA. We have shown this by measuring the amounts of satellite DNAs present in DNA fragments of different size at various stages of digestion of interphase chromatin. The DNA fragments were recovered from Agarose gels and analysed by analytical caesium chloride density centrifugation or thermal denaturation in 0.1 × SSC. The three satellite DNAs of *D. ordii* band on the heavy side of the main band DNA. HS-α and HS-β satellite DNAs have a density of 1.713 g cm^{-3} and MS satellite DNA has a density of 1.707 g cm^{-3} (ref. 12). The HS-β satellite has a G+C content of 66%, and can be distinguished clearly as a separate component in a thermal melting profile. Buoyant density analysis has the advantage that it can identify all three major satellite components, but the disadvantage of giving poor resolution at the molecular sizes of the smaller DNA fragments. Thermal denaturation, on the other hand, can reliably distinguish HS-β satellite DNA component in large and small DNA fragments, but can only detect about 20% of the total satellite DNA.

Buoyant density analysis of DNA of different fragment sizes from partially digested chromatin (Fig. 2) shows that the DNA remaining as high molecular weight structures—larger than six times the single subunit size—is almost entirely satellite DNA. DNA fragments of single subunit size, or low multiples thereof, have broad banding profiles, but with a peak density characteristic of main band DNA. The enrichment of satellite DNA in high molecular weight DNA fragments is unambiguous, but the depletion of satellite DNA in low molecular weight pieces is less convincing, owing to the diffuse banding profiles.

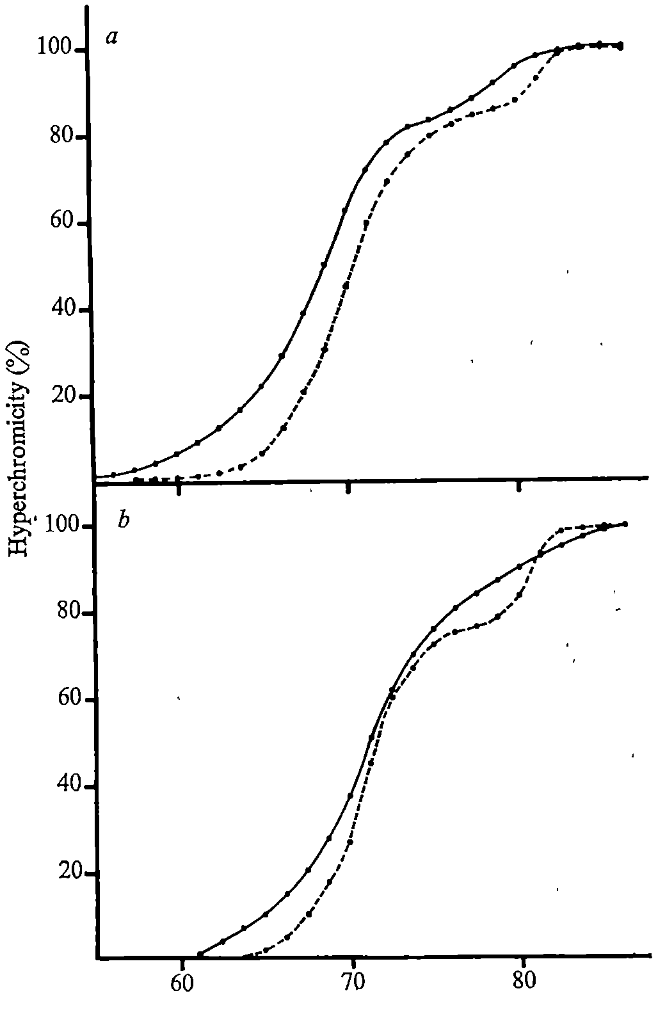

Fig. 3 Thermal denaturation profiles of *a*, total undigested DNA (— — —) and single subunit sized DNA after complete nuclease digestion (———). *b*, Single subunit sized DNA (———) from partially digested (20% acid soluble) chromatin and high molecular weight DNA (— — —) fragments of partially digested (20% acid soluble) chromatin. Total undigested DNA was isolated from nuclei by the method of Marmur[19] with slight modifications. DNA fragments from digested chromatin were recovered from the supernatants of crushed gels (see Fig. 1) by adding NaCl to a final concentration of 1 M, extracting twice with 2 volumes of water-saturated phenol, and precipitating the DNA by addition of 2 volumes of ethanol followed by storage overnight at −20 °C. The precipitates were collected by centrifugation, dissolved in 1/100 × SSC and dialysed exhaustively against 1/10 SSC. All samples were thermally denatured in 1/10 SSC in a Unicam SP800 spectrophotometer. (SSC is 0.15 M sodium chloride, 0.015 M sodium citrate.)

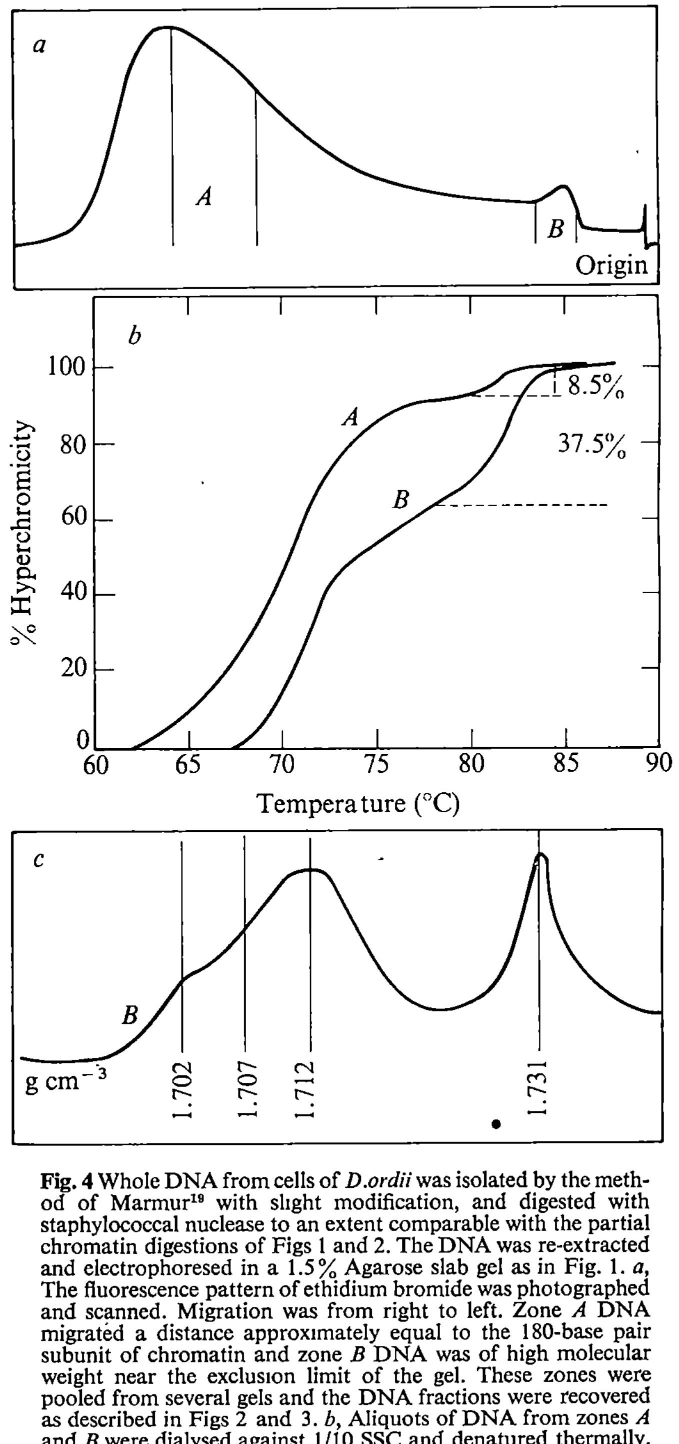

Fig. 4 Whole DNA from cells of *D.ordii* was isolated by the method of Marmur[19] with slight modification, and digested with staphylococcal nuclease to an extent comparable with the partial chromatin digestions of Figs 1 and 2. The DNA was re-extracted and electrophoresed in a 1.5% Agarose slab gel as in Fig. 1. *a*, The fluorescence pattern of ethidium bromide was photographed and scanned. Migration was from right to left. Zone *A* DNA migrated a distance approximately equal to the 180-base pair subunit of chromatin and zone *B* DNA was of high molecular weight near the exclusion limit of the gel. These zones were pooled from several gels and the DNA fractions were recovered as described in Figs 2 and 3. *b*, Aliquots of DNA from zones *A* and *B* were dialysed against 1/10 SSC and denatured thermally. *c*, DNA of high molecular weight from zone *B* was centrifuged to equilibrium in neutral CsCl as described in Fig. 2.

This ambiguity is overcome by thermal denaturation. When chromatin was digested for 1 h (as in Fig. 1) the 50% of DNA that remained acid insoluble was entirely at the size of single subunits. The melting profile of this DNA was similar to that of total undigested DNA (Fig. 3*a*). Although the T_m of the single subunit-sized DNA is lower because of its decreased molecular weight[20], the second transition (HS-β satellite DNA) is about 15% of the total hyperchromicity in both samples. Thus, at this stage of digestion to single subunit size, the distribution of satellite and non-satellite DNAs is the same as in undigested chromatin. In a partial digest of chromatin, however, (Fig. 3*b*) DNA of single subunit size is considerably depleted HS-β DNA, whereas DNA remaining at high molecular weight is enriched in HS-β to a degree consistent with the sample containing only the total satellite mixture

We are grateful to a reviewer for the suggestion that the apparent resistance of satellite DNA-containing chromatin during brief digestion could be due to the known preference of the nuclease for AT-rich DNA[21]. As a result, free DNA isolated from cells of *D. ordii* was digested to various extents in the same conditions as for chromatin digestion. Similar to the partial chromatin digestion (Fig. 3), most of the DNA fragments formed a broad band in 1 5% Agarose gel, the size of the single subunit of chromatin and smaller, whereas a small amount of DNA was almost excluded from the gel (Fig. 4*a*). Zones at approximately 180-base pair size and of high molecular weight were extracted and the recovered DNA fractions were centrifuged in a CsCl gradient and melted. The density gradient pattern of the high molecular weight DNA (Fig. 4*c*) corresponded with the 1,070-base pair pattern of Fig. 2, thus showing enrichment in satellites and depletion of main band DNA. Thermal denaturation (Fig 4*b*) revealed that the second transition (representing HS-β satellite) was smaller than that of whole DNA for the low molecular weight fraction and very much larger for the high molecular weight fraction.

The results with partial digestion of free DNA are very similar to those of chromatin. The apparent resistance of chromatin containing satellite DNA to nuclease digestion may be due to the base preference of the enzyme rather than to a difference between extended and condensed chromatin in accessibility of DNA to the enzyme Other factors may, however, be involved since only HS-β satellite is substantially richer in GC content than main band DNA, yet all three satellites seem to behave similarly towards nuclease digestion. This question is receiving further study.

From our results it can be concluded that, firstly, the structures of extended and condensed chromatin in the forms of mitotic chromosomes or satellite DNA-containing interphase chromatin do not differ significantly in respect to accessibility to digestion by staphylococcal nuclease and secondly, the size and distribution of nuclease-resistant chromatin subunits are similar in extended and condensed chromatin. These findings support models of chromatin structure which place the DNA moiety in an exposed position outside the subunits[22–25]. A condensed state of chromatin does not arise therefore from greater coverage by proteins in a manner that obstructs the access of nuclease to the DNA.

Amphipathic enzyme–polymer conjugates

IMMOBILISATION of enzymes on solid supports to give reusable and stabilised catalysts has been studied extensively[1] but the concept of chemically modifying a water-soluble enzyme to enable its activity to be utilised in the form of a water-immiscible liquid phase has received little attention. Potential advantages of liquid-phase immobilisation include ease of continuous operation, freedom from the effects of solid particle breakdown and the possibility of enhanced activity against water-insoluble liquid substrates. Although the effects of detergent–protein association on protein extractability into *iso*-octane have been studied[2] and considerable effort has been expended on the liquid membrane entrapment concept[3,4], another possible type of liquid-phase immobilised enzyme system seems to have been neglected. The latter comprises droplets of a water-immiscible liquid bearing a surface layer of modified enzyme. We have found that some enzymes may be converted into surface-active amphipathic conjugates by covalent coupling to certain types of polymeric detergents (polysoaps) and that the resulting conjugates may bind sufficiently strongly to dispersed water-immiscible liquids to give an enzymatically active emulsion that can be handled as a quasi-liquid phase. The amphipathic enzyme conjugates are analogous to certain membrane-bound proteins such as cytochrome b_5, which have been shown to comprise a hydrophilic protein core anchored to a lipid bilayer by a hydrophobic polypeptide tail[5,6].

A particularly simple and convenient route to conjugates of proteins with random copolymer amphipaths is shown in Fig. 1.

A linear hydrophilic polymer such as the non-cross-linked types of ethylene–maleic anhydride copolymers previously used for enzyme immobilisation[7,8] or the maleic anhydride–vinyl methyl ether copolymer Gantrez AN[9] can be modified with hydrophobic nucleophiles (for example, RNH_2) by partial substitution of the anhydride functions. The remaining anhydride units may then be used to couple the polymer to a protein.

The modification reaction is conveniently carried out in *NN*-dimethylformamide in the presence of an organic base and the reaction mixture can be added directly to a solution of the enzyme with homogenisation. Alternatively, the modified polymer can be hydrolysed and the protein coupled to it using established carboxyl group activation techniques such as conversion to the acid azide[10] and the use of water-soluble carbodiimides[11] or Woodward's reagent K (ref. 12). These general methods enable control of net hydrophobicity, degree of enzyme substitution and, since cross linking by the protein can be minimal, of conjugate molecular weight. There is scope for introduction of spacer groups, different enzymes on the same polymer and other refinements.

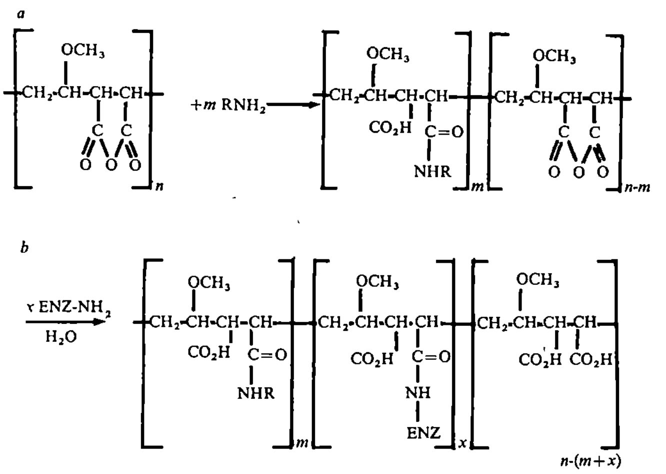

Fig. 1 Route to conjugates of proteins with a random copolymer amphipath.

Using the technique described, penicillin acylase and other enzymes have been conjugated with good recovery of enzyme activity. For example: a polymer solution prepared from Gantrez AN119 (0.5 g) and *n*-octadecylamine (0.28 g) in *NN*-dimethylformamide (2 5 ml) and pyridine (0.1 ml) was homogenised with *Escherichia coli* penicillin acylase (175 mg partially purified enzyme) in water (30 ml). After reaction at 4 °C overnight, sodium chloride (5.8 g) was added to precipitate the amphipathic solute, and the polymer conjugate isolated by centrifugation at 25,000*g* at 0 °C for 1 h A gel (4 0 g wet weight) of high specific activity resulted, and recovery of enzyme activity was 70%. Table 1 lists further conjugates of the same type. The physical form of these preparations varies from highly aggregated solids that sediment rapidly to materials that are soluble in low ionic strength aqueous media according to the extent of substitution by hydrophobic groups in the polymer or protein in the final conjugate. Some conjugate preparations may be fractionated by salt precipitation into materials of varying net hydrophobicity. Enzyme lability does not usually increase on conjugation, indicating that linkage to a polymeric detergent does not necessarily destabilise the catalytically active conformation of a protein.

Homogenisation of such conjugates with buffer and liquids such as *n*-decane, *n*-decanol and glycerol trioleate results in emulsions which can readily be separated by flotation or gentle centrifugation into an aqueous phase and a droplet phase with which the enzyme activity is associated. For example. homogenisation of the penicillin acylase conjugate described in the text above, with *n*-decanol in a wet gel–solvent weight ratio of 1 : 5 resulted in 90% of the enzyme activity being associated with the droplet phase on separation. The unconjugated enzyme does not bind significantly to solvent droplets formed using the Gantrez-based polysoaps. Some of the enzymatically active emulsions are quite stable: the droplet phase described above retained more than 40% of the initial enzyme activity after ten flotation–reuse cycles (batch cleavage of 5% w/v benzylpenicillin) Binding of the conjugates to dispersed phospholipid–cholesterol mixtures and whole cells has been observed. Photomicrography of solvent dispersions produced with penicillin acylase and other conjugates shows that solid gel particles are not visible at the droplet surfaces; and it is likely that the conjugate is distributed largely as a monolayer If bifunctional spacer groups or enzyme coupling agents such as glutaraldehyde are used in the preparation of conjugates, the resulting cross-linked gels form visible aggregates which, when dispersed with a solvent, adhere to the surface of the droplets Such a three-phase sludge can, nevertheless, be handled as a discrete enzymatically active layer.

Table 1 Amphipathic enzyme conjugates*

Enzyme	Hydrophobic group $CH_3(CH_2)_yNH-$	*m*/*n*†	Method of coupling polymer to protein	% Recovered enzyme activity
E. coli penicillin acylase	$y = 11$	0.33	Direct reaction with anhydride polymer¶	80
E. coli penicillin acylase	17	0.33	Conversion to half hydrazide polymer and activation to polymer azide‖	32
Bovine trypsin	9	0.30	Direct reaction with anhydride polymer**	24
Bovine trypsin	17	0.33§	Carbodiimide activation of hydrolysed polymer carboxyl groups††	~ 5

*Based on Gantrez AN119-substituted polymers. *m* and *n* refer to Fig. 1.

†Stoichiometry in polymer modification reaction, $n \simeq 1{,}500$.

‡Based on activity in original coupling mixture.

§$n \simeq 5{,}000$.

¶Ether-precipitated polymer (0.25 g) dissolved in *NN*-dimethylformamide (1 ml), homogenised with acylase (100 mg) in 0.1 M sodium phosphate, *p*H 7.0 (14 ml), reacted for 16 h at 4 °C, and conjugate gel isolated by precipitation with ammonium sulphate (70% saturation).

‖Hydrazide polymer prepared from anhydride polymer (21 μmol) and hydrazine hydrate (0.2 mol) in *NN*-dimethylformamide (50 ml). Polymer isolated by precipitation from 1.4 M aqueous NaCl (500 ml). Wet polymer (5 g) activated with $NaNO_2$ (0.5 g) in 2 N HCl (50 ml) and reacted with acylase (55 mg) in water (100 ml). Gel isolated by centrifugation.

**Polymer reaction mixture from Gantrez AN119 (1.0 g), *n*-decylamine (0.3 g) in *NN*-dimethylformamide (6 ml) added to trypsin (0.3 g) in 0.1 M sodium phosphate, *p*H 7.0 (60 ml). Titrated with 2 N NaOH until base uptake complete and gel isolated by successive precipitations with 1 M NaCl and 70% saturated ammonium sulphate.

††Hydrolysed polymer gel (15 g wet weight) reacted with 1-cyclohexyl-3-(2-morpholinoethyl)-carbodiimide metho-*p*-toluenesulphonate (0.5 g) in 0.1 M sodium phosphate, *p*H 4.7 (25 ml) for 5 min at room temperature; then treated with bovine trypsin (75 mg) at *p*H 5.9 and room temperature for 3 h. Conjugate gel isolated by centrifugation.

The amphipathic conjugation technique is a novel method of modifying proteins and has a large number of possible applications. In the field of biotechnology it provides a means of immobilising enzymes on solvent droplets, or, in the case of water-soluble conjugates, effecting the extraction of enzyme activity from an aqueous phase. It could also be used for locating well-characterised enzymes on natural or model biological membranes. Further details of the techniques, for which patents are pending, will be presented elsewhere.

I thank Dr J. Green for discussions and Mr I. Dodd for assistance.

reviews

Nutrition and the developing brain

John Dobbing

Malnutrition and Brain Development. By Myron Winick. Pp xv+169. (Oxford University· Oxford and New York, April 1976.) £5.

Nutrition and the Developing Nervous System By Philip R. Dodge, Arthur L. Prensky and Ralph D. Feigin. Pp. xvi+538. (Mosby: Saint Louis; Kimpton: London, January 1976.) £27.25.

THE suspicion is very strong that malnutrition during fetal and early neonatal life may lead to an irrecoverable diminution of intellect: and since the majority of the pregnant mothers and children in the world are underfed, this adds up to an assault on one of man's most distinguishing features by environmental circumstances which are theoretically within his control. The problem is proving it.

Human achievement is difficult to measure in any significant terms. Human growth from babyhood to adulthood is very slow, and nothing short of a longitudinal prospective study over many years is going to be satisfactory in communities where a reliable retrospective history of fetal and baby life is always especially difficult. Environmental contributions to the shaping of personal development (which are of course so numerous and so powerful compared with any genetic contribution) are nevertheless very difficult to enumerate and evaluate separately, especially as they are interacting as well as additive.

One mechanism amongst many by which early malnutrition may reduce eventual performance, may be by way of permanent alterations to the structure and some of the metabolic biochemistry of the physical brain, and we are now beginning to understand a great deal about this; Unfortunately the less well nourished members of any infant community who will probably suffer from this physical neuropathology are usually the most impoverished in every other facet of their environment, both physical and 'emotional'; and so it is exceedingly difficult to know whether the newly discovered growth pathology of the brain matters, and if so how (relatively) much?

Both these books are predominantly about the physical effects of nutrition on the developing brain, and as such inevitably only consider that one aspect of the huge problem in any detail. Dodge's book is a compendious and suitably critical account for the serious student and is likely to have few competitors for a good time to come.

If Winick's much smaller book had been simplified in the sense of being a reliable introduction for the less professionally interested it could have been very useful for a wider readership. Unfortunately it is not. I think Winick confuses the main issues of vulnerable periods in developing brain and the relative importance of fetal and postnatal brain growth, to the point of being potentially misleading to nutritionist and politician alike; and in spite of its attractive appearance I am worried by it.

Dodge, painstakingly and with abundant references, reasons his way through a morass of much incompletely collected and questionably argued literature with remarkable astuteness; although he and his colleagues have occasionally tended to catalogue the information rather than evaluate it.

Both books in their way cover the elements of normal brain growth; and since the brain is an organ of the body like any other, both have paid attention to the very relevant effects of nutrition on somatic growth.

Dodge, as a clinical paediatric neurologist, adds some valuable shorter sections on minerals, vitamins and diseases of amino acid metabolism with implications for the brain. Neither book seems to have heard of our own finding that the period of vulnerability of the human brain is almost certainly predominantly postnatal, an important fact for practical social and political policy; or perhaps they do not agree At all events they might have said so. Dodge discusses the rest of our work in Manchester very fully and appreciatively, but I do not think my very strong preference for his version over Winick's is entirely due to that. □

John Dobbing is Professor of Child Growth and Development in the Department of Child Health of the University of Manchester, UK.

Aspects of polymeric carbons

Polymeric Carbons· Carbon Fibre, Glass and Char. By G. M. Jenkins and K. Kawamura. Pp. vi+178. (Cambridge University: Cambridge and London, May 1976.) £8.50.

THE decomposition of resins at temperatures up to 2,500 °C gives rise to graphite in the form of small and highly distorted crystals. As every Materials Scientist knows such distortions can confer strength well above that of more perfect graphite; the resultant materials are very useful but very difficult to characterise. Vitreous carbon is used for crucibles and in some biomedical applications where high strength, chemical inertness or high temperature resistance are needed; whereas carbon fibres are used in a wide range of composites.

This book covers the production, properties and structure of these polymeric carbons and puts them in the context of other forms of carbon. The style is easy to read and the treatment is mainly factual, the emphasis being on what happens rather than why. The 200 references cover the scientific and patent literature up to 1973. A lot of attention is given to the author's own work on pyrolysed phenolic resins, which lends the book coherence.

As a text it has its limitations; there is not enough theoretical explanation and the treatment of chemistry is sloppy. For instance, the statement that "Commercial PAN is atactic and so contains two-dimensional order only" is simplistic, considering the importance of the resultant carbon structure on properties. It is also regrettable that there is no discussion of surface structure and properties when these are so important in practice.

In spite of this, for people in research or development using polymeric carbons, this monograph will be a good introduction and guide to the literature. Here, it fills a real lack.

Paul Calvert

Paul Calvert is a lecturer in polymer science in the School of Molecular Sciences at the University of Sussex, UK.

Beauty of original experiments

Landmark Experiments in Twentieth Century Physics. By George L. Trigg. Pp. x+303. (Crane Russak: New York; Edward Arnold: London, February 1976.) £11.50.

It is a sad fact, but unfortunately a true one, that most physicists' knowledge of the fundamental papers of their subject can only be described as fragmentary, even if one is feeling charitable. How many of us have in fact read the paper by Michelson and Morley, or the verification using α-particle scattering of the Rutherford nuclear atom by Geiger and Marsden, or nearer at hand the papers on the de Broglie wavelength of the electron by Davisson and Germer or G. P. Thomson.

We all know of the existence of these experiments and what they prove but our knowledge is second-hand, acquired from the writings of others. It is perhaps not as bad as reading Shakespeare through the eyes of another person, since aesthetic appreciation doesn't enter. If as sometimes happens for a colloquium or lecture course however, we have to examine a bit of fundamental experimentation in detail it is surprising how much rationalisation and perhaps even falsification enters the conventional picture

This is not deliberate misrepresentation, but it is just that the removal of an awkward corner or fact here and there facilitates understanding and is thus tacitly accepted. For example, one often finds the Michelson–Morley experiment discussed in terms of the time of arrival of pulses of light going down the separate paths. No doubt if the experiment were done this way the result would still be as given and the consequences would be identical; but it is a pity to depart from complete accuracy.

The whole situation stems from the expansion in physics over the past few decades, the need to keep university courses to a sensible length, and the reluctance of physicists to split their subject into more manageable parts. Tiresome examiners at the end of the three undergraduate years demand that we show some powers as practising physicists able to marshal our equations and solve our problems. They are not so concerned as a rule with the way the subject has developed to its present state. Schrödinger's equation, or operators in quantum mechanics, or matrix algebra take precedence over Davisson and Germer, and de Broglie. In this of course they are right, but something important is being lost

This is true also of books, in which as a particular subject matures so the formal structure grows and the experimental details recede. The present book, however, is of a different kind and attempts to redress the balance. The author takes a list of important twentieth-century experiments, first puts them briefly in their context, and then goes on to describe what was really done in great detail. To do this he uses long sections taken from the original papers which he joins and makes coherent by a minimum of connecting explanation. He thus maintains the authentic flavour of the subject at the time of the experiment, and much of the work is described in the original author's phraseology.

The list of experiments discussed is reasonably well chosen. It begins with the discovery of the wave nature of X-rays using diffraction from crystals, of isotopes, of the concept of atomic number and of superconductivity During this early period of the century many other possible subjects could of course be chosen but the ones used are not at all unreasonable. It may be that if the book is successful the author might return to this early era and write a second volume on some of the experiments he has omitted.

After this early period, and in fact, coming within the reviewer's memory, the list becomes more restricted and progressively less open to variation. From the early 1930s to the present day the complete list of topics covers the fluid properties of liquid helium below the λ point, the use of molecular beams for the determination of magnetic moments, the Lamb-Retherford effect, the anomalous g factor for the electron, the transistor, the non-conservation of parity for weak interactions, the Mössbauer effect, the experimental verification of the existence of the neutrino, the maser and laser, tunneling and superconductivity, the Ω^- meson and the microwave demonstration of the 3K intergalactic radiation temperature.

In spite of its intrinsic interest the book is not easy to read. The subjects cover quite a good cross section of contemporary physics and the use of extracts from the original papers sets a level of difficulty which cannot be entirely overcome by the explanatory connecting parts. This, however, cannot be helped. A student of scientific history or of scientific logic or of experimental technique or anyone just interested in how things really happened could not do better than begin with this book. The reader will get in a few hours an insight which has obviously taken the author a long time and much labour to achieve, and will be left with a feeling that at least some experiments in physics have a beauty which is more akin to art than science. **R. Latham**

Dr Latham is a reader in the Department of Physics at Imperial College, University of London, UK.

Nucleon–nucleon forces

The Nucleon–Nucleon Interaction By G. E. Brown and A. D. Jackson. Pp. viii+242. (North-Holland. Amsterdam and Oxford; American Elsevier: New York, 1976.) n p.

When students start research on a particular topic in theoretical physics their first problem is to learn all the essentials of previous work in a finite time. This nearly impossible task is helped by providing them with courses of lectures in which early developments are outlined and more recent work is spelled out in sufficient detail for the student to proceed immediately to the frontiers of the subject equipped to make further progress. G. E. Brown and A. D. Jackson have given such courses in Copenhagen which form the basis of their book The first four chapters give a simple outline of the well-established theory of nucleon interactions at low energies. In chapters 5 and 6 the reader is introduced to techniques in scattering theory, the use of relativistic equations and form factors; a description is also included of a more specialised technique, the eikonalisation of soft vector bosons, which is used by the Copenhagen group to provide convergence.

The final four chapters (half the book) are devoted to a detailed and explicit account of the steps required to derive realistic internucleon potentials and their relativistic corrections from one- and two-boson exchanges. The intimate interweaving of the various pion–nucleon and nucleon–nucleon amplitudes is explicitly demonstrated and a clear picture emerges of the physical principles underlying the calculations. This book will be essential reading and remain a basic reference for all those working on nucleon–nucleon forces, as well as being an introduction to the subject for the uninitiated.

Leonardo Castillejo

Leonardo Castillejo is Professor of Physics and head of the theoretical elementary particle physics group in the Department of Physics and Astronomy at University College, London, UK

Living history of science

Pioneers in Neuroendocrinology. (Perspectives in Neuroendocrine Research, Vol. 1.) Edited by Joseph Meites, Bernard T. Donovan and Samuel M. McCann. Pp. viii+327. (Plenum: New York and London, 1975.) $27.

THE majority of the scientists that have ever lived are alive at the present time. Thus it is possible for followers of the ever-growing subject of the History of Science to actually discourse with the people who made this history: they have the opportunity to examine at first hand the politics, philosophy, and circumstances that resulted in the scientific progress that has been made.

The subject of Neuroendocrinology—the study of the effects of the nervous system on the release of hormones, as well as the study of the effects of hormones on the nervous system—is a particularly young discipline, having only evolved since the period between the two world wars. Thus Joe Meites, Bernard Donovan and 'Don' McCann (themselves pioneers in this field) have been able to seize successfully the opportunity to call on 21 neuroendocrine pioneers "to write a personal, and even idiosyncratic, account" of the background behind the major contributions that each felt he or she had made to this subject. The editors have indeed extracted idiosyncratic accounts from their authors, and each chapter can very much be considered to reflect the character of the respective contributor. Whereas some authors, therefore, have used their publications as mileposts in the passage of time, others have given only a very technical and clinical survey of their research careers, without reference to other events occurring at the time, either in the scientific world, or in the world at large (such reference, if included, being of the greatest value and interest to the historian and to the lay-reader).

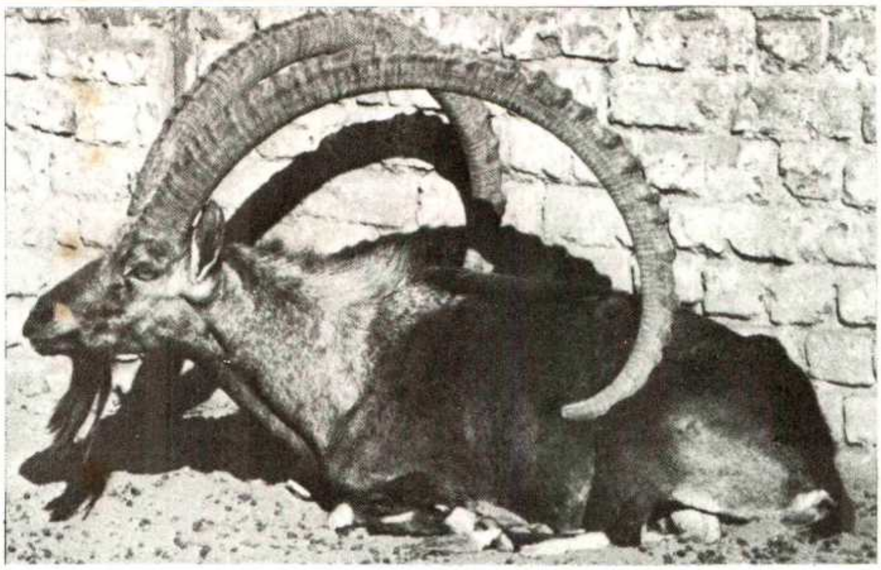
There are three chapters that I should particularly like to single out—those by the late Hans Heller, by Dora Jacobsohn, and by Dorothy Price—in that not only do they excel in the good qualities described above, but they also reflect the charm and humility of their respective authors.

It is regrettable that in the present volume two of the chapters are of a similar nature to the respective chapters in a comparable volume, *The Neurosciences: Paths of Discovery* (MIT Press, Boston). This book has, however, already met sufficient acclaim in America that the editors are presently commissioning writers for a second volume. That there should be so many pioneers available, and willing, to write presumably indicates that each and every scientist is a pioneer in his or her own way: the willingness, as pointed out by M. C. Shelesnyak, derives, at least in part, from the scientist "seeking self-satisfaction and nurturing (his) ego".

Although I would recommend that anyone involved in endocrine or physiological research should read this book, since they will do so with interest, I feel that the price is such that few will be able to afford to buy it. I fear, too, that this book is not sufficiently 'applied' for most science libraries to purchase, unless, that is, they have a shelf principally intended for reference by after-dinner speakers.

Barend ter Haar

Barend ter Haar is a Senior Scientific officer (MRC) attached to the ARC Institute of Animal Physiology, Babraham, Cambridge, UK.



Hunting Nubian ibex (*Capra nubiana*) in the Red Sea Hills of the Sudan. Nubian ibex have long, slender, knotted horns, gracefully curved. Among males, 42-inch trophies are not uncommon, and the new world record (*shown above*) measures 54.5 inches. Taken from *African Hunter*. By James Mellon. Pp. xx+522. (Cassell: London, June, 1976.) £15.00.

Climate and man

Climate and the Environment: The Atmospheric Impact on Man. (Environmental Studies.) By John F. Griffiths. Pp. vii+148. (Elek: London, May 1976.) £2.95.

INTENDED for "students of geography and environmental studies at undergraduate and pre-university level" this book is a useful quick guide to the relationship between the workings of the atmosphere and the activities of man, without anything like the in-depth treatment of M. I. Budyko's classic work *Climate and Life* (Academic: New York and London, 1974; for review, see *Nature*, **251**, 362). The comparison is a natural one, since Griffiths approaches his subject through the energy budget–heat balance approach, drawing to some extent on the work of the Voeikov Geophysical Observatory, where Budyko was until recently Director. He also draws on the work of many other climatologists, as is usual in a book of this kind, but with comprehensive references to the original sources at the end of each chapter—a rarer, but welcome, practice for a text at this level.

There are many clear and useful illustrations, again culled from a variety of published works, and the text is well suited to the intended readership, with some of the mathematical details contained in appendices, again conveniently at the end of the appropriate chapters. The success of the author in reaching his planned market does, however, limit the usefulness of the book to anyone with a more advanced knowledge of the physical sciences who might have become interested in the subject through the continuing debate about the impact of climatic change on man, and the impact of man on climatic change. In the specified teaching context this book is likely to prove invaluable and is strongly recommended; at the next step up the academic ladder, however, Budyko's book remains the essential introduction to the subject. **John Gribbin**

John Gribbin is a Visiting Fellow in the Science Policy Research Unit at the University of Sussex, UK.

obituary

Alexander Naumovich Frumkin the father of modern electrochemistry died in Tūla (200 km from Moscow) after a heart attack on May 27, 1976.

He was born in 1895 in Kishinev, capital of Moldavia (now the Moldavian Soviet Socialist Republic), and attended the St Paul's Real School in Odessa, 150 km from his birthplace. On leaving school in 1912, he studied in Strasbourg and Bern but returned to graduate in the physico-mathematical faculty of the Novorussian University at Odessa, and become a staff member there. During this period he laid the foundations of the electrochemical studies which formed the mainstream of his work. His thesis, published in 1919 (he never in fact received a doctorate, as such distinctions were abolished in the early days of revolutionary Russia) besides giving a masterly survey of the current views on these problems, contained several notable original contributions (among which, many of the major themes of Frumkin's later work may be seen to have their origin): a careful experimental test of the basic equations of electrocapillarity, the identity of the point of zero charge determined by several methods, how Gibbs' equation may be used to derive surface excesses from electrocapillary curves, the nature of the potential-dependence of the adsorption isotherm, the lack of a simple relation between the double-layer capacity and the bulk dielectric constant, and finally the origin of the e.m.f. of a galvanic cell (one of the basic problems of electrochemistry).

In 1922 he moved to the Karpov Institute of Physical Chemistry in Moscow, formed to investigate the fundamental physico-chemical basis of industrial processes. Here he extended his interests to the gas–liquid interface, to the adsorption of electrolytes on activated charcoal and platinum black and to the problems of wetting and contact angles. He made pioneer measurements of the Volta potentials of solutions and showed how they depended on molecular orientation at the surface. His outstanding research was recognised by his election to the Academy of Sciences of the USSR.

His work in the decade after 1930 was even more important for electrochemistry. His first achievement was the marriage of surface chemistry and electrode reactions, in a paper which brilliantly used some earlier polarographic studies to give a rational theory of the salt effect on electrode reactions. The second major success was the first reliable direct measurement of the double-layer capacity and the demonstration of the catastrophic effect of minute traces of impurities. This led to the first reproducible measurements of hydrogen overvoltage through the use of adequate purification by adsorption (on platinum black) and by electrolysis. Similar careful studies of the charging curves of the platinum electrode were used to study the adsorption properties of this complex system for hydrogen and oxygen as well as electrolytes, and culminated in the proposal of the logarithmic adsorption isotherm as well as in the first use of the alternating current method for the measurement of the rate of electrode reactions. He later showed how this method may also be used for studying rates of adsorption.

During the second world war Frumkin was Director of the Colloido-Electrochemical Institute and, after the war, became for a time Director of the Institute of Physical Chemistry before, in 1958, a new Institute of Electrochemistry was formed with him as its Director, a post he held until his death. His own work broadened and extended in all directions in collaboration with the eminent coworkers he had attracted. This work was characterised by the intimate collaboration of experimentalists and theoreticians (notably V. G. Levich) which led to such developments as the rotating disc and ring-disc electrodes, the laws of photo-electric emission into solutions and the detailed understanding of the structure of electrified interfaces. His own interest in the last few years centred on the development and testing of the thermodynamic theory of interfaces across which charge may be freely transferred.

His encyclopaedic knowledge of all parts of electro- and surface-chemistry earned the admiration of everyone who knew him and his achievements were recognised by many honours (including the title of Hero of Socialist Labour, on his 70th birthday). He was also a man of broad general culture. He spoke English, French and German fluently and had a passionate interest in literature and the visual arts—he would travel far under difficult conditions to see an early church with fine frescoes. His other passion was mountaineering; naturally his activities were more restricted in recent years, yet as late as last September he organised a car trip from Alma Ata as high as possible into the Tien Shan range, and was delighted to find that he suffered no ill effects. **Roger Parsons**

announcements

Appointments

Dr R. C. Smith as professor of Physical Electronics at the University of Southampton.

Drs J. B. Harborne and **D. M. Moore** as Professors of Botany at the University of Reading.

Professor Sir John Dacie has been nominated President-elect of the Royal Society of Medicine.

M. Hubert Curien has been appointed president of the Centre National d'Etudes Spatiales (CNES).

Meetings

August 2–6, **Cell Wall Biochemistry Related to Specificity in Host–Plant Pathogen Interactions,** Tromsø, Norway (Jan Raa, University of Tromsø, Tromsø, Norway).

August 17–19, **Water Relations in Membrane Transport in Plants and Animals,** Philadelphia (American Physiological Society, c/o Dr Robert E. Forster, A-201 Richards Building G4, University of Pennsylvania, Philadelphia 19174).

August 23–27, **Congress of the International Primatological Society,** Cambridge (Dr D. J. Chivers, c/o Laundry Farm, Barton, Road, Cambridge, UK).

September 7–9, **Arboricultural Conference,** Worplesdon, Guildford (P. H. Bridgeman, c/o Merrist Wood Agricultural College, Worplesdon, Guildford, Surrey GU3 3PE, UK).

Aftermath of the Mark VA

THE tale of the Jodrell Bank Mark VA radiotelescope that was never built is a gloomy one from any point of view. The Fifth Report from the Commons Committee of Public Accounts (HMSO; £3.45) takes a look at it.

Original plans were for the Science Research Council (SRC) to construct a 400-foot steerable dish (the Mark V); the council sought approval from the Department of Education and Science (DES) in 1970 on the basis of an estimate of £6.2 million (January 1970). A revision of the cost to £8 million caused the SRC to propose a smaller telescope—the Mark VA, with a 375-foot aperture, which they hoped could be built within the £6.2 million figure. A detailed design was to be prepared by the consulting engineers Husband and Company (a firm well experienced in radiotelescopes), covering drawings, bills of quantities and an invitation to tender for construction. The United Kingdom Atomic Energy Authority (UKAEA) would act as project managers, and it was estimated that £245,000 would be needed in consultants' fees. A large fraction of this figure was tied to the final tender price for construction.

Treasury approval for the design stage was given in June 1971. Ten months later the consultants were given the go-ahead to complete the design, if possible, within twelve months. They were told to alert the UKAEA if it seemed that the construction would cost more than was originally planned (due allowance had been made for inflation). Within six months they reported that the limit had been reached. After that, however, they were under no obligation to report costs further, and indeed had declined to have any further reporting written into their contract. The SRC's explanation for this was that "the consulting engineer . . . was designing the telescope to make it as cheap to build as he could. He was still finding out how it could be built cheaply, and it was more important for him to do that than to keep estimating what the cost was".

The inevitable happened. In October 1973 the consultants finished; tenders received in March 1974, reflecting the great uncertainties then prevailing in the construction industry, were around the £14 million mark. The total cost was put at £16 to £17 million. (It had been estimated just before by the UKAEA that the £6.2 million—at 1970 prices—which was the original total cost would have inflated to £10.7 million by January 1974.) Faced with a 50% growth in real terms in costs, and having to live with negligible overall growth, the SRC abandoned the telescope in June 1974, having learnt that total costs had risen even more in the interim to £22 million.

But this left one matter outstanding—the consultants' fee. As it was related to the tender price, it now amounted to the sum of almost £600,000, although on this the consultants eventually offered a rebate of £30,000. Even so, the amount they received was rather more than double what they must have expected on starting—a tidy windfall even when inflation had taken its toll. The SRC, which had not been informed itself of price escalation, had in its turn not been able in 1973 to keep the DES and the Treasury alerted to rising real costs, and had to seek special Treasury authority for the total design bill of £660,000.

It is fairly easy now to look back and see what went wrong. People were unused to dealing with inflationary conditions, and so didn't exercise such stringent controls as they would now. Even so, the telescope might have come through unscathed were it not for the situation which developed nationally during precisely the months that potential contractors were preparing their tenders. As it is the SRC gets a mild rap over the knuckles for letting matters drift, and rightly so, although the report has a rather optimistic view of the willingness of the scientific community to drop major projects when costs escalate. But what about the method by which the consultants were paid?

It must be made clear that the issue here is in no sense one of indulging in any gold-plating. The figures mentioned and the evidence of the SRC and the DES all fit in with the appalling way in which construction costs escalated. Be that as it may, the taxpayer ended up paying the consultants an "uncovenanted benefit", in the words of the committee, totally unrelated to the cost of the project. What is more, the SRC, having decided not to go ahead, would have to pay an additional fee if it chose to think again, as the plans are the copyright of the consultants. The SRC did at the very outset enquire about retaining the drawings, but was told that this would roughly double the fees.

All of this is legal and common practice. Fees are related to tender price, and copyright stays with the designer. But it does seem to the outsider to be open to charges of being inequitable, and it can lead to cynicism. The Public Accounts Committee calls for further consideration to be given to the way consultancy agreements work in the public sector. We hope someone is doing just that. □

Energy from warm rocks

Ron Oxburgh examines the prospects for geothermal energy in Britain, where a new research programme is to begin

IN the first few years of this century, an electrical generator with an output of several kilowatts was installed at Lardarello in northern Italy, to be driven by the steam which emanated naturally from the ground. It was the first modern attempt to harness the natural heat of the Earth to man's purposes. Relatively little further progress was made until the 1930s, but since then the use of geothermal energy has increased considerably, until today about 1100 MW are generated by this means in seven countries. Most of these installations pre-dated the rapid rise in fossil fuel prices of the past few years, and even then were competitive with conventional means of power generation. Today their situation is still more favourable.

Fifty or more countries are now involved in geothermal exploration. The number was recently increased by one with the decision announced by the UK Department of Energy to spend £840,000 on the geothermal exploration of Britain over the next three years. That decision was made largely on the basis of Energy Paper No. 9 (*Geothermal energy: the case for research in the United Kingdom*), a special report prepared by the Energy Technology Support Unit at Harwell, in which Dr John Garnish, the author, argues cogently for a cautiously optimistic approach to the prospects of geothermal energy in the UK.

Heat by convection

Heat is continuously generated within the Earth by the radioactive decay of unstable isotopes (mainly of U,Th and K) and is lost from the surface at an average rate of about 1.5 μcal cm^{-2} s^{-1} (63 mW m^{-2}). At depths greater than about 80 km heat transfer within the Earth is mainly by convection, but above that mainly by conduction; rocks are relatively poor conductors of heat and within this outer zone the conductive thermal gradient ranges from less than 10 °C km^{-1} to about 60 °C km^{-1}. This is true over more than 95% of the Earth's surface, within the interiors of the great tectonic plates.

Along the margins of the plates, however, and very occasionally within them, heat may locally be transferred to the surface or to within a few kilometres of it by convection. The convective medium in these cases is magma, or molten rock, at temperatures between 800 °C and 1100 °C. The magma commonly interacts with ground water circulating in the pores of the near surface rocks to give rise to geysers, hot springs or fumaroles. Drilling to 1,000 m or so in such areas may provide flows of water or steam at between 200 °C and 300 °C which, in favourable circumstances, can be used to drive turbines and generate electricity. All the major producers of geothermal electricity—Italy, the Western USA, New Zealand, Japan and Mexico (1,030 MW together)—exploit situations of this kind, and are all situated in the tectonically unstable earthquake and eruption-prone margins of plates.

Rocks at comparable temperatures may be found beneath other parts of the Earth's surface, such as the UK, where subsurface temperatures are governed largely by conduction, but they are much deeper. At the depth limit of present drilling experience (~9 km for a cost of £2–3 million), temperatures in such areas rarely exceed 300 °C. Furthermore, it is not sufficient to reach hot rock; if the heat is to be used it must be extracted by means of circulating fluids, and for this process to be effective the fluid must be able to permeate the hot medium thoroughly through pores and fissures. With increasing depth, however, the weight of the overlying rock tends to close pores and fissures and reduce the permeability to a very low value.

For these reasons, in most places the hot rocks which everywhere underlie us are at present both too expensive to reach and too impermeable to exploit, and are rather unlikely to provide the large quantities of water suitable for the economic generation of electricity by conventional technology (temperatures in excess of 200 °C are required).

Alternative applications

If, however, we consider alternative applications of geothermal energy, the position is quite different. There is a wide range of uses for water above 65 °C when it is used directly in a heat exchanger rather than to generate electricity. Taking 100 °C as a convenient reference value, rocks at this temperature may be reached virtually anywhere in the world by drilling holes well within the depth range of present technology. Whether these "warm rocks" constitute an exploitable natural resource depends upon the drilling costs of reaching them, their permeability structure, and the availability of a local demand for the low grade heat they can supply.

The economic considerations are now more finely balanced. As a very rough indication: given both suitable reservoir conditions at depth, and a suitable local market for the hot water, warm rock geothermal energy is at present competitive with fossil fuels if temperatures of 100 °C can be reached at 3 km or less. If, however, the cost of fossil fuels rises faster than drilling costs, this depth will be increased and the position of geothermal resources relatively improved.

Viewed in this way, the evaluation of UK geothermal resources becomes a problem of identifying those areas with slightly higher than average geothermal gradient and of understanding the subsurface distribution of permeability sufficiently well to distinguish those which are capable of successful exploitation. This latter problem is not a simple one, but is tractable by combining the expertise of the oil industry in understanding and controlling the flow of fluids underground with experience of hydrogeologists of rock permeabilities and natural underground circulations of water in the UK.

The problem of identifying regions of sufficiently high temperature is less easy. In the UK these are unlikely to be so pronounced that they give rise to significant perturbations of the surface magnetic field or the electrical conductivity structure of the crust, and there is little alternative to some kind of direct measurement of temperatures. Broadly, two approaches are possible. Deep holes may be drilled and temperatures measured at the proposed depth of exploitation. This is undoubtedly the safest method of exploration, but it is impossibly expensive unless the hole has been drilled for some other purpose which meets most of the costs.

The other approach is to make very precise measurements in shallow holes and use these as a basis for extrapolation to greater depth. The difficulty here is that near surface temperatures may be influenced by climatic changes (ice age effects may still be recognised hundreds of metres below the surface), the circulation of ground water, topographic irregularities of the surface and even erosional processes; for these reasons measurements are made in holes more than 200 m deep and preferably more than twice that depth, and are then corrected for the effects of the various perturbing factors. The heat flux, q, is given by $q = k\beta$ where k is the mean thermal conductivity of the rock, and β the mean thermal gradient, over a particular depth interval. The heat flow value determined in this way may then be used to predict the temperature at some greater depth with an accuracy which depends largely upon how well the thermal conductivity of the rocks down to that depth is known. Heat flow measurements of this kind must form the main basis of any exploration programme.

Although a relatively large number of underground temperatures have been measured in the UK, there have been relatively few reliable heat flow measurements—about 25. Although many of the temperature measurements were sufficiently accurate for the purposes for which they were made (ventilation in mines, for example), they do do not form a reliable basis for extrapolation to significantly greater depths. Similarly the temperature logs obtained by oil companies, by measurement in holes when drilling is complete, are subject to very large errors because the temperatures around the hole have been seriously perturbed by the drilling process itself; the circulation of cold drilling fluid from the surface to the bottom of the hole may change the rock temperature by some tens of degrees and it is months or years before the rock returns to its initial temperature.

Information inadequate

Energy Paper No. 9 synthesises the observational information at present available from a variety of sources and concludes that although there are some parts of the country where it is very likely that geothermal energy would be competitive with fossil fuels, the temperature information at present available is inadequate to make any overall assessment of the country's geothermal resources. Detailed cost analyses are presented to support the main recommendation that the possible benefits to the national energy budget justify the initiation of a national programme of geothermal exploration. Although the report itself makes an excellent case for such a programme, perhaps the most telling argument is that in France today there are several district heating schemes operating competitively on low grade geothermal energy, and that a number more are planned or are under constructon; these schemes have been established in situations which can be matched closely in the geology, and probably in thermal structure, by the Mesozoic sedimentary basins of this country.

It should perhaps be emphasised that although heat is continuously generated within the Earth, in most situations geothermal energy must be regarded as a depletable resource, and its exploitation as heat mining; the rate of convective removal of heat from the rocks of a hot source area is orders of magnitude faster than the heat can be replaced by conduction from below. In most cases geothermal fields are exploited at a rate designed to exhaust them in about twenty years. In a minority of situations (active volcanic regions, for example), the transport of heat to the surface by magma may match or exceed its extraction rate and the resource is not depletable, at any rate not significantly so. Questions now arise of just how and when possible geothermal resources should be exploited, and how large a contribution they might be expected to make to the national energy budget.

The answer to the first of these questions to some extent depends upon the answer to the second. If legitimate geological expectations were satisfied and suitable markets for the available energy were found, it would not be unreasonable to think of geothermal energy providing 1% or even 2% of the country's energy for 20 years. The greatest uncertainty must, however, be the availability of the market. The energy is available in the form of hot water in the temperature range 65–100 °C, temperatures which at present are generally considered too low for the efficient generation of electricity, and so the heat must be extracted from the water directly.

Furthermore, if additional heat losses by conduction are to be avoided, the hot water should ideally be used within a few miles, but certainly a few tens of miles, of the well head. There are various uses for low grade heat of this kind—domestic and industrial space heating, greenhouse heating, soil warming, fish farming and animal husbandry, various industrial fermentations, the drying of a range of organic materials and so on. It has also been shown to be economically viable to use geothermal energy for pre-heating of water, which may then be heated further by electricity, for a wider range of applications.

Policy decisions required

The problem therefore of exploiting "warm rock" geothermal resources is not purely scientific or technological. It involves either a happy geographical coincidence, by which suitable consumers who are willing to change to a geothermal supply are situated in or near a geothermal source area, or the deliberate encouragement of suitable industrial development in the geothermal areas and the use of district heating schemes in any new housing developments in the area. These clearly require major decisions of public policy. Attractive features of such developments would be the fact that warm-rock geothermal energy is virtually pollution-free—rejected warm water which has been used is reinjected into the ground for re-circulation. The surface plant is small and inconspicuous by comparison with any conventional power station.

The time scale of possible exploitation of UK geothermal resources now becomes clearer. It is reasonable to expect that the programme planned for the next three years will give reconnaissance information for much of the country. If the prospects appear reasonable at that level it would be appropriate to undertake a more intensive study of areas of particular interest. This second stage would require extensive shallow drilling (about 500 m) and some deep drilling, and could take five years; the rate of progress would be constrained by both the availability of drilling capacity and the time taken for drilling—although there is great variation, a 4 km hole could

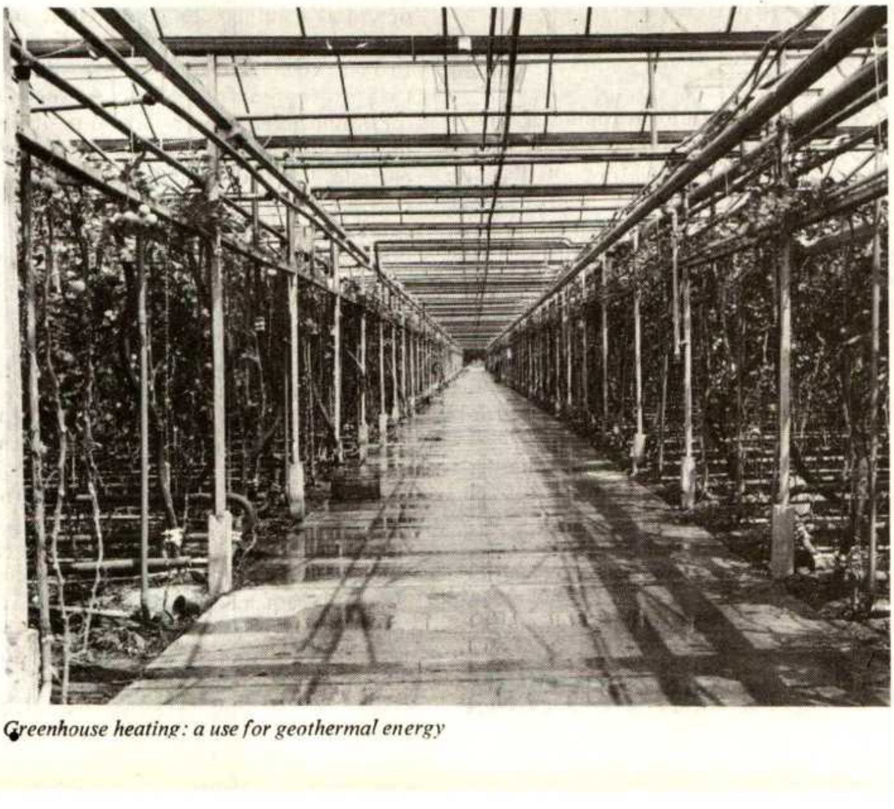

Photo: *The Grower*

Greenhouse heating: a use for geothermal energy take nearly 12 months to drill. It might then be possible to make an informed decision on whether to attempt commercial exploitation of the country's geothermal resources in the latter part of the 1980s.

If a positive decision were taken at that stage a third phase of development could begin with drilling of production holes, the planning of distribution systems and the stimulation of the potential market. The use of geothermal energy on any significant scale could not be expected before the turn of the century. This timetable is probably about the fastest which is practicable, and if desirable it could easily be lengthened; it would, however, mean that geothermal power became available about the time that production from the North Sea oil and gas fields began to drop significantly, and Britain changed from being a net exporter of oil to an importer once more.

Any consideration of the geothermal prospects of the UK, however, goes beyond the question of the heat which may be extracted from warm rocks of the upper crust. Experiments have been going on for some years at the Los Alamos Scientific Laboratory in the United States with a view to generating fractures artificially to permit water circulation both through rocks which are naturally impermeable, and through those which are so deeply buried in the crust that natural pores and fissures have normally closed. If these experiments were successful, it could become feasible to use such "hot rocks" to heat circulating water sufficiently for the generation of electricity.

The economic viability of such a scheme would be much enhanced by improvements in deep drilling methods; at present drilling costs roughly double for every 2 km increase in hole depth. Such a development would increase the available geothermal resource by more than a factor of 10 and free it from the geographical constraints which limit the use of warm water. The national long term geothermal strategy should, therefore, be seriously re-appraised if the Los Alamos experiments are promising. But no one should pretend that geothermal energy will solve the UK's energy problem; a small and possibly highly profitable resource, on the other hand, probably does exist—it is also a resource for the exploitation of which there are no large savings of scale, so that piecemeal development to satisfy local requirements is possible.

No complacency

It is probably fair to say that in the present world economic climate a country cannot afford not to investigate its geothermal resources further. It might be asked whether it is proposed to carry out the UK's geothermal exploration sufficiently rapidly; at present there is neither the drilling capacity nor sufficient trained manpower to mount an extensive crash programme, but even if there were it would not necessarily be more effective than a phased and progressively increasing effort over the next 10 years. The essential point is that no one be lured into a false sense of energy complacency during the next two decades of oil abundance, to the detriment of the development of other resources on which everyone will later depend.

A few may wish to ponder the point that many of the UK's large power stations reject hot water at temperatures which are regarded as suitable for geothermal exploitation in other parts of the world, and perhaps to question the wisdom of today continuing to charge a government authority with the limited mandate of generating electricity at the lowest possible price. And for those to whose lot it falls from time to time to defend the role of "pure science" in straitened economic circumstances, it is worth pointing out that the study of terrestrial heat flow which was until two years ago one of the most esoteric, albeit fascinating, branches of geophysics, has overnight become directly "relevant" and applied. Had not the Natural Environment Research Council (NERC) supported two university groups in this fields for a number of years, the UK would have completely lacked the technical expertise with which to implement fully its present geothermal programme. ☐

Adjust, amend and heal

The face of big science is changing constantly. **Wil Lepkowski** reports from Berkeley, California, on the way a famous laboratory has tried to adapt

OSCAR WILDE was once heard to say of an old acquaintance, "There goes a man with a promising past." One might be tempted to direct the same comments at the Lawrence Berkeley Laboratory of Berkeley, California, where eight men have won Nobel Prizes for work in high energy physics, nuclear physics, nuclear chemistry, and photosynthesis. All winners, save the famed, forceful Ernest Orlando Lawrence, still live and form a solid command of senior directors who continue to chart the fortunes of the facility.

It is clear that the time of grand high drama in research is over at the old Lawrence Radiation Laboratory. For one thing, its support now comes from the Energy Research and Development Administration (ERDA), whose mission is much more broad and ambitious than that of its predecessor, the Atomic Energy Commission (AEC). For another, the research budget for the things the Rad Lab always did best no longer arises at the rate it once did. And for a third, ERDA's new mission is not only much broader that the AEC's but is focusing its formula on industrial commercialisation of energy research and development, chiefly big scale systems.

Physics remains the most potent resource of the Lawrence Berkeley Laboratory (LBL). But the Laboratory is no longer the mecca for the brightest young minds seeking achievement through that once unique Rad Lab combination of men and machines. The men might still be around (and the use of the word "men" is deliberate, for the Laboratory is distinctly male dominated), but the machines are not. High energy physics is no longer done on site. The famed Bevatron is used now for cancer research and treatment and for nuclear physics. Officials say a new and exciting era could come into being through the Positron–Electron Project with Stanford University. In that project Stanford's Linear Accelerator would inject electrons and positrons into a new storage ring and the two particles would collide to produce energy patterns of unprecedentedly fine detail. But critics note that the new machine will not be at Berkeley but at Stanford. Laboratory officials may say it doesn't matter, but it really does. The place to be will be Stanford.

Sinking sensation

One thus hears oddments of commentary in the labs, and on the bus that shuttles researchers between the University of California campus and the Laboratory, that LBL is "sinking". The precise reasons are hard to track down because the Laboratory is no longer laying people off and the research budget is rising—from the current $47 million to around $60 million by the end of the next fiscal year. The sinking sensation is easily

•

Research for this article was supported by the Center for Science in the Public Interest.

explained on psychological grounds—anxiety over a vanishing pride and autonomy. Fundamental physics is no longer choice at LBL. Money in that field—once LBL's pride—is hard to come by. "The motto at this place once was, 'why use lead when gold will do,' " comments one researcher. LBL has had to become austere since 1970 and still is searching for a guiding star.

In 1970 the Atomic Energy Commission was still in existence. But its basic research budget was beginning to drop and LBL, along with AEC's seven other national laboratories, was forced to cut projects and personnel. The Laboratory formed an environmental division which with some success sought funds from agencies other than AEC. Still, the mood continued downward. As the concern over energy rose, the environment division became the energy and environment (E and E) department. By 1974, ERDA was created and with it an injection of energy research dollars. E and E will attain a budget of nearly $17 million by next year.

E and E's acting director Robert Budnitz, a physicist, literally bubbles with optimism over the future of at least his division. Programmes include geothermal power, solar energy, fusion, and energy conservation, and the enthusiasm a visitor unerringly sees comes from scientists who like their work and know that someone who funds it appreciates it.

But LBL must still live with the fact that it is no longer the centre for intellect and excitement in basic science. ERDA, in fact, defines it as a general purpose laboratory uniquely linked to a great university. The hope is that LBL will utilise university scholars in law, economics and the social sciences to integrate energy research and technology with their application. One always wonders about the effectiveness of this kind of activity under an agency whose theme is big systems. The work may be funded but will it make a difference? And even more fundamentally, will it be any good anyway? Yet, such work is supremely important in an era of rising terrorism and nuclear proliferation.

A style that suits?

An issue that is not being tackled directly as yet is whether the management style of LBL is really suitable for the kind of work that needs doing for the development of energy research. LBL created what Alvin Weinberg has called Big Science—the need to expend large sums of money on big machines to carry out research on the smallest particles of matter. The Lawrence Laboratory owes most of its Nobel Prizes to that style of research emphasising machines, teams, and discipline. But was the work really scientifically creative? Or was it creative engineering in the service of science?

The Lawrence Berkeley Laboratory, California

One critic, physicist Robert Yaes of Memorial University, St. John's Newfoundland, thinks LBL's science has been over-rated. He said the Berkeley group was more interested in building larger and larger machines rather than with "doing experiments with the ones they had." One of the most significant discoveries in nuclear physics, nuclear fission, he says, was made by Hahn, Strassman, Meitner, and Frisch in Europe, "even though the Lawrence group had the world's most intense neutron beam." Similarly, the first nuclear disintegrations were made by Cockroft and Walton with an electrostatic generator that produced protons of only several hundred KeV.

"In short", he says after citing other examples, "even though the Berkeley group possessed beams of energy and intensity available nowhere else in the world, the most significant discoveries were still being made by the 'string and sealing wax' people in Europe".

There is growing debate over whether large scale technology is in society's best interests, with its tendency toward more and more control by a technical elite, towards the necessity of producing elaborate security structures around it, and toward increasing social fragility out of the possibility of breakdown. It may be that at least one highly sophisticated laboratory would serve ERDA well by emphasising the "string and sealing wax" approach to energy research and development through a focus on small systems. At the very least ERDA might put aside one laboratory to question prevailing philosophy and probe the basics of energy systems. At the moment it has no such place—a place that preserves and nourishes first principles.

ERDA taking a view

ERDA is studying the future role of the national laboratories in light of its mission to commercialise energy technology. It is asking practical questions about how one goes about linking their research and development functions with industrial development and demonstration. In the case of LBL, it is serious about integrating research at the University of California, which is contract manager of the Laboratory, with research at LBL.

But ERDA is also undecided about its overall research management strategy. It talks of regional programmes and projects and speaks of using the national laboratories somehow in the regionalisation of energy research. At the same time it says many laboratories, especially Berkeley, have a broad spectrum of capability in many fields. And all the while, ERDA policies are subject to political whims, since their Associate directors are all politically appointed. It is little wonder LBL officials are confused and worried. It is a centre with a rich tradition in research, and once bursting with pri and confidence. Now it searches for prevailing philosophy against a b drop of an agency that cannot yet exactly how it plans to steer its ship.

Coping with variability

Wil Lepkowski reports on the response of US agriculture to climatic change, the subject of a recent report

THE one sure thing about the weather—and the climate—is that it will change. Therefore farmers, who depend on the weather, must be nimble. That is the essence of a report issued last month by the Washington-based Institute of Ecology under support from the Kettering Foundation of Dayton, Ohio. The report says climatoligists may not agree for some time over whether the climate is warming or cooling. But what they can agree on is that it will fluctuate. The strange point the report makes is that North American agriculture may be unprepared for the normal fluctuations in climate.

Why? It may have grown complacent over the good run of weather experienced during the 1950s and 1960s, when agriculture boomed. As a result, the technology of fertilisation, pest control, and plant genetics may have softened crop resistance to fluctuation with the result that agriculture may have made itself vulnerable to trouble.

The panel, which had only six months to study the issue, makes three major recommendations: that weather scientists step up research on the processes and mechanisms of climatic change, that scientists develop research leading to improved strategies for food production under climatic stress, and that governments expand agricultural information networks to inform farmers more quickly of conditions affecting their crops.

The saga of the American farmer is that of a crusty realist always prepared for climatological vagaries. But this report emphasises agriculture's soft underbelly — that behind the legend lies bureaucratic complacency. It says with world population continuing to expand by 200,000 souls a day, and virtually all arable land under cultivation, agriculture is at the brink. It must be more watchful of its assumptions, more anticipatory of trouble. And the bureaucracy isn't.

The study, which was chaired by Professor James E. Newman, a Purdue University bioclimatologist, is ecology's first major try at tackling the agricultural policy issue. Its range was limited to Canadian wheat and American wheat, sorghum, corn, and soybeans, and it traced the production record of these crops under various degrees of climatological stress during the past 40 years. Its tone is that of a gentle warning rather than a vigorous call to action. One senses that farmers gathered for gossip at the general store would nod tired agreement but that the boardrooms of agribusiness corporations would pay only passing heed.

There is an undercurrent of concern over the vulnerability of technological agriculture, especially in view of its dependence on fossil fuel technology. And climate remains a concern. Four big studies are continuing in the US and each bears watching:

- "Study of Changing Climate Patterns and their Effect on Agricultural and Renewable Resource Productivity", by the National Academy of Sciences.
- "Living with Climatic Change", co-sponsored by the American Meteorological Society, the Canadian Meteorological Society, the Geophysical Institute of the National Autonomous University of Mexico, and the Science Council of Canada.
- The Large Crop Inventory experiment, by the National Aeronautics and Space Administration, US Department of Agriculture, and National Oceanographic and Atmospheric Administration.
- "Impact of Climate Change on the Character and Quality of Human Life", by the Aspen Institute for Humanistic Studies. ☐

BRITAIN

Genetic manipulation: report due

For many of Britain's molecular biologists, a long wait is almost over. Eleanor Lawrence reports

THE long-awaited report of the Williams Working Party on the Practice of Genetic Manipulation is "being printed and will be published shortly", according to Mr Fred Mulley, the UK Secretary of State for Education and Science, in a written reply to a Parliamentary question last week.

Mr Mulley was giving few details away on the code of practice itself, except that it will in the first instance be a voluntary one, with the possible introduction of specific statutory controls later in the light of experience. It will set out principles for categorising experiments and recommend various levels of safety precautions necessary for particular categories of experiment. But he shed a little light on the intended role of the proposed central advisory group. From this it looks as though scientists will have to wait until the advisory group is set up before their long-deferred experiments can begin.

The provision of a central advisory service for laboratories wishing to carry out genetic engineering was originally recommended by the Ashby Working Party which reported in January 1975. The experiments involve the transfer of alien genes to the common gut bacterium *Escherichia coli* by splicing the foreign genes onto a plasmid or bacteriophage vector.

One consequence of this might be that *Escherichia coli* with unusual and possibly harmful properties conferred on it by the transplanted genes might escape from the laboratory and infect the population at large. One of the fears when these experiments were first proposed was that they would be carried out in laboratories with little previous experince of the microbiological techniques developed to contain potentially dangerous organisms.

The Williams Working Party has endorsed the idea of a central advisory service but apparently sees it as a watchdog as well as adviser. According to Mr Mulley's statement the Working Party has recommended that any laboratory contemplating experiments likely to come under the code should be required to notify the central advisory service before beginning work. This recommendation can be implemented through regulations which can be drawn up under the present Health and Safety at Work Act.

These recommendations will in some respects provide the proposed British scheme with an advantage over the recently-published American guidelines, which only strictly apply to work funded by the National Institutes of Health; in Britain, all laboratories, whether university, government or industrial, will be covered.

The Working Party report is expected within the month, and Mr. Mulley intends to appoint the members of the central advisory group as quickly as possible and make immediate arrangements for it to get to work. The Health and Safety Commission will also soon be circulating for comment its proposals for regulations requiring notification of proposed experiments. ☐

UK ENERGY

• The UK Energy Secretary, Mr Anthony Wedgwood Benn, rarely out of the news these days, has been asked to delay his autumn decision on the 1,300 MW demonstration fast breeder reactor, CFR-1, pending the forthcoming report from the House of Commons Select Committee on Science and Technology on alternative energy sources. The request came last week from Mr Arthur Palmer, the Committee's Chairman, and in response Mr Benn has indicated that he does not at the moment want to wait beyond the end of October.

This tight autumn schedule is not new, but Mr Benn's implication that he may not wait is. What is more, the UK Atomic Energy Authority (UKAEA) this time round is believed to be seeking clearance only for a firm timetable and site selection, and is prepared to wait as long as two years for a final decision on whether to build the fast breeder. As for the Select Committee, which is considering the likely future role of the reactor in Britain for the purposes of its report, it is understood to be more disposed towards the reactor than against it at present.

The UKAEA's drive to keep progress on the fast breeder ticking over smoothly is meanwhile slipping into a higher gear following Treasury approval of a £10.5 millions contract for three steam generators. The generators, expected to be ready for the 250 MW prototype fast breeder at Dounreay in Scotland by 1979, are exactly similar in design and size to those planned, in greater number, for CFR-1. The design in use at the moment is unlikely to prove entirely satisfactory for commercial operation, and represents little more than an interim stage of development.

Also making progress, it seems, is the Central Electricity Generating Board's (CEGB) attempt to negotiate a share in the 1,200MW Superphénix project on the Rhône. Discussions have been proceeding for some months, but details have remained secret. Now it is reported that the French–German–Italian consortium involved has offered the CEGB a 10% interest for an initial stake of £60 millions.

• Why has Mr Benn appointed Mr Francis Tombs, head of the South of Scotland Electricity Board, as successor to Sir Peter Menzies, Chairman of the UK Electricity Council, when he retires in March 1977? Insofar as it is a matter of alternatives, the simple answer is that Tombs is only 52, whereas his counterpart at the CEGB and his obvious competitor, Sir Arthur Hawkins, is himself close to retirement at 64.

But, like most problems facing the Energy Minister, this is not being seen as a simple matter of alternatives. In his present position, for instance, Tombs heads the only electricity board in the country which both generates and markets electricity. So, one argument runs, the government could be preparing to implement the Plowden Report's call for closer integration of both aspects of the business throughout Britain.

More controversially, there is the suggestion that Tombs' support for the Steam Generating Heavy Water Reactor (SGHWR), now under review by the Department of Energy (DEN), won him his new position—that he would be able to keep the SGHWR programme firmly on course. Equally, though, with Tombs placed where he may have to compromise with individual generating boards, the project might more easily slip quietly away

Not so, says the Department of Energy, chary of every hypothesis. Then why has Tombs been appointed so far in advance? Once bitten, twice shy, says the DEN, adding that it burned its fingers over the delay in the recent reappointment of Sir Derek Ezra as head of the UK National Coal Board.

• The SGHWR receives a mention in the report released last week of the Public Accounts Committee (PAC), the committee of MPs which oversees government spending. In the interests of "effective financial and technical control", it says, the financial responsibilities of the various parties involved "should be clearly defined as soon as possible". Every inducement to efficiency and economy should be incorporated in the contractual arrangements, and the absence of a fully costed design should not delay agreement in principle on these matters. The committee was told that the total cost of the SGHWR programme would be about £100 million.

The committee also made some comments on British Nuclear Fuels Ltd (BNFL). BNFL had in the previous week published its annual report showing an increase in both profits and export earnings; Alex Eadie, junior minister at the Department of Energy, had at the same time revealed in a Commons answer that the government had agreed a massive £715 million investment programme for the next ten years.

BNFL (profits last year: £11.9 million) has paid no dividends for the past four years; this, says the PAC, is equivalent to the Exchequer providing interest-free advances of capital, and the no-dividend policy should be re-examined if the company is to operate on a normal commercial basis. There should also be close control of BNFL's investment programme; expenditure should be approved only if there are good prospects of an adequate return.

The main feature of BNFL's investment programme is the expenditure of £300 million enlarging the capacity of its uranium enrichment facility at Capenhurst in Cheshire. The plant, based on the gas centrifuge process, involves BNFL working in association with West Germany and Holland as partners in Urenco, which last year won sizeable enrichment orders. Another £130 million focuses chiefly on the conversion of uranium oxide to uranium hexafluoride for enrichment, for which BNFL also won orders last year; £245 million is going on extensions and improvements to the facilities at Windscale used for reprocessing nuclear fuel; and £40 million is being devoted to developing the process for the vitrification of waste.

According to Mr Eadie, the saving to the balance of payments through Magnox fuel reprocessing for domestic customers is "at least £200 million", and the revenue from reprocessing carried out at Windscale for overseas customers has so far been "about £12 million".

• A British Government reply made recently to the 42 recommendations on energy conservation from the Select Committee on Science and Technology last year latches on to some of the committee's ideas but parries the criticisms about weakness in central direction on conservation by saying that there are "limits on how active a part government can play without getting into a situation where it is taking consumers' decisions for them". That said, the government has gone some of the way to meeting the committee's call for a full-time task force of Ministers and others, and has also announced more help for small companies, an extension of the energy-saving loan scheme for companies, the provision of better information on energy-saving, and an extra £1 million for the "Save It" campaign (described by the Select Committee as a "feeble" exercise). If these moves are more than marginally effective they will need to be factored in to the ongoing debate on Britain's future requirements of nuclear power.

IN BRIEF

More nuclear deals

There's no relief in sight for those campaigning for greater restraint in the burgeoning international trade in nuclear technology. At the end of last week the delayed Franco–South African deal for the construction of two pressurised water reactors finally went through when Escom and the French consortium headed by Framatome signed contracts in South Africa. Only a couple of days earlier France's Foreign Trade Minister initialled an agreement in Seoul under which Framatome will build two similar reactors for South Korea.

France's sale of a small reprocessing plant to South Korea was stalled earlier this year following US pressure. Now similar pressure has been brought to bear over an almost identical deal between France and Pakistan. At the weekend Dr Henry Kissinger told President Bhutto that Pakistan risked losing US military and economic aid if it went ahead. Bhutto reportedly insisted that Pakistan be treated in the same way as Iran, which apparently wishes to reprocess nuclear waste from its reactors locally rather than outside the area Israel and Egypt, on the other hand, with which the US has now initialled agreements on the sale of reactors, have agreed to let any reprocessing be done outside the Middle East.

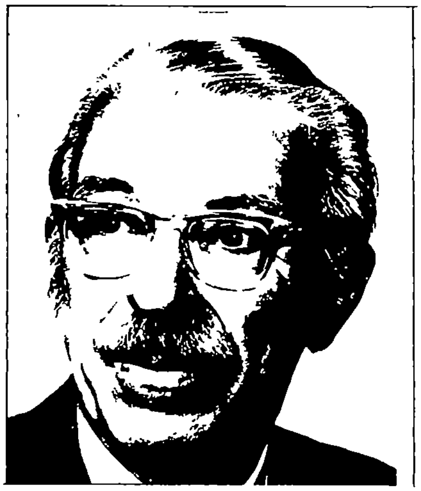
In the US, meanwhile, the State Department has conceded that American materials may have been involved in India's nuclear explosion in 1974.

Biblis problems

A senior executive of Kraftwerk Union (KWU) announced this week that the huge nuclear power plant at Biblis, West Germany, would be technically capable of returning to service by the end of the week, although clearance from the relevant authorities would still take some time.

The twin pressurised water reactors were closed for a routine inspection three months ago. In a joint statement last week, the operators, RWE, and builders, KWU, disclosed that "incipient cracking" had been found in the cooling water reservoirs of both reactors, and that steel bolts which had sheared off in the main cooling circuit of the commercially operating 'A' block reactor had been carried close to the nuclear core. The shutdown was originally scheduled to last eight weeks. The Biblis installation is the model for the four reactors to be built by KWU in Brazil and Iran, and officials are stressing that the breakdowns are not a cause for alarm One estimate which has been made of the cost to the operators is $50 million.

Mountain streets



THOMAS H. JUKES

JULY is the prime time for the High Country in the southern Sierra Nevada of California. This was so in 1976 more than usual, because of the severe drought that had prematurely melted the big snowbanks. It was in July 1935 that I had first tasted their icy waters, as addictive as the most insidious of narcotics. And so, for the 39th summer, in a series broken only by war years, I set forth to regions above timberline, knapsack on back. What new changes would I find that had been wrought by technology and human beings?

Within the mountains of California, Yosemite, Kings Canyon and Sequoia National Parks are known for small areas that can be reached by road, but beyond these are hundreds of square miles that are reserved for what has been called "the aristocracy of the physically fit." Even this elite group dwindles as one heads away from the trails. It is curious that, even in the mountains, human beings tend to collect in herds. I still have no difficulty in finding big lakes, above 11,000 feet, where I am alone with peaks, trout and jet planes.

Thirty years ago, many beauty spots of the High Country were defiled by monumental piles of cans and bottles. Most of these have been patiently removed by volunteer labour. The volunteers, helped by officials, have also removed wrecked planes, piece by piece. Travel by horses and mules has been greatly reduced by high costs, and has been mostly replaced by the use of ingenious lightweight backpacking equipment and dried food.

The US Government, as may be expected, increasingly regulates travel in the wilderness. The official and praiseworthy concept is that "man as a temporary visitor, should leave no permanent imprint." One has to file the equivalent of a "flight plan" before being permitted to take off. Simultaneously, nine pages of "suggestions" and rules are thrust into one's hand Enforcement of these is often by female rangers who are the spiritual granddaughters of members of the Women's Christian Temperance Union. One of these rangers is spoken of with admiration by her colleagues as having recently written twenty "traffic tickets" for offences committed by feckless hikers on the eastern slopes of Mount Whitney.

Years ago, the "organic waste problem" in mountain travel was officially given only a casual reference We were archly advised to "do like the cat; dig a hole and bury it " Today the instructions for "sanitation and waste disposal" occupy seven column inches. The dimensions of the pertinent hole are now specified as 5 to 6 inches deep and 8 to 10 inches across. I notice that the indigenous cats (*Felis couguar*) apparently do not read, and do not dig holes, preferring to leave evidence of their passage in the open as a defiant challenge to territorial intruders.

On July 15, I lay for twelve hours in a small plastic tube tent, at 10,800 feet, as a magnificent electric storm crashed incessantly in the darkness and, at midnight, a huge rain-loosened rock avalanche roared down a nearby granite cliff Next day, in the bright sunlight, I caught golden trout. A few nights later, a Pacific Fisher (*Martes pennanti*) stealthily and silently made off with a string of golden trout that I had hung above my head in a pine tree while I slept in the open, well above the altitudes where bears live. My vexation was tinged with admiration when I got up at dawn to find the loss. I headed for the lake to replace the theft, and then walked for nineteen miles, through the rocky streets of the mountains, back to the road-head

news and views

Chromatin superstructure

from H. G. Davies

PROGRESS in understanding the structure of chromatin and eukaryotic chromosomes continues apace. Early electron micrographs by Ris and others had shown that the long fibres obtained from chromosomes were either thin, about 10 nm, or thick, about 25 nm, depending on the presence or absence of chelating agents Hitherto, however, it has not been clear how the two fibres are related. The past few years have seen the emergence of evidence that chromatin has a subunit structure; nuclease digestion of chromatin yields pieces of DNA which are multiples of about 200 base pairs, histones occur as oligomers, and electron micrographs of suitably lysed nuclei show linear arrays of interconnected roughly spherical particles about 10 nm diameter called beads, ν-bodies, or nucleosomes. Kornberg has put forward a model for the 10 nm fibre—a flexible chain of repeating structural units, like "beads on a string" (*Science*, **184**, 868; 1974), each bead containing two each of the four major histones.

Finch and Klug (*Proc. natn. Acad. Sci. U.S.A.*, **73**, 1897; 1976) now provide evidence to show that thin fibres about 40 repeat-units long, obtained from rat liver nuclei by brief nuclease digestion, can undergo helical folding to form a solenoidal structure about 30 to 50 nm wide. The evidence for helices is based first on electron micrographs which show more-or-less clear striations, separation about 12–15 nm crossing the thick fibre, and second, on new X-ray diffraction data and a reinterpretation of the earlier patterns obtained by Wilkins and collaborators, and Luzzati and Nicolaieff, showing maxima 11.0, 5.5, 3.7, 2.7 and 2.2 nm The key experiment is a comparison of the X-ray spectra of thin and thick fibres and the results are different from those obtained previously, due, presumably, to improved methods of preparing chromatin. Sperling and Tardieu (*FEBS Lett*, **64**, 89, 1976) find that the scattering from thin fibres in the region of spacings 40 to 3 nm fits the theoretical curve for a continuous density rod with no peaks at 11 and 5.5 nm. The 11 nm and other reflections appear, however, under conditions where solenoidal structures can be seen in electron micrographs. Hence Finch and Klug now propose that the reflections at about 11 nm and higher orders arise from the spacings between the turns of solenoids of low pitch angle and not from an interbead spacing of 10–11 nm along the thin fibre as had been universally, and quite reasonably, assumed, and indeed used by Kornberg to support his model. The new explanation of the spectra is similar to that originally proposed by Pardon and Wilkins (*J. molec. Biol.*, **68**, 115; 1972) except that they thought in terms of supercoiling DNA, rather than the continuous 10 nm fibre The data appear to confirm a suspicion held by many that the repeating unit in the thin fibre only becomes visible as ν-bodies or nucleosomes under special conditions. Those electron microscopists who, for one reason or another, did not see the thin fibres as beaded, but continuous, a result confirmed by Finch and Klug, will be unable to resist a smile at this latest turn of events.

Another key observation is that by Carpenter *et al.* (*Nucleic Acids Res.*, **3**, 1739; 1976) on neutron diffraction from oriented fibres of chromatin. The meridionally oriented reflection at about 10 nm, is now seen to be split, forming a cross pattern with semi-meridional angle of 8° to 9°. This is a sure sign to the cognoscenti that it originates from a helix. They propose as a model a coil of nucleosomes of pitch 10 nm and an outer diameter about 30 nm, dimensions corresponding to about six nucleosomes per turn of the helix. Of course, such a splitting of this meridional reflection could also be expected in the solenoidal model formed from a continuous 10 nm thread.

On the basis of electron microscopy of sections, we have described thread-like units within condensed interphase chromosomes, or chromatin bodies. These "superunit threads" about 28.0 nm diameter, are clearly recognisable because they tend to line up into layers at the surfaces of nuclei, and can also form monolayers, width independent of species, plant and animal Davies and Haynes (*J. Cell Sci*, **21**, 315; 1976) now report that nucleoli are attached to the nuclear envelope by a monolayer of these superunits. We have suggested that the superunit thread is formed from some type of helical arrangement of a subunit thread—"close-packed beads-on-a-string". This would account for the earlier observation that the unit appears tubular. Finch and Klug comment that their solenoidal model being of similar geometry can be equated with superunit threads found within nuclei.

Much clearly remains to be learned about the detailed molecular structure of these proposed helically arranged repeating units, how they are further folded up in mitotic chromosomes and how they unfold in those parts of interphase nuclei where RNA transcription occurs Also the way the DNA molecule is folded around the repeating unit is not clear, but results on sections suggest the repeating unit is asymmetric with more DNA on an inward pointing face. The spiralling of mitotic chromosomes and the helical nature of the DNA molecule have long been known and the above results will come as no surprise to those who believed that there were orders of coiling in between. The point is that speculation is now being replaced by fact □

A hundred years ago

IN the *Bulletin International* of August 3, M. de Tastes relates some interesting particulars of a waterspout (*trombe*) which was observed near Tours, on May 25 1876. It first appeared as a mass of whitish vapour against a background of dark-coloured clouds, which gradually assumed the form of an inverted cone pointing to the ground, and terminating in a long sinuous band A whitish sinuous column soon appeared suddenly between it and the ground, and rapidly enlarged upwards, the whole phenomenon soon assuming the appearance of two cones united at their summits. The lower cone, at first lightish-coloured and in a certain degree transparent, gradually assumed a darker shade, which was propagated from the base towards the summit.

from *Nature*, **14**, August 10, 320, 321; 1876.

Anaesthetic mechanisms

from C. D. Richards

ANAESTHETICS affect every variety of living system, from microorganisms to mammals; they are very nonspecific drugs which depress a whole battery of cell functions including cell motility, cell division, photosynthesis, oxidative metabolism and electrical excitability. Their mode of action poses one of the fundamental problems in biology. Their clinical value rests solely on their ability (at low concentrations) to impair certain higher nervous functions such as consciousness and memory without disrupting the function of the heart and respiratory system.

Four key observations suggest that anaesthesia is the result of some physical interaction of the anaesthetic with certain constituents of the cell rather than a specific chemical reaction. First, the effects of anaesthetics are freely and rapidly reversible; second, the potency of an anaesthetic is directly related to its lipid solubility; third, anaesthetic properties are shown by a wide variety of chemically unrelated substances; and fourth, the effects of anaesthetics can be reversed by high pressures.

The critical volume hypothesis first discussed by Mullins more than 20 years ago (*Chem. Rev.*, **54**, 289, 1954) seems to be the most successful of the various hypotheses proposed to explain the action of anaesthetics. In its simplest form it proposes that anaesthesia (narcosis) occurs whenever a critical fraction of anaesthetic has been achieved in the membranes of the cell; this critical volume is held to be dependent on the species under study but independent of the nature of the anaesthetic.

In its original form the critical volume hypothesis added little to the well established Meyer–Overton concept of a role for lipid solubility in the mechanism of anaesthetic action, but recent investigations of the reversal of anaesthesia by pressure by Miller *et al.* (*Nature*, **231**, 368; 1971; *Molec. Pharmac.*, **9**, 131; 1973) have led to a more satisfying model. They propose that anaesthetic dissolves in some hydrophobic region of the cell—presumably lipid—causing that region to expand, thereby impairing some vital function From the amount of pressure required to reverse the effects of various doses of anaesthetic they calculated that during general anaesthesia the hydrophobic region should expand by about 0.4% (v/v). This prediction has subsequently been verified by Seeman and Roth (*Biochim. biophys. Acta*, **255**, 171; 1972) for erythrocyte membranes.

This still leaves four important questions. How is the membrane expansion brought about? How does the membrane expansion lead to impaired membrane function? Which of the many functions of the membrane are impaired by anaesthetics? Does anaesthesia result from the impairment of one or several specific functions?

Membrane effects

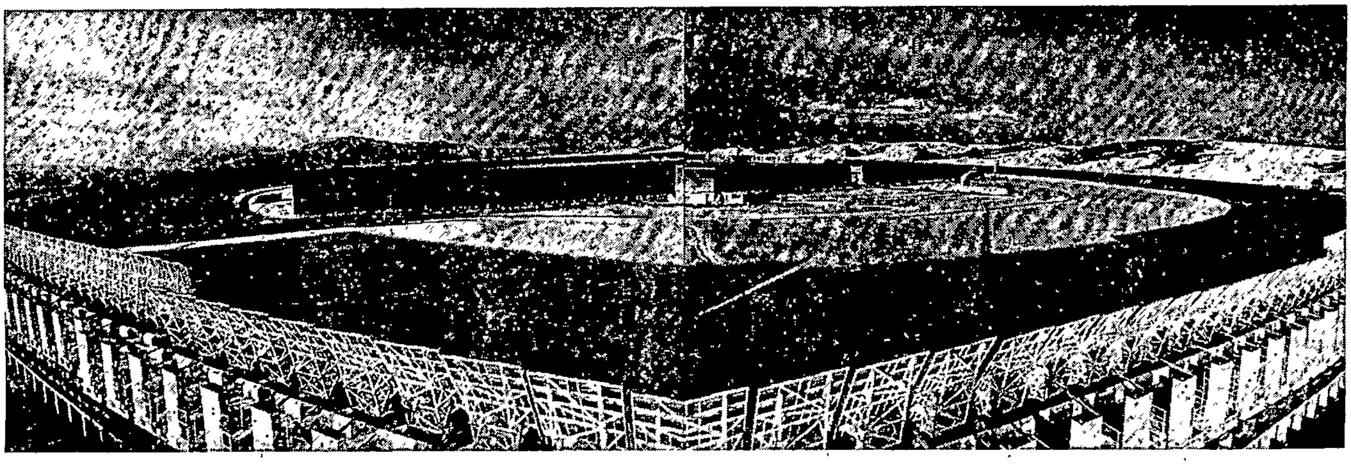
Metcalfe *et al* (*Mol Pharmac*, **4**, 87; 1968) found that benzyl alcohol which can act as an anaesthetic increased the fluidity of biological membranes This observation was later extended by Trudell *et al.* (*Biochim. biophys. Acta*, **291**, 328; 1973) to include clinically important anaesthetics, such as halothane. It was subsequently proposed that anaesthetics cause membrane expansion by increasing the disorder of the fatty acid chains of the phospholipids of the membrane bilayer. During general anaesthesia, anaesthetics occupy only 0.2% (v/v) of the membrane whereas membrane expansion is of the order of 0.4% Seeman has shown, however, that artificial phospholipid bilayers only expand by 0 2% and so he proposed that changes in the conformation of the membrane proteins are the cause of the large expansion of natural membranes (*Experientia*, **30**, 759; 1974). Furthermore, in a recent paper Boggs *et al* (*Molec. Pharmac.*, **12**, 127; 1976) have shown that concentrations of anaesthetic sufficient to cause general anaesthesia or which block the conduction of impulses along a nerve ("local anaesthesia") have little or no effect on the fluidity of artificial membranes Although such observations cast doubt on the view that anaesthetics impair membrane function through a generalised perturbation of the structure of the lipid membrane they are consistent with the view that the interface between lipid and protein may be the site of anaesthetic action.

There is now evidence to suggest that at least some membrane-bound proteins require the presence of a layer of tightly bound lipid to stabilise them in their active form. This has been shown for cytochrome oxidase (Jost *et al.*, *Proc. natn. Acad. Sci. U S A.*, **70**, 480; 1973) and for the calcium transport protein of the sarcoplasmic reticulum (Warren *et al*, *Nature*, **255**, 684; 1975). By studying the effects of temperature on the calcium transport protein reconstituted in defined lipid mixtures, Warren *et al* (*Biochemistry*, **13**, 5501; 1974) showed that the enzymatic activity of the complex decreased as the lipid became more crystalline This suggests that the activity of this protein is governed by the fluidity of the lipid in which it is embedded In the light of this data, Lee (page 545, this issue of *Nature*) has proposed that the sodium channel in nerve membranes may be surrounded by a ring of rigid lipid molecules that serves to keep it open. He suggests that anaesthetics block nerve impulse conduction by fluidising this boundary lipid so causing the sodium channel to collapse inwards. One consequence of the model is that a nerve blocked by an anaesthetic should have its conduction restored when the temperature is lowered, and this has indeed been shown for the action of ethanol on squid axon (Spyropoulos, *J. gen. Physiol.*, **40**, 849; 1957).

Specific interactions

It is not difficult to envisage other membrane proteins such as receptors being similarly surrounded by boundary lipid which serves to keep the protein poised in an optimal conformation. The fact that some anaesthetics affect one function rather than another could then be explained by relatively specific interactions either with the boundary lipid or with the individual protein. Certain volatile anaesthetics have been shown to inhibit the bacterial enzyme luciferase apparently by competing for the substrate binding site (White, in *Molecular Mechanisms in General Anaesthesia*, Ch 13, Churchill–Livingstone, London, 1974; Middleton and Smith, *Proc. R Soc. Lond.*, **B193**, 173; 1976)

Moreover, specific interactions of this sort could account for the antagonism of the depressant effects of the steroid anaesthetic alphaxalone by the non-anaesthetic steroid Δ16 alphaxalone observed in isolated preparations of mammalian brain tissue (Richards and Hesketh, *Nature*, **256**, 179; 1975). Nonetheless, such ideas must remain speculative until it becomes possible to isolate receptors and reconstitute them in artificial membranes of defined composition With the recent developments in understanding the rôle of lipid-protein interactions in membrane biochemistry, the next period of anaesthetic research should be an exciting one. ☐



New giant Soviet radiotelescope

from Boris Belitzky

THE RATAN-600 radiotelescope, under construction at Zelenchuk in the North Caucasus since 1968, is now completed and fully operational. RATAN-600 is an acronym derived from the Russian for "radio-astronomical telescope of the Academy of Sciences" and a figure approximating the 576-m diameter of the telescope. Zelenchuk is also the home of the world's biggest optical telescope, the fully-operational 240-inch BTA reflector. Together with a large neutrino detector, under construction nearby, this unique array of instruments comes under the general umbrella of the Special Astrophysics Observatory founded there by the Soviet Academy.

Unlike Britain's Mark I instrument at Jodrell Bank or the slightly bigger West German instrument in the Efflesberg mountains, RATAN is not a 'steerable' dish, but embodies the variable profile concept.

Despite its size—its geometric area equals 10,000 square metres—the new radio telescope has been designed to operate in the short-wave spectrum down to 8 mm (Cornell University's Arecibo instrument, by way of comparison, stops short at 10 cm). As for RATAN's upper limit, this was selected to take in both the 18-cm hydroxyl wavelength and the 21-cm neutral hydrogen wavelength.

It is at the less well explored, shorter end of this spectrum, however, that the designers (a Pulkovo team under Dr Y. N. Pariisky and Dr N. L Kaidanovsky, with support from Moscow University) expect it to yield the most valuable results, and RATAN's record sensitivity and resolving power are, accordingly, in that region. Its aerial comprises a circular reflector, a flat reflector, and several feeds. The circular reflector is a variable profile aerial consisting of 895 cells mounted on a circular foundation and capable of tilting, rotating and moving radially. The flat reflector, mounted in the southern part of the circle, consists of 124 cells that can only be tilted.

The principal mode of operation requires pointing the telescope's axis at a source and observing its passage through the aerial pattern Observations of sources near the horizon involve approximately a quarter of all the reflecting cells and can be conducted according to four independent programmes simultaneously. At angles of 30 to 80° about a third of the cells are operational and three independent programmes can be pursued simultaneously. Finally, zenithal observations involve the entire circular reflector, and the telescope has a pencil-beam pattern equivalent to that of a continuous-surface reflector 576 m in diameter.

Each cell is fitted with pickups, which control all its movements and adjust it to the exact position required. Feed movement takes place along 12 radial tracks spaced azimuthally at 30° intervals. A turntable in the centre of the circular reflector serves to shunt a feed from one radial track to another Apart from the variable profile mode, the flat reflector makes it possible to use the telescope as a parabolic cylinder according to the Kraus system In this case the telescope has a constant knife-edge pattern, and the time needed for sky surveys is substantially reduced. By combining the circular and flat reflectors in the southern sector it is possible to use the telescope in certain other operational modes, such as tracking a source. This mode of operation is, of course, a particular asset whereever maximum sensitivity is required.

RATAN was begun in 1968, and the first part of the project—the northern sector of the circular reflector—became operational in 1974. Some significant astrophysical results were obtained during the running-in period These included the discovery of a solar "radio granulation"—a fine structure of the Sun's radio emission in the centimetre range, which appears to coincide with its chromospheric net. The radio astronomers at Zelenchuk have been able to observe the radio emission of the solar corona at large angular distances from the Sun and to observe quasars through the corona.

Simultaneous observations of radio sources on several frequencies have yielded their instantaneous spectra and permitted the sources to be separated into components. One of the most interesting findings concerning the structure of radio sources has been the discovery of a bar linking the components of such well-known double sources as Cygnus A There have also been measurements of the Einstein effect—beam deflection in the Sun's gravitational field.

Now that the telescope is fully operational, the programme of research is being expanded. Inside the Solar System it is proposed to study physical conditions on the surfaces of the planets, their satellites, and the minor planets. Solar studies, which command growing interest among Soviet astronomers, will include investigations of the brightness distribution in the active regions of the Sun to determine the structure of magnetic fields and condensations in the lower corona and the upper chromosphere, and also the structure of the chromosphere and the transition zone.

Further afield there are to be radio observations of the Galaxy and of the Solar System neighbourhood, of the Galactic nucleus, of the fine structure and kinematics of gaseous and planetary nebulae, and of pulsars and the nearest stars.

Extragalactic studies, which in Pariisky's view are the most interesting application for RATAN, will be conducted mainly in the decimetre range. Naturally, there is particular interest in studying quasars and radio galaxies with anomalously intense radio emissions in the hope of learning more about the nature of these objects and the sources of their energy. There are also to be studies of the fine structure of many radio galaxies, with particular reference to their brightness distribution spectrum and magnetic field structure. According to Dr Lev Gindilis, who has been concerned with planning the RATAN sky surveying activities, these are to be conducted on a systematic basis and at the highest frequencies possible. This is prompted by the paucity of information in this range and the hope of observing quasars at the initial stage of their evolution. Gindilis considers RATAN to be an optimal instrument for surveys in the entire range from 4 mm to 20 cm, in which there is a minimum of natural interference for observing cosmic sources. RATAN sky surveying work will also take in account the wishes of radio astronomers interested in the problem of communication with extraterrestrial intelligence (CETI).

Ultimately the RATAN control complex is to be linked to the main radioastronomical centres of the Soviet Union, with the result that the potential of this giant instrument will be used more effectively. RATAN-600 is also seen by Soviet radio telescope designers as a stepping stone towards far more powerful facilities. ☐

Aspects of plasmid behaviour

from J. R. Saunders

A NATO Advanced Study Institute on the Biology of Bacterial Plasmids was held at Kavouri, Nr Athens from July 5–16, 1976.

INTEREST in the biology of bacterial plasmids has been stimulated both by their use as cloning vehicles for genetic engineering and by the increasing knowledge that a multitude of important bacterial properties are plasmid specified. The role of R plasmids in mediating antibiotic resistance in clinically important bacteria is well known. Bacterial pathogenicity for plants can, however, also be encoded by plasmids. N. Van Larebeke (University of Ghent) showed that the ability of *Agrobacterium tumifaciens* to cause "crown gall" tumours in wounded plant tissues is determined by tumour-inducing (Ti) plasmids Furthermore tumorigenic ability can be transmitted to other Agrobacteria either by transformation or by conjugation mediated by the R plasmid RP4. M. Holsters from the same group demonstrated that Ti plasmids allow host bacteria to synthesise and utilise either nopaline or octopine. It is interesting that tumours produced by *A. tumifaciens* contain, (depending on the strain) either of these unusual amino acids, suggesting that certain plasmid genes may be expressed in tumour cells.

P. Williams (University of Wales, Bangor) hailed the 'degradative' plasmids of *Pseudomonas*, unlike most plasmids, as being totally beneficial to the biosphere as a whole. The ability of some *Pseudomonas* species to degrade and utilise many natural and synthetic organic substrates is due in part to the existence of plasmids determining the enzymes of specific catabolic pathways The manipulation of these plasmids could therefore be used to construct bacterial strains capable of 'mopping-up' oil spillages and industrial wastes.

The translocation of resistance genes continues to generate interest. S N. Cohen (Stanford University) stated that Transposon A (TnA) encoding resistance to ampicillin comprises part of the larger transposon TnS which specifies resistance to ampicillin, streptomycin and sulphonamides and that TnA may provide the driving force for the translocation of the larger unit. Evidence for interactions between transposons was also presented by M. H. Richmond (University of Bristol) He reported that the presence of TnA on a plasmid reduces the frequency of transposition of a second copy of TnA to it by a factor of 10,000 in recombination-deficient (*rec*$^-$) cells. On the other hand, in *rec*$^+$ cells the presence of a resident copy of TnA merely reduces the frequency of accretion of a second copy by 90%. In the latter case however the incoming copy of TnA apparently replaces the resident TnA probably by reciprocal recombination rather than transposition The results therefore suggest that one transposon in some way interferes with the *rec*-independent translocation of like elements. The as yet unpublished work of several laboratories on the genetic structure and nature of proteins required for transposition may help to elucidate these phenomena.

J. Davies (University of Wisconsin) and R. Hermann (University of Heidelberg) advocated the use of λ and fd phages respectively as host molecules for studying transposons. Phages possess the distinct advantage in that generally their genetical and physical properties, for example the location of promoters and partial known base sequences, are better characterised than those of plasmids. The ability to synthesise antibiotic-modifying enzymes *in vitro*, described by G. Hogenauer (Sandoz, Vienna) should also help our understanding of the structure and operation of resistance genes.

A major problem in genetic engineering is the expression of eukaryotic genes in prokaryotes (see *News and Views*, **262**, 256, 1976). D. H Gelfand (University of California, San Francisco) described the construction of plasmids carrying inserted *Xenopus laevis* 28S rDNA "downstream" of the operator–promoter region and part of the β-galactosidase gene of the lactose operon. Induction of the *lac* operon in cells carrying such plasmids causes increased production of RNA complementary to rDNA Furthermore, some derivatives with inserted genes produce β-galactosidase with reduced enzymic activity but increased molecular weight The production of polypeptides fused to this enzyme suggests that it may be possible to 'translate' some foreign genes in bacteria.

Potential vectors for natural spread of genes between bacterial genera are plasmids of the P incompatibility group (Datta *et al.*, *J. Bact*, **108**, 1244; 1971). P group plasmids are characterised by an extraordinary ability to transfer themselves to a wide range of Gram negative bacteria. They are thus attractive research tools for studying intergeneric gene transfer (see, for example, *News and Views*, **260**, 191; 1976) and for the promotion of chromosomal gene transfer in species which lack their own sex factors. They could in addition contribute to the spread of resistance genes by crossing species barriers and depositing transposons in new hosts V. Stanisich (University of Bristol) has also found that genes of plasmids normally restricted to *Pseudomonas aeruginosa* can be transferred to and expresed in *E. coli* by a technique essentially involving the formation of genetic hybrids with P group plasmids.

What then confers on these plasmids their unusual capacity for intergeneric transfer? One possibility is that their conjugation mechanism and specificity of attachment of P group sex pili is unaffected by the nature of recipient cells D. R. Helinski (University of California, San Diego) pointed out that P group plasmids not only exhibit a paucity of cut sites for many restriction endonucleases, but also that their replication machinery may be more complex and hence less dependent on host chromosome function than other plasmids. This could endow them both with some immunity against the battery of restriction enzymes likely to be encountered in intergeneric transfer and with the ability to replicate in a wide range of cellular environments. Accordingly the ability of P group plasmids to cross interspecies barriers in bacteria could well make them mediators of 'natural' genetic engineering. ☐

Iliopoulos wins his bet

from F. E. Close

The 18th International Conference on High Energy Physics was held in Tbilisi, USSR on July 15-21, 1976

It was the moment of truth for J. Iliopoulos. In his talk at the 17th International Conference on High Energy Physics held in London in 1974 (*Nature*, **250**, 186, 1974) he had declared "I am prepared to bet a whole case of wine that the next conference in this series will be dominated by the discovery of charmed particles". Anyone who accepted the wager should now be preparing shipment because the 18th International Conference, which has just taken place in Tbilisi, USSR, was indeed dominated by that very discovery—the latest in a series of dramatic developments that have revolutionised particle physics in the past two years.

Readers will recall the dramatic breakthrough that occurred in November 1974 when workers at Stanford Linear Accelerator Center, California, and at Brookhaven National Laboratory in New York independently and simultaneously announced the discovery of a heavy metastable meson (called J or ψ) (see *Nature*, **252**, 438, and **254**, 387; 1975) In the decade preceding this discovery all known mesons and baryons that were discovered had fitted in nicely with the idea of Gell-Man and Zweig (*Phys. Lett.*, **8**, 118; 1964) that there should exist quarks coming in three types or "flavours" distinguished by quantum numbers such as isospin or strangeness and that the mesons and baryons were bound states of these quarks The high mass and remarkable stability of the J/ψ suggested that this meson might be a bound state of a fourth flavour of quark ("charmed quark") and its antiquark In the jargon this state had "hidden charm" and theoreticians expected that there should be a spectroscopy of similar states which has become known as the "charmonium spectroscopy" by analogy with the spectroscopy of positronium Several heavy metastable states have been discovered since November 1974 and the latest information on their properties was discussed at Tbilisi The spectrum that is emerging is in excellent agreement with that expected for charmonium though the precise values of the masses are in some cases not quite what had been theoretically predicted.

The idea that there might be a charmed quark had been suggested by many people as long ago as 1964. Theoretical interest in this idea took on new significance when Glashow, Iliopoulos and Maiani noticed (*Phys. Rev* , **D2**, 1285; 1970) that a charmed quark could provide a mechanism (the GIM mechanism) for overcoming a stumbling block that had arisen in attempts to unify theoretically weak and electromagnetic interactions. Their theory required that there should exist mesons made from a charmed quark and its antiquark and that the lightest of these mesons should have a mass around 3 GeV/c^2 (about three times as heavy as the proton). The J/ψ and the other heavy metastable states certainly fit in with this idea and are even in the predicted mass region.

The second consequence of their theory is that there should exist mesons made from a charmed quark and one of the old faithful uncharmed quarks. After the discovery of the J/ψ it was predicted that the lightest of these states ("charmed mesons") should exist with a mass of about 2 GeV/c^2. Furthermore it was predicted that strange particles (such as the K meson) should be an important feature of the decay products of these charmed meson states.

In May of this year came a strong suggestion that such a state had been found in a study of the debris produced in the annihilation of electrons with their antimatter (positrons) at SPEAR in Stanford, California. An electrically neutral metastable particle was observed with a mass of 1.86 GeV/c^2 (compare the predicted 2 GeV/c^2!) decaying into K and π and sometimes into K and three pions. A study of the energy and momentum balance suggested that in the electron–positron annihilation a state with mass of 2.02 GeV/c^2 was being produced in conjunction with the 1.86 GeV/c^2 state, although the decay modes of this second particle have not yet been isolated. These two states were reported on at Tbilisi and the popular feeling was that they are charmed mesons where the quark and antiquark, from which they are composed, have coupled their spins to give a total angular momentum of 0 or 1 respectively (like π and ρ mesons). The observations of the strange meson, K, in the decay products is as anticipated for a charmed meson.

Only two weeks before the conference physicists at SPEAR working in collaboration with colleagues from the Lawrence Radiation Laboratory at the University of California, Berkeley, discovered the electrically charged partners of these mesons. The masses of these states are identical to or perhaps marginally heavier than their neutral counterparts. The charged state at 1.86 GeV/c^2 was seen decaying into a K and two pions. The important discovery, which is crucial to the charm interpretation, is that the positively charmed meson (D$^+$) is predicted to decay to K and two pions with electrical charges distributed as in

$$D^+ \rightarrow K^-\pi^+\pi^+$$

but should not decay by the mode

$$D^+ \not\rightarrow K^+\pi^+\pi^-$$

This is precisely what is observed in the data presented at Tbilisi.

Other phenomena that are probably due to charmed particle production were reported from several laboratories around the word. Of most immediate comparison with the SPEAR results are the experiments involving electron–positron annihilation at the Hamburg facility (DORIS) B. Wiik (Hamburg) reported that when electrons and positrons annihilate at DORIS with a total energy of just over 4 GeV (the same energy region in which SPEAR saw the simultaneous production of the 1.86 and 2.02 GeV/c^2 mesons) an electron was observed in the debris more frequently than expected from previously known sources It was reported last year (see *News and Views*, **257**, 535; 1975) that anomalous production of electrons and muons were seen in this energy range by Perl's group at SPEAR where it was argued that these were the decay products of a heavy lepton. Several features of the DORIS results suggest that at Hamburg, on the contrary, one is seeing electrons produced in the decays of charmed mesons (probably the same mesons that were seen decaying into K and pions at SPEAR). Furthermore, in two independent experiments at DORIS, it has been found that these electrons tend to be produced in conjunction with K mesons. The nature of these events is therefore consistent with pair production of charmed mesons (D,D*) followed by their "semileptonic" decay

$$e^+e^- \rightarrow D(1.86) + D^*(2.02)$$
$$\hookrightarrow e + K + \text{pions} + \text{neutrino}$$

the ubiquitous K meson is as expected in charm theories.

While it seems fairly certain that these leptons are coming from the weak decay of long lived particles, the precise relation of this signal with the anomalous lepton signal observed by Perl's group at SPEAR is unclear and generated much discussion. While the majority opinion still appeared to be that the Perl group's leptons are coming from a heavy lepton source several people were unhappy with this interpretation.

Now that the first charmed particles have apparently been found, the status of the heavy lepton has taken on a particularly pivotal position in the theoretical development of high energy physics as was emphasised in the talk given by A. de Rujula (Harvard University). As noted above, the priorities of the charmed mesons appear to be in line with those expected by Gashow, Iiopoulos and Maiani if charm is the way to overcome the stumbling block in the weak and electromagnetic unified theories. The discovery of charm with, apparently, these very properties lends indirect support to these theories. Other tests of these ideas were presented at Tbilisi. What seems astonishing is the amount of evidence that has accumulated in the last two years increasingly suggesting that the GIM mechanism allied with the original unification idea of Weinberg (*Phys. Rev Lett*, **19**, 1264; 1967) and Salam (in *Elementary particle physics,* edit. by Svartholm, N , 367, Stockholm, 1968) could be, if not the whole story, at least a first qualitative approximation to the correct theory. Almost all of the data on weak interactions reported at the conference agree with the Weinberg–Salam theory with four flavours of quark. There was some discussion as to whether a fifth and sixth flavour of quark may be necessary to describe data (on the theoretical front, confirmation of Perl's heavy lepton would lead people to prefer six flavours of quark—hence its "pivotal position") There does not yet appear to be any widely accepted need for extra complexity however.

The weak neutral currents (where neutrinos scatter from a target without any transfer of electrical charge taking place), reported on in London in 1974 have been studied in detail. Several groups reported evidence that parity is violated in these interactions, moreover the nature of this violation appears to be in accord with the Weinberg–Salam theory. Beautiful evidence for parity violation in atomic physics was also reported, again in line with the Weinberg–Salam theory.

The consensus of opinion was that it is rapidly becoming accepted that weak and electromagnetic interactions are indeed probably unified and that the "gauge field theories" are underlying not only weak-electromagnetic but perhaps also strong interactions (the new jargon here being quantum chromodynamics, or QCD, analogous to quantum electrodynamics). One consequence of such theories is that the scaling phenomenon seen previously in deep inelastic scattering of leptons on hadron targets should be violated in a systematic way at the very high energy experiments now taking place at the Fermi National Accelerator Laboratory near Chicago. Experimental data were presented by T. Quirk (University of Oxford) which showed a pattern of scaling violation consistent with the predictions of such theories.

One possibility raised by QCD theories is that quark confinement inside hadrons may be a natural consequence There was discussion among theorists of this possibility but as yet no clear idea has emerged. Some thoughts on how to proceed were presented by K. Wilson (Cornell University), and one contribution that excited much interest was that of A. Migdal of the Soviet Union who reported his calculations of meson spectroscopy in QCD with some phenomenological success

When in the future we look back on the two years leading up to this conference, they will surely be seen to rank with the most significant periods of advance in our understanding of subatomic behaviour. A very clear direction for investigation has emerged. With SPEAR having already been perhaps the most productive machine in particle physics history, and DORIS still in its infancy, these electron–positron annihilation machines promise yet more to come. There was also excitement at the great successes in building the new super proton synchrotron at CERN which promises to be ready for experimental research within a few months. East and West at Tbilisi were united in their belief that the next few years in high energy physics may reveal further significant advances that will rank alongside those just made in the past few weeks. I think Iliopoulos would not bet against that. ☐

Britain in European space

from David W. Hughes

A one day meeting to discuss the future scientific projects to be undertaken by the European Space Agency was held at the Royal Society, London on July 23, 1976 under the sponsorship of the Science Research Council.

DURING the current year ESA will spend £270 million, £200 million of which goes on the space applications programme (which includes Spacelab, communications satellites and the development of Ariane, a three-stage rocket which will make Europe independent of American launch facilities) and £26 million on the science programme. Great Britain contributes about one sixth of this (£6.5 m). The science programme budget is mainly spent on scientific satellites, a typical satellite being funded for five years, the expenditure maximising between the second and third year and totalling in all about £20 million (on average one satellite is launched each year). At present COS-B, GEOS, IUE, ISEE-B and EXOSAT are in orbit or about to be launched. COS-B was launched in August, 1975 and is measuring high energy gamma rays. 1977 is the planned launch year for GEOS which will study particle fluxes and electric and magnetic fields in the outer magnetosphere, IUE, which is an ultraviolet observatory in a geosynchronous orbit (so the satellite is always above the same place as Earth), and ISEE-B which will look at wave–particle interactions in conjunction with the NASA satellite ISEE-A. It is planned to launch EXOSAT in 1980 to study X-ray sources using lunar occultation techniques These satellites account for a considerable amount of the projected budget but obviously the amount of uncommitted funds will increase as each satellite comes to fruition, so that in 1978 and beyond there is a considerable amount of money to spend.

Scientific projects in ESA go through a series of stages. First comes the mission definition study in which a group of scientists and space technologists discuss the feasibility of the project in general terms. Then follows a more detailed and searching Phase A study, a Phase B study, construction and launch. Needless to say there is a pyramid structure to this series, the twelve or so mission definition studies per year leading to about three phase A studies and one probable launch.

The main purpose of the London meeting was to canvass the opinions of British space scientists as to what the next main mission should be, what should be flown on the second test launching of the Ariane rocket and which phase A studies should be instigated in 1976/77. With these opinions in mind the Science Research Council will then brief the British delegation for the October meeting of the Science Program Committee of ESA. The fact that the British voice only makes up 17% of the votes makes the discussion rather academic but democracy being what it is a firm decision by Britain's 17% could sway the day.

Four major missions were discussed, the Space Telescope clearly winning the day and being regarded as an instrument of outstanding and paramount importance. It is hoped that the telescope will appear in NASA's 1978 budget although it has already slipped considerably in time and in size, the main mirror now being 2.4 m in aperture. From its 500–600 km high orbit it will be able to detect objects 100 times fainter that those detectable from the Earth's surface (it will be able to pick up 29th magnitude stars) and will have an angular resolution better than 0.1 arc s, some 10 times better than attainable from the ground. Coupled with this diffraction-limited performance is the fact that being free from atmospheric absorption it will have a spectral range of 912 Å to 1 mm. Within our Galaxy it will study the early and late stages of stellar evolution, the position and proper motion of stars, the dust distribution and hydrogen concentration and also our Solar System. Extragalactic work will include investigations of the structure, scale and evolution of the Universe, the structure and content of galaxies and also quasars. It is obviously a project that no astronomical nation wants to be left out of. NASA and the US Congress look to ESA to contribute more than 10% of the cost in return for an equal percentage of the observing time and an involvement in directing the project. This 10% of the cost would be spent in Europe, designing, developing and constructing some of the instrumentation and the technology (for example the faint object camera and the solar arrays). This cooperation would of course mop up a considerable amount of ESA's science budget for a few years and, while recognising the great importance of the project, some of the scientists present at the meeting pointed out that science *per se* would not suffer if we did not participate, the Americans probably going on by themselves, whereas spending the money on specifically European ideas might open up new horizons in different fields.

The second mission considered was again a cooperation wth NASA and involved two spacecraft launched simultaneously towards Jupiter from a space shuttle, and then guided in such a way that one would be deflected by Jupiter towards the north pole of the Sun, the other passing over the south pole. ESA would supply one spacecraft and NASA would use a Pioneer type spacecraft for the other. This "out of ecliptic" mission would provide a new insight into interplanetary and solar physics and the science of the Jovian magnetosphere, mainly by taking the observer away from the plane of the planetary orbits where the large majority of observations have been made to date. The two satellites would obtain a stereoscopic view of the Sun and help to test the fundamental symmetry of the Solar System. The basic experiments would consist of a magnetometer, a plasma probe, a solar particle telescope, a cosmic ray telescope, a receiver for studying radio propagation, a coronagraph and a XUV heliograph The 85° inclination of the orbits to the ecliptic will enable the development of equatorial structures on the Sun to be followed continuously through several solar rotations.

Three other projects are to be studied further. LIRTS, a 2–3 metre classical, uncooled Cassegrain infrared telescope on Spacelab would provide high sensitivity photometry with high spatial resolution enabling many astronomical objects to be studied through the measurement of atomic and molecular lines in the far infrared. EXPOS again uses Spacelab to fly a set of instruments to study the spectra of cosmic X-ray sources and to detect polarised X-ray emission. The payload comprises a number of large area Bragg spectrometers each selected to study particular features in the 0.5 to 10 keV range. Spatial resolution of about 1 arc min and energy resolution of 10 to 20% at 1 keV is obtained by using an X-ray grating with a large area Walter I grazing incidence mirror. The third project concerned magnetospheric experiments from Spacelab and drew the fascinating picture of a series of tethered subsatellites around Spacelab, like dogs on leads, making multipoint plasma measurements. All these projects have the advantage to the UK that they support research fields in which British scientists are very active and proficient.

The afternoon session of the meeting discussed last year's batch of mission studies and chose the ones that the British scientists would like to go forward for a phase A (feasibility) study. These projects stretched the

Aphids, ants and pheromones

from our Insect Physiology Correspondent

It was shown by J. S. Edwards many years ago that the secretion from the cornicles of aphids consists of oily droplets, now known to be a mixture of triglycerides, in aqueous suspension. On release in contact with a solid surface this secretion quickly crystallises to form a hard waxy plaque. It thus provides a mechanical protection against small predators and parasites.

In recent years the cornicles have been found to liberate also alarm pheromones, which are secreted in response to predators and parasites. Bowers *et al.* (*Science*, **177**, 1121; 1972), isolated and identified *trans-β-*farnesene (TBF) as the alarm pheromone in several aphid species; this secretion seems also to repel other aphids encroaching on occupied feeding sites. As with the alarm pheromones of many insects, TBF is interspecific: it is present in all species examined in the subfamily Aphidinae, and all of them (with the exception of the turnip aphid *Hisdaphis*) show alarm activity to pure synthetic TBF. But other unidentified alarm pheromones are present in addition to TBF and these different blends of pheromone probably account for the different responses in different aphid species. Thus the turnip aphid which fails to react to TBF, secretes this pheromone in its cornicle fluid, and it reacts to the secretions of other aphid species.

Nault, Montgomery and Bowers (*Science*, **192**, 1349; 1976) have now studied the response to these pheromones in the ants which herd certain aphid species. These myrmecophilous aphids enjoying, as they do, protection by their ants from predators, are much less responsive to the alarm pheromones than non-myrmecophilous species. They may walk away on exposure to the alarm pheromone, but they do not drop off the feeding site. At the same time, and not surprisingly, the ants themselves respond to aphid alarm pheromones In experimental trials it appeared that the ants were prepared to stroke with their antennae any aphid species they were offered; but the different aphid species vary widely in the readiness with which they excrete droplets of honeydew for their ant keepers Some species will not respond at all. The Macrosiphini were caused to disperse by the ants' stroking: this provoked a predatory response by the ants, and the aphids were carried off to the nest and presumably eaten.

The acceptance of the attentions of ants replaces response to alarm pheromones· the myrmecophilous aphids rely on their ants for protection. Indeed, artificial liberation of TBF leads to attack by the ants, not on the aphids but on any suspected predators by which they appear to be attacked. The threshold of response to the pheromone by the ant is, indeed, even lower than the threshold in the aphids themselves.

imagination much more than the morning's batch as now people were looking towards the space research of the late 1980s.

Space astrometry had an instant appeal, bringing space science and technology to bear on one of the fundamental tasks of astronomy, the observation of the positions of stars and planets as a function of time. The increase in accuracy from ground-based observations has been very limited in the last half-century and no breakthroughs seem to be around the corner. Space astrometry would give positions to between 0.001 and 0.003 arc s (0.04 arc s is the present best for ground-based work); proper motions (the star's velocity perpendicular to the line of sight) could be measured to about ± 0.002 arc s yr^{-1} after 3 years of observation, such accuracy requiring 50 years at present; parallax (stellar distance) of stars of 11th magnitude, as opposed to 7.5 magnitude at present could be measured to $\pm$ 0.001$-$0.004 arc s (in contrast to $\pm$ 0.013 arc s from the ground). This increased accuracy has enormous astrophysical significance—improving the definition of the cosmic distance scale, calibrating Cepheid variables, increasing the accuracy of stellar luminosity and cluster age estimations being only a few examples to which it might be applied.

The Solar Probe also caused much discussion. Using a Jupiter gravity assist this can get to within 10 solar radii of the Sun's surface. The mission definition scientists decided that the problems of thermal control and telemetry coverage within the corona could be overcome. Scientific objectives are the measurement of the solar gravitational field (J_2), the testing of Einstein's theory of general relativity and the measurement of the rate of change of Newton's constant of gravitation. Also a whole series of experiments dealing with particles and fields in the expanding corona would be flown. A Climatology satellite, to obtain measurements of the Earth's radiation budget and especially a value of the solar constant to $\pm$ 0 1% (as opposed to $\pm$ 1.5% at present) was widely welcomed as was a more unusual Dumb-bell Mission Here two satellites launched into a near polar Earth orbit are deployed so that they are 10 to 20 km apart but tethered together by a long wire Measurement of the tension variations in the tether gives the gravity field anomalies in the Earth's upper crust. The tether would also be used to measure induced electric fields and the two satellites would be used for active and passive magnetospheric experiments Finally, an ultraviolet and X-ray satellite (10–1000 Å) with two Baez telescopes and a spectrograph on board was considered. A year's observation with this satellite would provide a 5 arc min resolution map of the whole sky plus detailed spectra of new sources.

Although one could not help getting the feeling that Britain was a small fish in the ESA pool (which is itself small in comparison to NASA and the USSR's Space Agency) whenever brains combine, new ideas are forthcoming and Britain and Europe can still provide ideas even if they cannot compete in finance and firepower.

Phase changes at 650 km

from Peter J. Smith

It has often been assumed that the Earth's 650-km seismic discontinuity, which involves a large increase in bulk modulus as well as seismic velocity, is largely the result of a phase change in the olivine component of the mantle. Anderson (*Science,* **157,** 1165; 1967), for example, attributed this discontinuity to the disproportionation of spinel to a structure with the properties of mixed oxides—a phase involving the simple oxides, a Sr_2PbO_4 structure or perovskite plus periclase, all of which have similar densities. But as Anderson himself now admits (*Geophys. Res. Lett.,* **3,** 347; 1976), there are problems with this interpretation which suggest that the discontinuity in question may have little to do with transformations in olivine after all.

For example, although the disproportionation of spinel to oxides involves a large increase in density, it also involves an increase in coordination, increasing the average silicon-oxygen separation and reducing the repulsive forces between ions. The increase in bulk modulus is therefore much reduced (and may even be converted into a decrease) compared with that expected from a transformation with no associated change in coordination—a point previously made by Liebermann and Ringwood (*J. geophys Res.,* **78,** 6926; 1973) In fact, the elastic moduli of spinels and mixed oxides are similar. On this basis, disproportionation as envisaged would be expected to produce a decrease, rather than an increase, in seismic velocity.

Because this is clearly unsatisfactory, Anderson now suggests that the 650-km discontinuity is primarily the result of phase changes in the pyroxene and garnet components of the mantle rather than in the olivine. The basic premise upon which this proposition rests (and detailed evidence for which is promised in a later report) is that the bulk moduli of silicate and oxide solid solutions are almost independent of iron content. In particular, as Mg^{2+} is replaced by Fe^{2+} in systems such as pyroxenes, olivines and garnets, the density increases in accordance with the Birch formula but the bulk modulus increases or decreases only slightly. The bulk modulus cannot therefore be used to make deductions about the composition of the mantle It is, on the other hand, a good indicator of crystal structure, its magnitude's increasing from pyroxene to α-olivine to β-spinel to garnet to γ-spinel to oxides in pyroxene proportions to perovskite.

With this in mind, Anderson has attempted to extrapolate the bulk moduli (K) and densities (ρ) of the various regions of the mantle to a pressure of 1 bar and a temperature of 20 °C and has compared the resulting K-ρ points with the K-ρ curves for the appropriate crystal structures. He thus deduces that between depths of 200 and 400 km (Region I) the mantle is predominantly olivine and pyroxene with subordinate garnet, the pyroxene to garnet ratio being 7 · 2 to satisfy the bulk modulus. Region II, between 400 and 500 km, is close to β-spinel and is consistent with olivine-pyroxene-garnet with a higher proportion of garnet than Region I. Anderson concludes that Region II comprises olivine in the β phase, pyroxene and pyroxene–garnet solid solution with garnet structure.

By contrast, Region III, which lies between 500 and 650 km, is closer to garnet. Its most likely composition is $(\beta+\gamma)$-olivine and pyroxene–garnet solid solution, all the pyroxene now having entered the garnet structure. However, because of uncertainties in the data upon which the K-ρ curves are based, Region III could be entirely β-spinel and garnet. The properties of Region IV (650–800 km) are consistent with this layer's being either mixed oxides or γ-spinel plus stishovite (SiO_2). And finally, Region V, below 800 km, could be either mixed oxides with more stishovite than Region IV or perovskite plus MgO.

In the light of these phase changes Anderson thus proposes that it is the pyroxene–garnet component, transforming from the garnet structure to the mixed oxides or perovskite structure, which is chiefly responsible for the 650-km discontinuity. Unfortunately the thermodynamic data currently available are insuficient to enable the reaction boundary between the mantle pyroxene-garnet solid solution and mixed oxides to be calculated However, calculations made assuming this complex garnet to behave as almandine–pyrope garnet imply that the transition is sharp (perhaps less than 12 km thick on the basis of admittedly inadequate data and questionable assumptions), a property required by some of the seismic data ●

This article describes an alternative approach to small-angle scattering experiments on biological specimens. The method makes use of the unique properties of synchrotron radiation and provides very fast data acquisition with good resolution. Preliminary experiments on rat-tail tendon are described.

UNDERSTANDING the mechanism by which a biological sample responds to a perturbation is a subject of continuing interest and an obvious way of dealing with the problem is to study structural changes by X-ray diffraction. The lattice periodicity in biological specimens is usually larger than that commonly encountered in non-biological crystals and may be as great as 1,000 Å or more. A conventional X-ray tube is normally used to produce characteristic X-ray lines with wavelengths between 0.6 Å and 2.0 Å, and so the first-order diffraction peak will be produced at a small angle to the direction of the incident X-ray beam. As a consequence, the experimenter uses a long camera to achieve reasonable separation of the diffraction pattern from the main beam. Because of the rapid fall-off in intensity with distance from the source, photographic recording of the intensities requires long exposure times, but, in practice, a compromise between spatial resolution and exposure time has to be made. If focusing techniques are used, the exposure times can be shortened but at the expense of complexity in instrument design. Even so, the intensities are still recorded over a long interval.

If one could achieve more rapid data acquisition, then it would be possible to carry out low-angle X-ray diffraction studies of biological material during some temporal process, for instance, muscle contraction. With the technique described here it is possible to record the pattern rapidly and with high resolution using simple apparatus, thus making a dynamic experiment of this type feasible. To do this, we make use of the unusual properties of synchrotron radiation.

Synchrotron radiation has four important characteristics: high intensity, low beam divergence, a high degree of linear polarisation and, probably most important, a smoothly varying white radiation profile[1].

At present, work is in progress to study the applications of this rather special radiation to X-ray diffraction problems. Preliminary work has already been carried out in the field of X-ray topography[2–4] and in powder diffraction (J. B. and A. M. G., unpublished).

Synchrotron radiation

In the synchrotron NINA, at the Science Research Council's Daresbury Laboratory, electrons are accelerated up to 5 GeV and emit electromagnetic radiation which extends as a continuum from the infrared to the hard X-ray region (about 0.1 Å). The radiation is 100% linearly polarised in the electron orbital plane. The emitted X-ray beam is well collimated, with the photons confined to a cone of half angle between 10^{-3} and 10^{-4} rad. When NINA is operating at 5 GeV with a circulating current of 20 mA, approximately 10^9 photons s^{-1} are predicted at 1 Å within a band width of 0.1% for the apertures used in the experiment (J. H. Poole, private communication). This high flux is particularly valuable for small-angle scattering experiments. Focusing X-ray diffraction cameras have already been constructed and used with synchrotron radiation at DESY (Hamburg), NINA (Daresbury) and SPEAR (Stanford). These cameras use vertically focusing mirrors and curved monochromatising crystals to collect as many photons as possible and, at the same time, to provide small, high contrast diffraction spots on a position-sensitive detector or on a photographic plate.

Here we present an alternative approach to the measurement of X-ray diffraction patterns, which we believe makes good use of the unique characteristics of synchrotron radiation and which does not require any optical components. Furthermore, it allows the very fast collection of data already mentioned. To illustrate the method we have used rat-tail collagen because it combines a large fundamental lattice spacing (670 Å) with well defined, sharp reflections.

Extending energy—dispersive techniques

Our approach to the measurement of X-ray scattering at small angles is conceptually very simple and is an extension of the recent use of energy-dispersive techniques with white radiation from conventional X-ray sources[5–8].

The Bragg equation for X-ray diffraction is usually expressed by

$$2d\sin\theta = n\lambda \qquad (1)$$

From this it is clear that for a particular spacing, d, and a single X-ray wavelength, λ, the orders $n = 1, 2 \ldots$, will appear at the angles 2θ which fulfil equation (1).

If, however, a parallel beam of white (polychromatic) radiation falls on an oriented sample, then for a particular spacing and for a selected scattering angle there will be a number of discrete wavelengths, λ/n, which will satisfy equation (1).

In other words, in place of a conventional X-ray scattering experiment in which the sample is illuminated with monochromatic radiation and the spatial distribution of the scattered radiation is measured, one measures a photon energy spectrum giving all the wavelengths diffracted at a preselected angle.

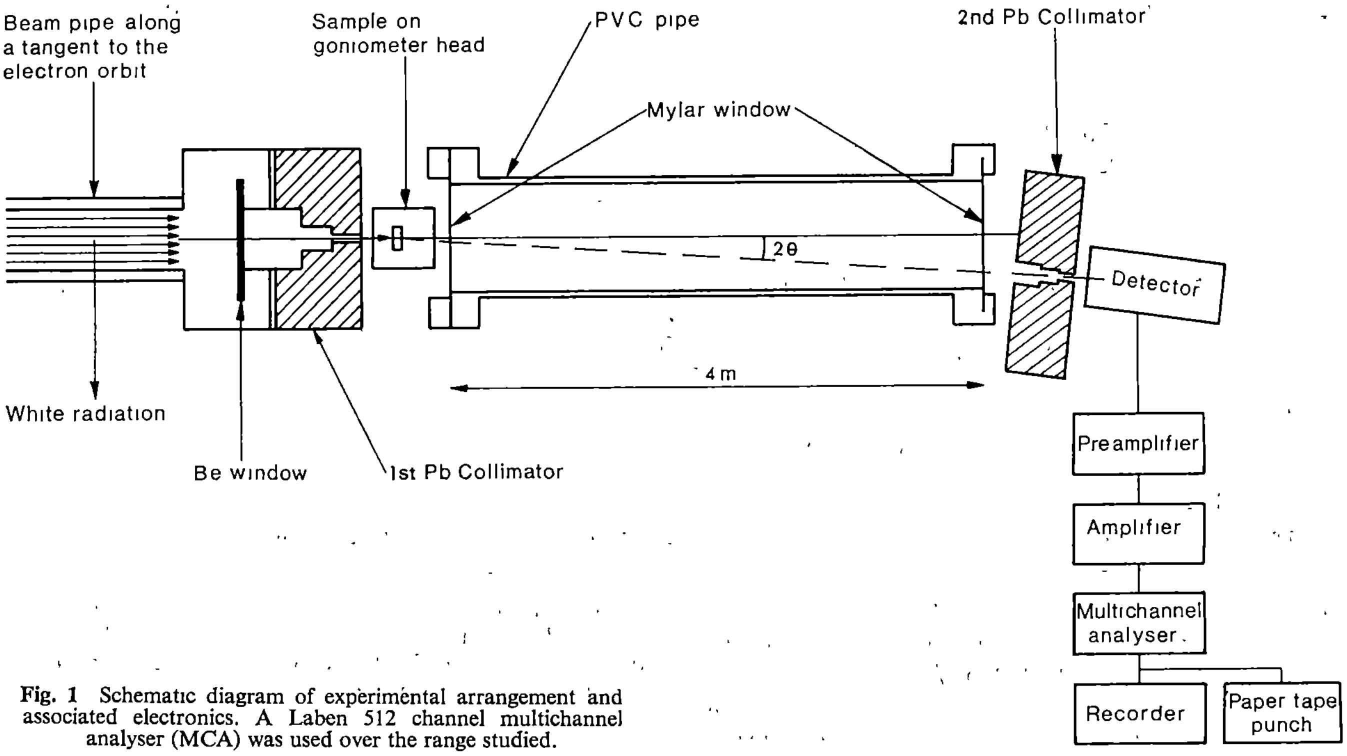

Fig. 1 Schematic diagram of experimental arrangement and associated electronics. A Laben 512 channel multichannel analyser (MCA) was used over the range studied.

We can write the energy, E, in the form

$$E\,(\text{keV}) = \frac{12.4}{\lambda\,(\text{Å})} = \frac{12.4n}{2d\sin\theta} \qquad (2)$$

Thus, taking θ to be constant we have a strict proportionality between E and n/d. In the normal diffraction experiment, λ is held constant and then sinθ is proportional to n/d. Thus, a plot of intensity against energy is similar, qualitatively at least, to the conventional plot against θ. There is a 1:1 spatial correspondence between peaks observed in the two plots for small θ.

The precision of this method relies on the performance of an energy-resolving solid state detector which is commercially available with an energy resolution at best of about 150 eV at 12 keV (information supplied by AERE Harwell and Ortec Ltd). With conventional X-ray sources this technique is handicapped by the complicated X-ray profile comprising white and characteristic wavelengths, as well as the inherent lack of collimation. This means that the measurement of intensities is difficult and, furthermore, in a small-angle scattering experiment high collimation is vital. Most of the uses of energy-dispersive techniques so far have been of a relatively qualitative nature and confined to large scattering angles. In our experiments, a lithium-drifted silicon solid state detector (supplied by AERE Harwell) was used to give a combined resolution for the detector and amplifier system of about 230 eV FWHM, at 12 keV. The time constant of the overall system (25 μs) could be reduced at the cost of decreasing the energy resolution. The experiments were run at maximum count rates of 1.6×10^4 c.p.s. with a collection efficiency of better than 95%.

Experimental arrangement

A schematic drawing of the apparatus is shown in Fig. 1. White X radiation from circulating electrons in NINA passed down an evacuated pipe, 47 m long, before traversing a 0.016-inch (0.041-cm) beryllium window into air at the end of the pipe. A lead X-ray collimator shaped to minimise any scattered radiation at the detector (mainly from fluorescence of the collimators) was placed in air immediately after the beryllium window. The sample was supported on a goniometer head and could be rotated within the beam to provide equatorial and meridional reflections at the detector. The collimator aperture was adjusted to suit the size of the specimens and was of diameter 1.0 mm or 0.5 mm. The specimens used were less than 0.25 mm in diameter and 1 mm long.

Immediately behind the sample, a 4-m-long evacuated plastic tube with Mylar end windows was used to eliminate any effects of air scatter or of absorption between the sample and the detector. The angular acceptance of the detector was accurately defined by a second lead collimator placed directly in front of the solid state detector. The main, undiffracted beam was absorbed in a lead beam stop. The scattering angle (2θ) was defined by measuring the distance between the main beam and the detector collimator aperture using X-ray sensitive paper to locate the undiffracted radiation. The entire apparatus was aligned simply and rapidly using a small, portable He/Ne laser. The beryllium windows on the beam pipe and detector restricted the lowest energies available to less than about 3 keV (~ 4 Å). Because of the relatively low counting efficiency of the detector and the source cutoff at high energies, the highest energies accessible were about 40 keV (~ 0.3 Å). The synchrotron was running at 4.6 GeV and approximately 10 mA.

The samples of rat-tail tendon were kept wet during the experiment and were usually stretched, although they were not kept under tension. Orientation of the samples to yield equatorial and meridional reflections was defined by reference to the line joining the centre of the detector collimator aperture to the centre point of the undiffracted beam.

From equation (1)

$$\Delta\theta = \tan\theta(\Delta\lambda/\lambda) = -\tan\theta\frac{\Delta E}{E} \qquad (3)$$

and therefore for the particular resolution $\Delta E/E$ of the solid state detector used, the correct angular acceptance Δθ (that is, the appropriate diameter for both collimators) for a particular angle θ was easily calculated. A typical detector collimator would be ~ 0.5 mm in diameter with a separation of aperture from the main beam of from 10 to 50 mm. To calibrate the energy at a particular channel of the multi-channel analyser we used calibrated X-ray fluorescence lines obtained from commercially available sources. The calibration energies (wavelengths) were those of Cu, Mo, Ag, Rb, Ba and Tb.

Handling the data

In Fig. 2. we plot the raw data from the multi-channel analyser (MCA) display obtained from the meridional diffraction of wet rat-tail tendon. The detector collimator angle (2θ) was set at 3.14 mrad in order to ensure that the first-order diffraction peak fell within the range transmitted by the beryllium window. In the example shown, the prominent first-order peak was already well resolved after only 1 s of data accumulation. A qualitative view of the full spectrum could be obtained within a few seconds but to obtain good statistics data were collected for 200 s. In this experiment, the collimator apertures at the detector and at the sample were chosen to be 1.0 mm and 0.5 mm, respectively. This, combined with the sample size, gave a geometrical resolution comparable with that of the detector. The observed peak widths were twice that expected for the detector resolution and are almost certainly due to the finite size of the aperture collimators. Although the rate of data accumulation could be significantly increased by enlarging the collimator apertures (for a large sample), these experiments are normally limited by count-rate saturation at the detector output.

To make quantitative estimates of the structure factor for each reflection, it is necessary to correct the data in Fig. 2 for the NINA intensity profile, the efficiency of the detector and any other instrumental factors. The first two quantities are, in principle, calculable, but the uncertainty in the remaining correction factors makes it essential to calculate the effect of all of the factors taken together (the total instrument function). Normally, this would be done by using the detector to measure the intensity spectrum of the main beam; but, unfortunately, the detector saturates at a count rate of 10^4 photons s^{-1}, much less than that of a synchrotron source.

There is, however, a neater and simpler method which can be used. The intensity of the background in Fig. 2 arises from incoherent scattering by random atoms, mainly in the air traversed by the X-ray beam, and is given by

$$I = \text{constant} \times (\sum_j f_j)^2 \tag{4}$$

where f_j is the scattering factor for the jth atom. Although it is possible to eliminate this background scatter almost completely, it is better to allow some of this scatter to occur, because it can be used to normalise the diffraction peak intensities. To do this, we note that the value of $\sin\theta/\lambda$ used is extremely small ($\lesssim 7.5\times10^{-3}$ Å^{-1}) and corresponds to the flat part of the atomic scattering factor curve (flat to within 1–2% over the range of $\sin\theta/\lambda$ used). Thus, the background intensity, which is a measure of

$$(\sum_j f_j)^2$$

is also a direct representation of the total instrument function. It is then simple to correct for this function by dividing each data point by the background, taking care to extrapolate the background under the diffraction peaks, and then subtracting the number 1.

In Fig. 3 we show the background (total instrument function) on an enlarged scale It is clear that it rises to a maximum near 7 keV. The resulting normalised intensities of the first- to fifth-order peaks of our sample of rat-tail collagen are shown in Fig. 4. To extend the measurements to higher order peaks, the detector collimator angle (2θ) can be reset to a different angle five times larger than before. This has the effect of shifting fifth-order to the same energy at which first-order diffraction appeared previously. Therefore, if identical synchrotron running conditions are maintained, an angular increase (in 2θ) of five times yields the fifth- to the twenty-fifth-order diffraction peaks in place of first- to fifth-order peaks.

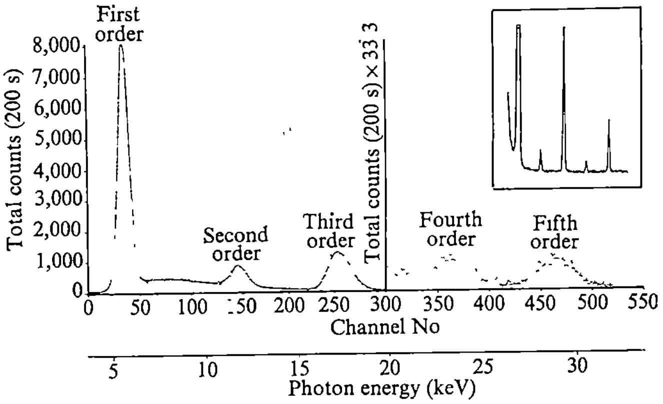

Fig. 2 Raw intensity data from the meridional plane of a wet and stretched rat-tail tendon. Total measuring time, 200 s. Note the low noise level and clean separation of diffracted peaks. Inset, meridional profile obtained with a conventional rotating-anode generator and focusing camera with intensities collected on a photographic film and subsequently densitometered (J C. Haselgrove, private communication). The sample was approximately 6×0.5×0.5 mm, camera length 0.65 m, generator at 40 kV, and 60-mA Cu target. Exposure time 30 min.

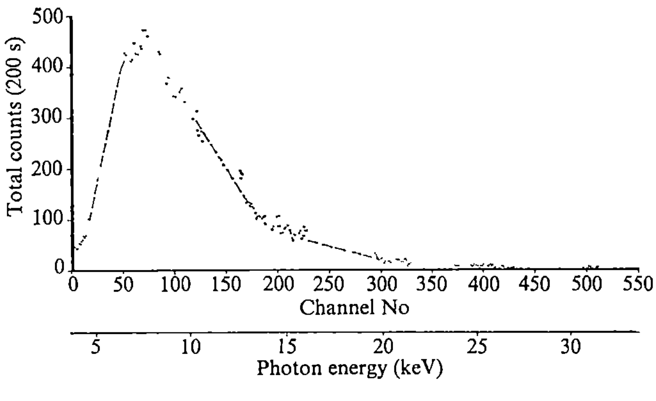
The relative intensities of the diffracted peaks given in Fig. 3 agree qualitatively with existing published results[9] for wet rat-tail tendon.

An example of a profile taken with a conventional rotating-anode X-ray source and a focusing camera is shown in the inset in Fig. 2 and is typical of what can be obtained with conventional sources (J. C. Haselgrove, private communication). The two measured profiles are closely similar: the important difference is in the exposure times and sample size used. The exposure time of the focusing method could be shortened but at a cost of resolution. We note also that in the energy-dispersive experiment all lines are very cleanly resolved with negligible noise. Moreover, the conventional experiment often requires sample preparation involving the mounting and alignment of many collagen strands to achieve sufficiently high intensities. This difficulty is not encountered in our experiment.

Table 1 shows the integrated intensities after the above corrections have been applied. Before we can compare these results with published values, however, it is necessary to take into account the special nature of the energy-dispersive technique. It can be shown[10] that with a white radiation source the integrated diffracted intensity, measured by an energy dispersive system, is a function of λ^2. Moreover, for small absorption, it depends inversely on the absorption coefficient μ.

Fig. 3 Background intensity profile (total instrument function). ———, Interpolations under diffraction peaks.



Since to a first approximation $\mu \simeq \lambda^3$, the scattered intensity is given by

$$I = \text{constant} \times \frac{|F|^2}{2\lambda \sin^2\theta} \sim \frac{E|F|^2}{2 \sin^2\theta} \qquad (5)$$

where E is the energy of the diffracted beam and F is the structure factor. The second column in Table 1 lists the intensities after correcting for this variation. The next two columns list published results[9] for wet and dry samples and the final column gives our results scaled to the third-order intensity of wet rat-tail collagen.

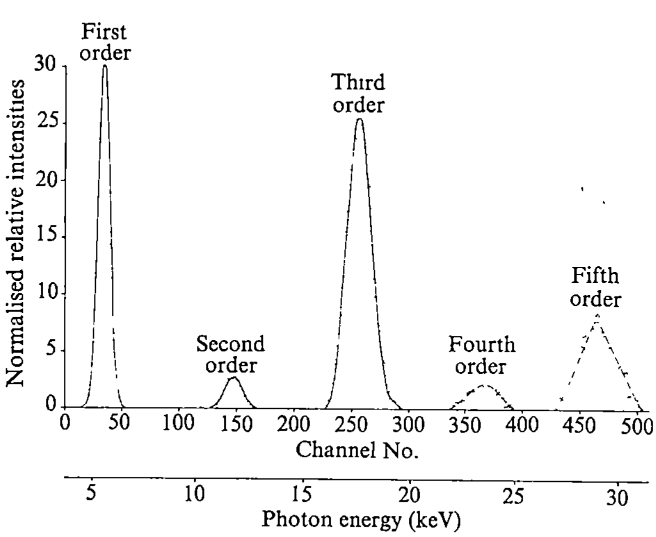
We find that the intensity of the first-order peak lies well below that measured by Tomlin and Worthington[9]. This probably arises from a combination of effects. In particular, the position of this peak is directly over that region of the background which is changing fastest (Fig. 3), and therefore in dividing by the small background values the resulting estimate of the integrated intensity is subject to a large uncertainty. In addition, this reflection corresponds to a longer X-ray wavelength (2.11 Å) than the other peaks, and, because the scattering efficiency depends on λ^2, it can be severely affected by extinction. Moreover, the higher absorption at this wavelength will mean that the inverse relationship between I and μ is no longer sufficiently good. One way of getting round these difficulties would be to remeasure the intensity of this peak accurately at a smaller angle. The two measurements thus obtained would allow the absorption effects to be precisely determined. Moreover, if the second angle is chosen to be a third of the present angle, the first-order peak will appear at three times the present energy where absorption becomes less serious.

The intensities of the remaining peaks agree very closely with those measured by Tomlin and Worthington for wet rat-tail collagen. The slightly high value for the second peak may be due to drying of the specimen. In fact, it was observed that the relative intensities of the diffraction peaks changed considerably as a result of drying out of the specimen in agreement with the results of Tomlin and Worthington. Also, in at least one of the muscle samples used, severe radiation damage (a brown spot on the sample) was observed after irradiation for about 20 min. The rapid rate of collection of data means, however, that radiation damage is minimised. The reasonably good agreement between our results for rat-tail collagen and the published intensities suggests that radiation damage is not serious with a collagen sample for the exposure times used. Experiments with muscle showed that exposures of up to 120 s were feasible with NINA at 5 GeV, 10 mA before any change in the pattern was observed.

Table 1 Integrated intensities after application of corrections

n	Integrated intensity (I)	I/E	Tomlin and Worthington Wet	Tomlin and Worthington Dry	Scaled I/E
1	396.1	67.36	1,000	1,000	190
2	52.6	4.47	8	188	13
3	695.9	39.45	111	132	111
4	71.4	3.04	8	49	9
5	307.9	10.47	33	43	30

Fig. 4 Normalised energy-dispersive pattern from Fig. 2. The basic periodicity is 670 Å.



Outlook

We have shown that with relatively simple equipment at a synchrotron, it is possible to obtain small-angle scattering patterns from biological specimens which are of extremely high quality and almost noise free. The technique has many advantages over other methods, namely, the high speed of data acquisition, the potential precision of relative intensity measurements, the low level of background radiation and high resolution for material with large spacings.

Data can be collected at very high rates using the collimated white radiation from a synchrotron source, and the data acquisition rate is restricted solely by the relatively slow response time of the solid state detector and its associated amplifier. When this limitation is overcome, there could be a further increase in data acquisition rates by several orders of magnitude. Even with presently available electronics we have been able to achieve a four- or fivefold increase in the speed of data collection, simply by using appropriate balanced filters to select a small range of X-ray energies, so that the counter is not saturated by unwanted photons. This allows a larger sample with a larger area of irradiation, and thus more diffracted photons within the energy range selected. Although only one or two reflections can be examined at a time, the advantages of the high speed of collection may compensate for this When the dedicated storage-ring facility becomes available at the Daresbury Laboratory the X-ray intensities produced will be about 100 times greater than from the existing synchrotron. The storage ring will provide a considerably more stable intensity source, but if full use is to be made of its high intensity output faster energy-dispersive counting devices are needed.

Lattice periodicities of from a few tens of Å to around 1,000 Å can be investigated simply by reducing the detector viewing angle from 10^{-2} rad to a few mrad A new experimental arrangement under construction at Daresbury will permit the detector to scan through an angular range of 1 to 20 mrad. This could, in principle, permit the observation of up to the 80th order ($\sim$ 8 Å) in materials such as rat-tail tendon. Peak-stripping computational techniques together with a high resolution detector should permit peak energy positions to be determined to an accuracy of at least 0.1%. This will offer valuable and complete structure determinations when combined with a two-axis rotation of the sample in the incident beam. Dynamic X-ray diffraction studies should now become feasible if the sample is perturbed periodically and the experiment carried out in the same way as in modulation spectroscopy. For example, an electrical stimulus applied to the sample periodically, with measurements made in and out of phase, would enable a derivative signal to be built up yielding important and new time-dependent structural information on biological specimens.

We thank Professor Zvi Kalman for drawing our attention to energy-dispersive methods and to Drs A. R. Faruqui and D. Hukins for samples and discussions. We are particularly grateful to Dr J. C. Haselgrove for advice and permission to publish measurements made with a conventional source.

We wish, also, to thank the Science Research Council and the staff of the Daresbury Laboratory for their cooperation.

Model for action of local anaesthetics

A. G. Lee

Department of Physiology and Biochemistry, University of Southampton, Southampton SO9 3TU, UK

Sodium channels in nerve membranes are postulated to be surrounded by lipid molecules in the gel (or crystalline) phase. Addition of local anaesthetics triggers a change in the surrounding lipids to the fluid, liquid crystalline phase, allowing the sodium channel to close with resulting local anaesthesia. The experimental evidence for this model is discussed.

DIRECT study of sodium channels in nerve membranes is made exceedingly difficult by their sparsity: it has been estimated that in $1\ \mu m^2$ of nerve membrane there are between 2 and 500 sodium channels, depending on the animal[1], compared with about 3×10^6 lipid molecules. Information about the molecular nature of the sodium channel has therefore had to be inferred indirectly, largely from electrophysiological studies. In particular, it has been postulated that the sodium channel contains a narrow slit 3×5Å surrounded by a ring of oxygen atoms, the slit being both the pathway for ion flow and the selectivity filter which determines which ions can flow[2,3]. I suggest here that the effects of local anaesthetics can be used to probe the lipid environment of the sodium channel.

The block of nervous conduction by local anaesthetics follows largely from a reduction in the sodium conductance[4], although there are also changes in the time course of the channel gating[5]. The mechanism of this block of sodium conductance has not yet been explained satisfactorily. Since a wide variety of different compounds can act as local anaesthetics, including neutral and both negatively and positively charged molecules, it is not clear whether there is a single mechanism for local anaesthesia, or whether each class of anaesthetic acts in a different way Staiman and Seeman[6], however, have shown that effects of anaesthetic mixtures are close to being additive, suggesting a single mode of action.

There are several theories for the action of local anaesthetics. One suggests specific receptors for local anaesthetics in the nerve membrane, and was proposed largely to explain the action of tertiary amine anaesthetics such as procaine, which are most potent in the charged, protonated form and which act only on the inside surface of the nerve membrane[4] But the receptor (probably the sodium channel itself) would have to be surprisingly unselective, since a very wide range of amines act as anaesthetics, their only obvious similarity being both a lipophilic region and a hydrophilic region[7]. In contrast, very minor changes in the structure of tetrodotoxin, which is known specifically to bind to the outside surface of the sodium channel, cause complete loss of activity[8]. Further, different sites of action would have to be postulated for the action of neutral and negatively charged anaesthetics. A second proposal is that effects of local anaesthetics on the membrane surface charge are important[4], and although this could account for the action of the positively charged amines, it fails to account for the action of neutral or negatively charged molecules.

The third, and perhaps most popular theory, is the membrane expansion theory. This proposes that anaesthetics increase the fluidity of membrane lipids and expand the membrane[9]. Although anaesthetics have indeed been shown to cause an expansion of erythrocyte membranes[10], it is not clear how an expansion of the nerve membrane would lead to a block of sodium conductance. Further, the theory would predict that an increase in pressure would reverse local anaesthesia, and whereas this is observed for ethanol[11], for some other anaesthetics, increasing pressure enhances nerve block[12]. Also, local anaesthetics at nerve blocking concentrations would be expected to have little effect on the fluidity of the bulk of the membrane lipids. Thus it has been estimated that the "microviscosity" at the centre of a bilayer of dimyristoyl phosphatidylcholine in the liquid–crystalline state is about equal to that in *n*-decane, and that the viscosity near the glycerol head group of the lipid is only approximately 15 times greater[13,14] Since rates of rotation about C–C bonds in short-chain alkanes and alcohols[15] are similar to those at the centre of the bilayer, addition of these alkanes and alcohols would be expected to have only relatively slight effects on membrane viscosity, and yet they are local anaesthetics[9]. Indeed, using a spin-label method, Boggs *et al.* have shown that anaesthetics do not affect order parameters in bilayers of egg lecithin at anaesthetic concentration[16].

The last model for local anaesthetic action is the protein perturbation model, in which interaction between anaesthetics and the sodium channel causes conformational changes resulting in a block of conductance[12] On such a model it is again surprising that neutral and both positively and negatively charged molecules should act as anaesthetics, especially since the tertiary amines can act in the neutral form, although being more effective when positively charged The observed competition between Ca^{2+} and the amine anaesthetics is also hard to account for[17], as is the "cutoff" effect (in a homologous series of compounds, anaesthetic potency increases with increasing chain length up to a particular compound, beyond which they cease to be anaesthetics[9]) binding of long chain alcohols to bovine serum albumin simply increases with increasing chain length[18].

A new hypothesis is now presented for the action of local anaesthetics, based on a particular model for the sodium channel.

Annular transition model

The basic postulate of the new model is that the sodium channel is surrounded by an annulus of lipid, which is in the crystalline, or gel, state. If the sodium channel has the

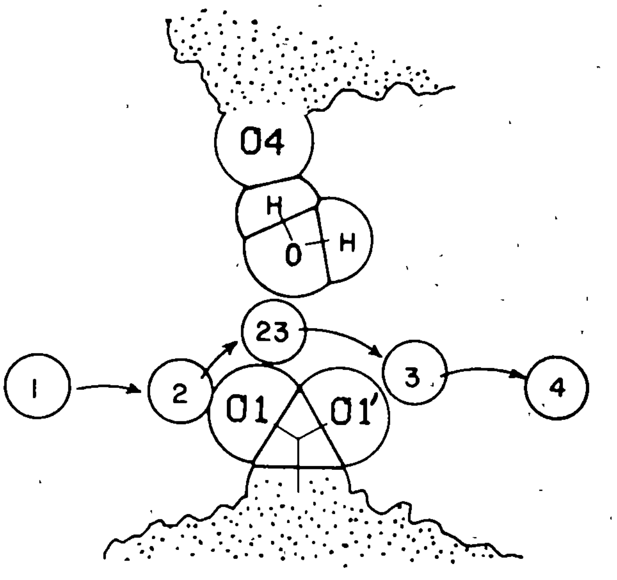

Fig. 1 Model for the sodium channel, with a sodium ion moving through the slit from position 1 to 4 (from Hille, ref. 3).

structure suggested by Hille[3], then it is the rigidity of the surrounding lipid microenvironment that keeps the sodium channel open. Addition of anaesthetics triggers a change in the surrounding lipid from the crystalline, gel state to a fluid, liquid-crystalline state. When the surrounding lipid is in a fluid state, the sodium channel is free to relax into its most stable state, with a consequent closing of the oxygen-lined slit which provides the ion channel through the membrane. Figure 1 shows the picture of the sodium channel presented by Hille[3], and it can be seen that relaxation of the protein would decrease the distance between the oxygens lining the slit, perhaps allowing hydrogen bonding between the water molecule postulated to be bound in the slit and one of the oxygens O_1 or O_1^1 of the carboxyl group.

Although the bulk lipids of the biological membrane seem to be free to diffuse within the plane of the membrane[13], there is strong evidence for relatively long-lived interactions between lipids and at least some membrane proteins. Persistent lipid–protein interactions giving rise to a lipid annulus have been proposed for cytochrome oxidase[19], rhodopsin[20] and the calcium transport protein[21,22]. The model for the sodium channel is, however, unusual in requiring the surrounding lipid to be in the gel phase to allow for activity. For the calcium pump, for example, it has been shown that the enzyme is only active when the surrounding lipid is in the fluid, liquid-crystalline state[23]. This presumably arises because in the energy-requiring pumping process, conformational changes occur which are inhibited by rigid, gel phase lipid In contrast to these relatively slow pumping processes[13], the rate of passage of Na$^+$ ions through the open sodium channel is so fast that any change in conformation during ion passage seems unlikely[24]. Two other membrane proteins have been established to operate within a rigid lipid matrix, bacteriorhodopsin in the purple membrane of *Halobacterium halobium*[25] and the microsomal cytochrome P-450 (ref. 26).

Experimental evidence

The fact that anaesthetics do trigger a change in state for lipids from a gel to a liquid-crystalline state has been established in several recent papers. Alcohols up to *n*-octanol have been shown to lower the phase transition temperatures of phosphatidylcholines and phosphatidylethanolamines[27,28]. The effects are linear with respect to concentration, and the concentrations required to produce a 5 °C drop in transition temperature are comparable with those required to block nervous conduction[9]. More interestingly, however, it has been found that whereas *n*-decanol lowers the phase transition temperature of dipalmitoyl-phosphatidylcholine (42 °C in the absence of alcohol), it raises that of dimyristoyl-phosphatidylcholine (24 °C in the absence of alcohol). Dodecanol raises the phase transition temperatures of both dimyristoyl- and dipalmitoyl-phosphatidylcholines[28]. This then is sufficient to explain the "cutoff" effect observed with the alcohols. *n*-nonanol is a local anaesthetic[9], and it has been reported that dodecanol is less effective than undecanol in suppression of swimming in tadpoles and that tridecanol has no effect[29]. Similarly, it has been found that the *n*-alkanes up to *n*-octane are anaesthetics, whereas decane is not.

The anaesthetic amines such as procaine and dibucaine also lower the phase transition temperatures of phosphatidylcholines and phosphatidylethanolamines[30,31]. Now, however, effects are nonlinear with respect to concentration, because of the buildup of charge on the liposomes caused by the binding of the positively charged anaesthetics. This can be overcome by the introduction of negatively charged lipid, which considerably increases the effect of the anaesthetic. When the added negatively charged compound is myristic acid, the effect of the negative charges is masked completely by addition of about 0.5 mM Ca^{2+} or Mg^{2+} (ref. 31). When the negative charge is due to phosphatidylserine, however, there is a differential effect between Ca^{2+} and Mg^{2+}: the effect of the negative charge is removed by about 0.6 mM Ca^{2+} or about 5 mM Mg^{2+} (ref 30). Differences between the effects of Ca^{2+} and Mg^{2+} on aqueous dispersions of phosphatidylserine have also been found in other studies. Thus the increase in temperature of the phase transition caused by addition of 0.5 mM Ca^{2+} is equal to that caused by 5 mM Mg^{2+}, and whereas Ca^{2+} causes a segregation of phosphatidylserine in mixed bilayers of phosphatidylserine and phosphatidylcholine, Mg^{2+} does not[32,33]. Furthermore, Hille *et al.* found that Mg^{2+} applied to the outside surface of myelinated nerve fibres had less effect than Ca^{2+} on the voltage dependence of peak sodium permeability, consistent with a weaker binding[34]. These observations are important because they provide, at least in part, a possible explanation for the fact that the amine anaesthetics are most active when applied to the inside surface of the nerve[4]. Negatively charged lipid has been postulated to be close to the sodium channel in nerve, with the highest concentration on the outside surface. But the Ca^{2+} and Mg^{2+} concentrations of the external medium are about 2 mM and 10 mM, respectively, whereas the Ca^{2+} concentration inside the nerve has been estimated to be micromolar or less[35] and the Mg^{2+} concentration is about 3 mM (ref. 36). Thus positively charged anaesthetics will partition most strongly into the inner membrane close to the negatively charged lipid Similar effects apply to the interactions of chlorpromazine and propranolol (my unpublished observations)

Barbiturates also lower the phase transition temperatures of phosphatidylcholines and phosphatidylethanolamines[31]. Because of the buildup of negative charge, they are most effective in the uncharged form at lower *p*Hs. It has been found that barbiturates are more effective local anaesthetics at low *p*H, and anaesthetic concentrations are comparable with those required to produce significant changes in lipid phase transition temperature[31,37]. There seems to be no significant interaction with the negatively charged dipalmitoyl-phosphatidylserine[31]. Connor *et al.*[38] have reported that anaesthetic steroids such as alphaxalone also lower lipid phase transition temperatures.

There are several other experimentally testable consequences of the model First, if anaesthesia results as a consequence of a lipid transition from the gel to the liquid-crystalline state, then a decrease in temperature should restore the lipid to the gel state and consequently reverse

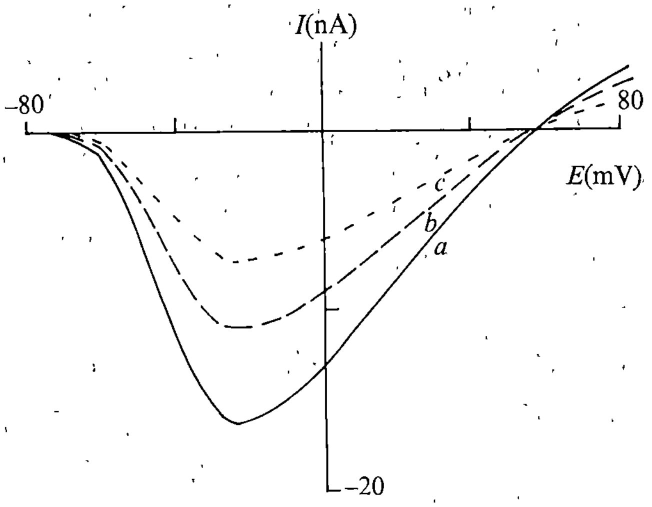

Fig. 2 Peak current (I)–voltage (E) relations as a function of the height of the selectivity barrier. Internal Na^+, 11.2 mM; external Na^+, 116 mM; T, 5 °C; curve a, barrier height G23 = 5 kcalorie mol^{-1}; curve b, G23 = 5.26 kcalorie mol^{-1}; curve c, G23 = 5.53 kcalorie mol^{-1}.

anaesthesia. Only one experiment of this kind seems to have been reported· Spyropoulos did indeed find that the anaesthetic effect of ethanol on squid axon at 22 °C was reversed completely by lowering the temperature to 4 °C (ref. 11) (in the absence of a lipid phase transition, the partition coefficient for small hydrophobic molecules between lipid and aqueous phases changes only slightly in this temperature range[39]). A second consequence is that the sodium conductance of nerve should be little affected by a decrease in temperature from the acclimatisation temperature of the animal (until a temperature is reached at which the gating mechanisms are affected), whereas an increase in temperature should lead to loss of conductance. Unfortunately, the appropriate experiments do not seem to have been performed. Moore[40], however, has observed that the sodium conductance of squid axon is a linear function of temperature within the range 5–25 °C with a temperature coefficient only slightly higher than that for electrolyte conductance in water: this contrasts with the very sharp drop in the activity of membrane-bound proteins such as the Na^+-K^+-ATPase with decreasing temperature. Interpretation of the effects of temperature on nervous conduction are likely to be complex, because of changes in rate constants and conductances for both the sodium and the potassium channels. Nevertheless, with frog nerve the spike amplitude increases slightly on cooling from 25 °C to 8 °C, even though spin-label studies have shown a considerable decrease in fluidity for the bulk lipids within the same temperature range[41,42]. In contrast, increasing temperature produces a reversible conduction block, the temperature of block depending on the animal[43,44]. Thus the available evidence certainly does not contradict the hypothesis of a rigid microenvironment for the sodium channel. Even if more detailed data were available on the effects of temperature on sodium conductance, their interpretation would likely be difficult because of the hysteresis effects expected in such a system. In fact Inoue *et al* [45] have found marked hysteresis in the effects of temperature on the membrane potential of squid axon internally perfused with NaF and bathed in $\mathrm{CaCl_2}$ and NaCl.

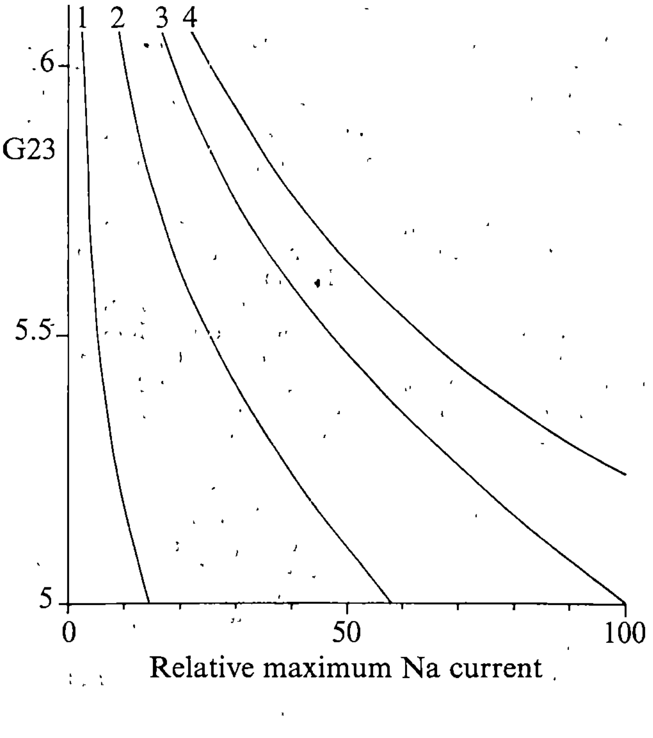
Increased pressure is predicted to have two distinct, and contradictory, effects. First, it has been found that increased pressure increases the temperature of a lipid phase transition, simply because a lipid in the liquid-crystalline state occupies a larger volume than one in the gel state[46]. Initially, therefore, an increase in pressure would be expected to inhibit the effect of an anaesthetic. Once the anaesthetic has caused the lipid to transform from the incompressible gel state to the compressible liquid-crystalline state, however, an increase in pressure would be expected to increase the relaxation of the protein (since a relaxed protein with a partially closed sodium channel occupies a smaller volume than that with a fully open channel) and so enhance the effect of the anaesthetic. Both inhibition and enhancement have been observed experimentally[11,12].

Simulation of anaesthetic effects

Although relaxation of the sodium channel caused by anaesthetics could cause blocking of the passage of sodium ions at any point along the length of the channel, the most likely point of blockage in Hille's model[3] is in the narrowest region of the channel, referred to as the selectivity filter. The size and molecular nature of this filter was chosen so that passage of Na^+ through the filter should be favoured over any other ions, whether larger or smaller than Na^+. Hille[3] has presented a four-barrier model for the sodium channel, with the largest of the barriers corresponding to this selectivity filter. It is interesting therefore to see how well the effects of local anaesthetics can be simulated by this four-barrier model, assuming that the relaxation of the protein affects only the height of the barrier constituting the selectivity filter. The following results were obtained using the equations for the one-ion pore model as presented by Hille, and the parameters for the energy profile found by Hille to give the best fit to the ion-selectivity of the sodium channel of frog myelinated nerve. Figure 2 shows the effect of varying the peak height of the selectivity filter (G23 in Hille's notation) on the peak current–voltage relations. The effect clearly is to reduce the sodium current, with no effect on the reversal potential or on the position of maximum sodium current. This is what is observed for the action of neutral anaesthetics such as ethanol[47], although charged anaesthetics sometimes cause shifts along the voltage axis.

As Fig. 3 shows, effects of increasing barrier height on

Fig. 3 Effect of external sodium ion concentration on peak sodium current as a function of barrier height G23 (kcalorie mol^{-1}), with internal 11.2 mM Na^+, 5 °C. The data are normalised to 100 for peak current with external 116 mM Na^+ and G23 = 5 kcalorie mol^{-1}. External Na^+ concentration: 1, 14.5 mM; 2, 58 mM; 3, 166 mM; 4, 200 mM.



peak sodium current gradually decrease Thus the expected dose–response curve would be hyperbolic. The anaesthetic would have no effect until its concentration was sufficiently high to trigger a lipid phase transition for some of the lipid surrounding the sodium channel. This would make possible a partial relaxation of the channel, with an increase in the height of the energy barrier of the selectivity filter, and a corresponding large effect on sodium conductance. Increasing anaesthetic concentration would increase the proportion of surrounding lipid in the liquid-crystalline state and further increase the height of the energy barrier, but with a gradually lessening effect on sodium conductance. Although no detailed comparison is possible, published dose–response curves have this general form[48,49]. The data for Fig. 3 also show that the effect of changing the barrier height is more marked at high external sodium concentration than at low, although complete block of the sodium current occurs first at lower sodium concentrations. This latter observation has been confirmed experimentally by Condouris[50].

Dietary practices and growth responses as predictors of longevity

M. H. Ross & E. Lustbader

The Institute for Cancer Research, The Fox Chase Cancer Center, Philadelphia, Pennsylvania 19111

G. Bras

Pathologic Institute, Faculty of Medicine, University of Utrecht, Utrecht, The Netherlands

The longevity of rats permitted freedom of dietary choice can be predicted accurately solely on the basis of their dietary behaviour and growth responses early in life.

CHRONIC underfeeding of a complete diet is the only means known for increasing the length of life of homoeothermic laboratory animals beyond the limits characteristic for the species[1–8]. At the other extreme, chronic overfeeding, or other dietary excesses or imbalances, curtails lifespan[2–5,9,10]. For animals allowed freedom of dietary choice, a mode of feeding that approximates natural conditions, longevity correlates highly with both the amount and type of diet an animal elects to consume before mid-life[11]. Dietary practices during early life are particularly important. The quantity and composition of the diet determines in large part the progression of body weight changes throughout life. Growth rate and other body weight-related expressions should therefore also correlate with longevity[1,2,8,12–16]. We show here that there are, in fact, several parameters involving body weight that correlate more closely with lifespan than any of the dietary variables.

The dietary practices, body weight changes and duration of life of rats fed on a self-selection basis differ from individual to individual. In assessing the extent to which an animal's lifespan is directly linked with its dietary and growth behaviour, we began the analyses at a stage similar to that used by others working with fixed dietary regimens. Each lifespan-related trait was thus considered separately, but the variety and interdependence among these traits require a more complex treatment to understand their synergistic effects. Here, therefore, we have stressed the multiple variable approach for forecasting lifespan. We show that regardless of the proximate cause of death, there are combinations of specific conditions early in life which allow accurate prediction of an individual's lifespan.

Dietary and growth traits

Individually housed male Charles River COBS-CD rats were offered daily, throughout postweaning life, three complete purified isocaloric diets[17] in separate containers. The diets differed only in their protein and carbohydrate content. To ensure that each of the 121 rats in this study had sufficient freedom to exhibit its individual preference, the proportions of the protein and carbohydrate components of the diets

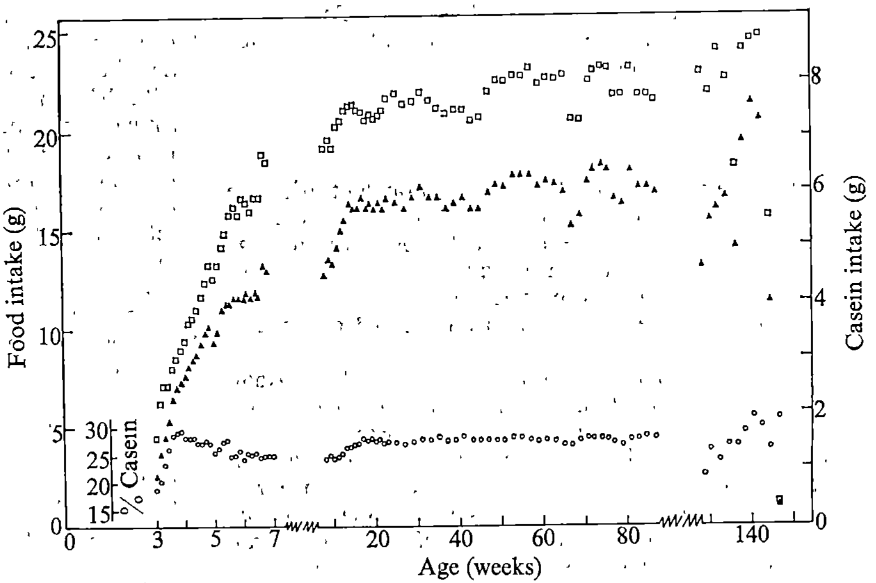

Fig. 1 Average food and protein intake of rats fed on a self-selection basis throughout life. □, Mean daily food intake; ▲, mean daily protein (casein) intake; ○, proportion of protein in the composite diet selected by the rats.

were set at 10 and 70.5%, 22 and 58.5%, and 51 and 29.5%. Vitamin-free casein, sucrose and corn oil (13.5%) were the sources of protein, carbohydrate and fat, respectively. The adequacy of the mineral (6%), vitamin and trace element content has been demonstrated earlier with conventionally fed animals[17–19]. The dietary history during gestation and suckling and the critical maintenance of constant environmental conditions have been described[17].

The absolute and relative intake of the diets differed; consequently, each rat selected a diet differing in quantity and composition In general, after an initial rapid increase in food intake (Fig. 1), the daily amount consumed remained relatively constant for a prolonged period. This phase persisted, for most of the rats, for as least 30 weeks.

The protein–carbohydrate content of the composite diet selected by some rats changed with age. A change in preference, if it occurred, was generally to diets of lower protein content and was detectable by the end of week 2 or 3 of feeding. At approximately 8 weeks of age, this trend reversed so that the diets subsequently chosen contained progressively higher percentages of protein. Beyond 4 months of age, the average protein content of the diet selected by some of these rats generally exceeded that preferred by rats whose preference had more or less stabilised within the first month. For the entire population, however, the average proportion of protein remained uniform throughout the greater part of life (Fig. 1).

The rats were weighed weekly, when they were also examined for gross signs of disease. No therapeutic measures were undertaken except for shortening excessively long incisors. The presence, type and severity of disease were based on histopathological assessment. These results have previously been reported[20].

The average changes in body weight with age are shown in Fig. 2. No two rats had identical rates of growth and durations of the growth period. The differences among the rats were further accentuated when body weight and changes in body weight were related to gross efficiency of food utilisation[18] and the quantity of food, or of protein, consumed relative to body weight.

The heavier the rat, the more food it tended to eat but, relative to body weight, the less food it consumed. The latter is explained by the fact that the heavier rats were generally more efficient than lighter, slower growing rats in

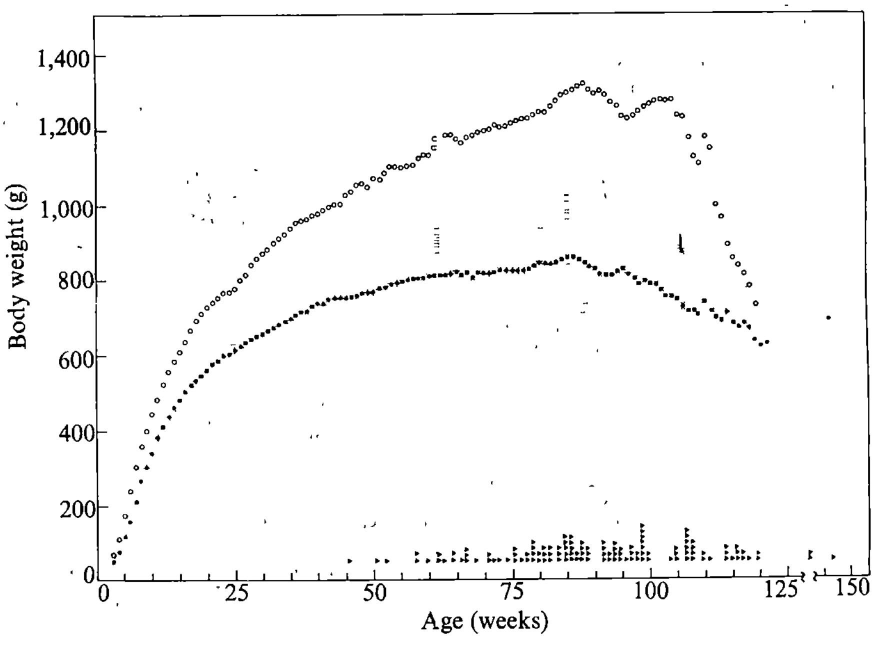

Fig. 2 Growth pattern of rats fed on a self-selection basis throughout life. ●, Mean body weight (shaded area represents 1 s.d. above and one below the mean); ○, heaviest weight attained by any individual; ▶, age at death of a rat. Irregularities in weight curves due to weight loss that generally precedes death.

converting what they consumed into body mass. The heavier rats thus tended to gain more weight than would be expected on the basis of food intake alone.

Correlation of individual variables with lifespan

The mean lifespan (632±125 d), population half life, age when most deaths occurred, and life expectancy[21] were in close agreement. The frequency distribution curve for age at death was nearly symmetrical and the age-specific mortality rates increased in a near-exponential manner. The age at death of the shortest lived rat was 314 d and the longest was 1,026 d (Fig. 2).

The correlation data are summarised in Table 1. Additional details on the relationships among lifespan and dietary practices have been presented elsewhere[12]. For most variables, significant associations were found relatively early in life and in all cases, before mid-life. In addition to differences in age when a correlation was first detected, the duration, direction and magnitude also differed. In general, the body weight variables correlated more closely with lifespan than did the dietary variables. The highest simple correlation values were obtained when lifespan was related to the number of days needed by the rat to reach a preassigned weight (Table 1). Of all the variables examined, only the maximum body weight attained during maturity did not correlate significantly with lifespan.

Combinatorial effects of diet and weight-related variables on lifespan

The simple correlation values presented in Table 1 represent only associations between pairs of variables; they do not imply causality. Furthermore, the interdependence among the parameters (Table 2) precludes ascribing to an isolated factor a direct connection to length of life. The correlation may be indirect, in that a variable might be closely associated with another factor that is directly related to lifespan. Since each variable has a unique period when it correlates with lifespan, there are added difficulties in interpreting simple correlation data. It is necessary, therefore, to determine how a number of variables interact and this can be best accomplished by construction of a model. If the mathematical model is accurate, it shows a dependence relationship and thereby allows the estimation of lifespan. Since countless factors can affect length of life, however, it would not be realistic to expect that the lifespan estimated from a mathematical model, based on a limited number of variables, would exactly match the observed lifespan. Deviations of the estimated lifespan from those observed represent errors; the smaller the error, the better a model explains the longevity data. Since on a simple correlation basis, nearly all the variables relate significantly with lifespan, model building was used to reveal the combination of factors that best explain the lifespan data. We applied the methods of Furnival and Wilson[22] to our problem and their usefulness lies in the fact that they minimise the total squared error[23]. When the best combination was identified, the relative importance of each variable was then determined by the least squares method[23] and expressed in terms of a multiple regression equation. In no case was a model acceptable unless the contribution of each factor was statistically significant ($P<0.05$). To compare models, the proportion of variance explained (R^2) was useful, in that it describes the extent to which the errors have been minimised.

The differences in length of life among the animals were best explained by a model that incorporated seven factors (see equation *a* in Table 3; the correlation matrix is given in Table 2). Four of these variables characterised the growth pattern and the remaining three defined the preference for protein and the efficiency with which the amount of food consumed is utilised for growth. Deletion of any one of

these variables, or the substitution of any parameter with data representing other age or time periods, or weight changes, led to a less informative multiple regression equation. The addition of other variables to the model or logarithmic transformations of the data did not improve the fit either.

The seven variables acting in concert, accounted for 46% of the variance in the length of life (Table 3). In contrast, on the basis of simple correlation analysis, no single variable explained more than 24% of the variance. The data given in Table 3 show that the changes in body weight occurring long before the growth pattern had been completed accounted for the greater proportion of the explained variance in the duration of life.

The predictive capability of the multiple regression equation was evaluated by comparing the estimated length of life with the actual length of life. This form of analysis also served to identify major sources of error in the predictions. The average absolute error of 12% from the actual number of days lived indicated that, at the very least, a rat's lifespan can be predicted as being of short, intermediate or long duration.

An additional series of analyses were made to determine to what extent the elimination of several of the shortest lived rats would improve the model for the others. Only those rats that lived longer than 425 d, representing 95% of the population, were used to derive the 'conditional' regression equation *b* (Table 3). The small changes in the coefficient values from *a* to *b* resulted in estimated lifespans that more closely approximated actual lifespans. The increase from 46 to 52% in the proportion of variance explained was greater than would have been obtained by the application of equation *a* to the same animals.

These observations suggested that as the number of animals in the population decreased because of attrition, a prospective, step-wise redefining of the best association between the independent variables and lifespan for the survivors would increase the accuracy of lifespan estimate. This was confirmed as indicated by the conditional multiple regression equations *c* to *f* (Table 3).

The most precise estimate of lifespan was obtained for rats that survived more than 700 d (equation *f*), where the average absolute error was less than 4% and, moreover, only four variables were needed. With the exception of this subset of animals, the progressive reduction in the absolute error with the other conditional regression equations was not due to an increase in the degree to which the specific combination of variables correlated with lifespan. Rather, the apparent increase in accuracy was the result of reductions in the number of cases of extreme over- and underestimates. These adjustments, however, were not as critical as changes in the type and relative importance of the variables comprising the series of conditional regression equations. Thus, the information required to estimate lifespan of all the rats was not identical to that needed for a segment of the population The contribution of dietary preference and food efficiency data became progressively less important as the number of short and intermediate lived animals included in a cohort decreased Body weight-related variables, however, took on greater importance (Table 3). Thus, those animals that choose and efficiently utilise early in life a low-protein but otherwise adequate diet, and that complete the greater part of their growth by the time they are approximately 100 d old, will probably be the shortest lived members of the population At the other extreme, rats that grow slowly, particularly between 50 and 150 d of age. will more likely have extended lifespans.

In view of the lifespan-dependent changes in the number and type of variables, a single all inclusive equation cannot be expected to describe adequately the length of life of all the rats At best it represents a compromise. The underestimation of lifespan for long lived rats obtained when equation *a* was used, was partly the result of having included dietary variables. At the other extreme, the overestimation for the short lived rats probably resulted from inclusion of body weight variables. A retrospective analysis confined to the shortest lived rats (25% of the population) confirmed that the weight of the rat *per se* was not needed to estimat lifespan. The protein intake was replaced by the amou of carbohydrate consumed, but the age to reach 500 g

Table 3 Estimation of individual lifespan as determined from growth and dietary practices early in life (conditional multiple regression analysis)

the time to double a body weight of 250 g were still significant lifespan predictors.

The sequential redefinition of the best combination of variables, therefore, afforded the only available means of improving the lifespan forecast over that obtained with a single mathematical model. The weighted, overall mean standard deviation from the actual lifespan determined by the step-wise application of the appropriate regression equation to each of the rats within a cohort, was ± 69 d This corresponded to an absolute error of 8% and the proportion of the variance explained approached 50%.

Comparison of fixed and self-selection regimens

In experimental studies using fixed diets, the changes in life expectancy and the frequency of age-related diseases attributable to chronic severe under-nutrition and excessive over-nutrition have stressed the influence of the quantity of food consumed[1–10]. Deviations in life expectancy and disease frequency that may occur among animals maintained on fixed diets differing in composition have also been interpreted to result in part from changes in appetite and therefore in intake of food or calories[7] These changes may accentuate or obscure the effects of a dietary component. With self-selection feeding, food intake data *per se* are not necessary to forecast duration of life. Useful information is however obtained from data which describe the composition of the diet, the efficiency with which it is used for growth purposes, and the manner in which age-dependent and age-independent changes in body weight occur The omission of caloric intake as an important factor which influences the rate of ageing should not be considered to be at variance with earlier conclusions Rather, it indicates that the interactions among lifespan-related factors provide other combinations of variables that are more revealing of future events. Some of these variables may be influenced by food intake. The absolute changes in body weights and time required to attain a specific weight act as substitute information for food intake. Body weight, which as an isolated variable correlated even more closely with lifespan than food intake, is also unnecessary, since these data are also incorporated in the absolute body weight changes and the time required to attain a specific weight.

A fixed diet high in protein and low in carbohydrate, when maintained throughout life, is associated with a higher life expectancy compared with that obtained with diets containing relatively lower levels of protein[17,24–26] With self-selection feeding, the proportion of protein in the diet early in life also correlates directly with lifespan, but later, the opposite condition prevails[11]. Only the protein–carbohydrate ratio of the diet selected early in life seems to be relevant in the context of the other variables. In the multiple regression equations *a*–*c*, however, the coefficient values for this variable are negative This does not indicate that a lower proportion of protein in the diet implies a longer lifespan Instead the negative value serves to moderate the effects on lifespan contributed by the absolute amount of protein consumed Thus, apart from the influence of the other variables, the magnitude of the life-shortening effect resulting from a low protein intake early in life is accentuated or minimised depending on the relative amount of protein in the diet selected. Analogous feedback systems are evident among the two pairs of variables in equation *a* that describe growth In both cases, one member of a pair exerts an influence opposite, but not of equal force, to that supplied by the other. ●

Since dietary intervention has been shown to modify longevity, regimens designed to conform with the dietary practices of long lived rats, may be effective in increasing lifespan The extent to which this type of dietary manipulation would be successful depends on the interactions among the specificity in dietary requirements of the individual, the stage of life when the new regimen is begun and the genetically determined growth potential. These interactions provide at least part of the explanation as to why there is such a high degree of variation in lifespan among animals maintained on a single fixed dietary regimen in identical environmental conditions.

Implications of long-lasting effects of early dietary and growth behaviour

The fact that 50% of the total variance in lifespan has been explained on the basis of early life dietary and dietary-related parameters, assigns to diet a major determinant function. No two rats are identical in their dietary preferences and growth characteristics; yet the long term interactions can be calculated with sufficient accuracy as to allow a close prediction of the duration of life of individual animals

All the weight-related data needed in the mathematical model can be obtained for nearly all the rats before 150 d of age. The dietary data can be obtained before they reach 100 d. The quantity of protein consumed and the protein–carbohydrate ratio of the diet selected during days 43–49 are most critical, since substitution of data obtained later greatly reduces the accuracy of the lifespan forecast.

The temporal specificity implies that the self-determined dietary habits and body weight changes during the mature phase have little bearing on lifespan This assumes that the same mode of feeding is kept throughout postweaning life and that essential constituents needed for life are always available. Additional persuasive evidence of the importance of the early dietary environment comes from fixed diet studies[10,18,24,27–31]. Certain forms of nutritional intervention limited to early life modify life expectancy and disease risk, whereas dietary intervention later in life may not result in the same degree or type of response We cannot, however, extend this proposal to include the role of dietary fat[26,28,32,33] and of the micronutrient[3,34,35] components, since their relative importance and age relationships were not investigated. Nevertheless, the temporal specificity demonstrated here raises the question whether, through a physiological imprinting mechanism, the variables serve as determinants or signals of an existing underlying programme of events to take place later in life The data obtained through short term self-selection studies indicating that dietary preference of young animals may have a genetic basis[36–39], supports the latter possibility Conversely, the compensatory changes in dietary preference associated with a variety of conditions that alter metabolism[40–46] supports the determinant view.

Throughout the greater part of life, the rats were vigorous, clean and free from symptoms of disease. At death, however, a pathological process could be assigned in nearly every case as a contributory or proximate "cause of death"[20] Tumours of different tissue origin occurring in many sites and other age-related affections of the lung, heart, kidney, and prostate were particularly prominent among the rats in this study The ability to make a long range lifespan forecast is therefore all the more remarkable, in that it incorporates differences in the age of onset and the rate of progression of one or more of the debilitating, fatal diseases It is difficult not to conclude that the individual specificity in early life conditions that govern lifespan are interwoven with those that regulate the susceptibility to several age-related diseases.

The models developed for rats maintained in an unvarying laboratory environment are not directly applicable to other mammals and probably not even for the same stock of rats living in natural conditions, experiencing many environmental forces. The feeding methods and analytical procedures are applicable, however, to other animals to determine whether the processes that regulate lifespan and disease susceptibility have common denominators and if so, to develop a model that is not restricted to one species The self-selection method of feeding also allows determination of the extent to which normal physiological or environmentally caused perturbations in appetite and growth at different ages modify length of life and disease risk. At the very least, our observation on the consequences of dietary habits and growth responses early in life have immediate relevance to questions concerned with the appraisal of nutritional adequacy, the relationship between diet and some diseases of age, and the mechanism of the ageing process.

gag Gene of mammalian type-C RNA tumour viruses

Mariano Barbacid, John R. Stephenson & Stuart A. Aaronson
Laboratory of RNA Tumor Viruses, National Cancer Institute, Bethesda, Maryland 20014

The translation product of the gag *gene of mammalian type-C RNA viruses is a 65,000–68,000 molecular weight precursor polypeptide (Pr65) whose cleavage leads to the formation of four virion proteins, p30, p15, p12 and p10. An immunological approach has been used to establish the arrangement of the sequences coding for these proteins within the viral genome as (5′) p15–p12–p30–p10 (3′).*

TYPE-C RNA viruses have been implicated as causative agents of leukaemias and sarcomas in many vertebrates. A genetic approach to the understanding of type-C virus-coded functions may be useful in determining the mechanisms of replication and transformation by these agents. It is well established that translational products of the viral genome include a reverse transcriptase, envelope glycoprotein, and several lower molecular weight proteins[1], some of which are known to be synthesised as part of a precursor polypeptide[2–7]. The regions of the viral genome coding for these functions have been termed *pol, env,* and *gag* genes, respectively[8]. Another gene, designated *src* (ref. 9), has been identified in transforming type-C viruses of avian and mammalian origin. Evidence obtained by the isolation of conditional and non-conditional mutants of sarcoma viruses indicates that the translation product(s) of the *src* gene are involved in cell transformation (for review, see refs 10–12). Whether type-C viruses, which do not transform fibroblasts in culture but induce lymphoid tumours *in vivo,* contain genes analogous to *src* responsible for lymphoid cell transformation is not yet known.

Among approaches used in attempts to sequence the type-C viral genome, the oligonucleotide fingerprint method has been useful in mapping regions near the poly(A)-containing 3′ end of the genome. Analysis of deletion mutants of avian sarcoma viruses by this method has led to mapping of the *env* and *src* genes[9,13]. Information concerning the composition and partial sequence of the avian *gag* gene has been obtained by techniques involving immunoprecipitation of pulse-labelled polypeptides synthesised by pactamycin-treated cells[14]. There is as yet no evidence concerning the genetic sequence of mammalian type-C viruses. There are, however, reports in which immunoprecipitation techniques have been used to detect a variety of intermediate precursor polypeptides involved in the synthesis of mature virion components[6,15].

A different approach to the definition of the composition and sequence of type-C virus-coded genes takes advantage of highly sensitive and specific competition radioimmunoassays for detection and identification of the known structural components of various mammalian type-C viruses. By such procedures, it has recently been shown that one class of temperature-sensitive mutants of Rauscher-murine leukaemia virus (MuLV) is restricted at the non-permissive temperature in cleavage of a precursor polypeptide[4]. We report here an analysis of the size and composition of this viral precursor polypeptide and of its partial cleavage-products. Analogous studies have been performed with cells infected with several naturally-occurring mammalian transforming type-C viruses, that express different numbers of type-C viral structural proteins[16–18]. The present studies make it possible to establish tentatively the components of the *gag* gene of mammalian type-C viruses, as well as to determine its genetic sequence.

Proteins coded by *gag* gene

Table 1 summarises some of the biochemical and immunological properties of type-C viral proteins for which competition immunoassays were performed. These proteins include gp70 (refs 19, 20), p30 (ref. 22), p15 (ref 23), p12 (refs 17), and p10 (ref. 24). Each has been demonstrated to be immunologically distinct from the others and to retain its antigenic characteristics when the virus is grown in cells of different species, indicating that each represents a mature translational product of the viral genome. In the first series of experiments, the distribution of these viral proteins was examined in extracts of NIH/3T3 mouse cells infected at the permissive (31 °C) or non-permissive (39 °C) temperature with *ts25,* a Rauscher-MuLV mutant defective in precursor polypeptide cleavage[4]. Post-microsomal cell extracts were subjected to Agarose gel filtration under denaturing conditions (6 M GuHCl). As shown in Fig. 1*A*, the antigenic reactivities of viral proteins in extracts of cells infected at 31 °C, eluted at molecular weight regions corresponding to those of each of the respective mature proteins isolated from intact virions.

When the same cells were infected at 39 °C instead, antigenic reactivities corresponding to all four proteins, p30,

‡Determined by sodium dodecylsulphate–polyacrylamide gel electrophoresis.

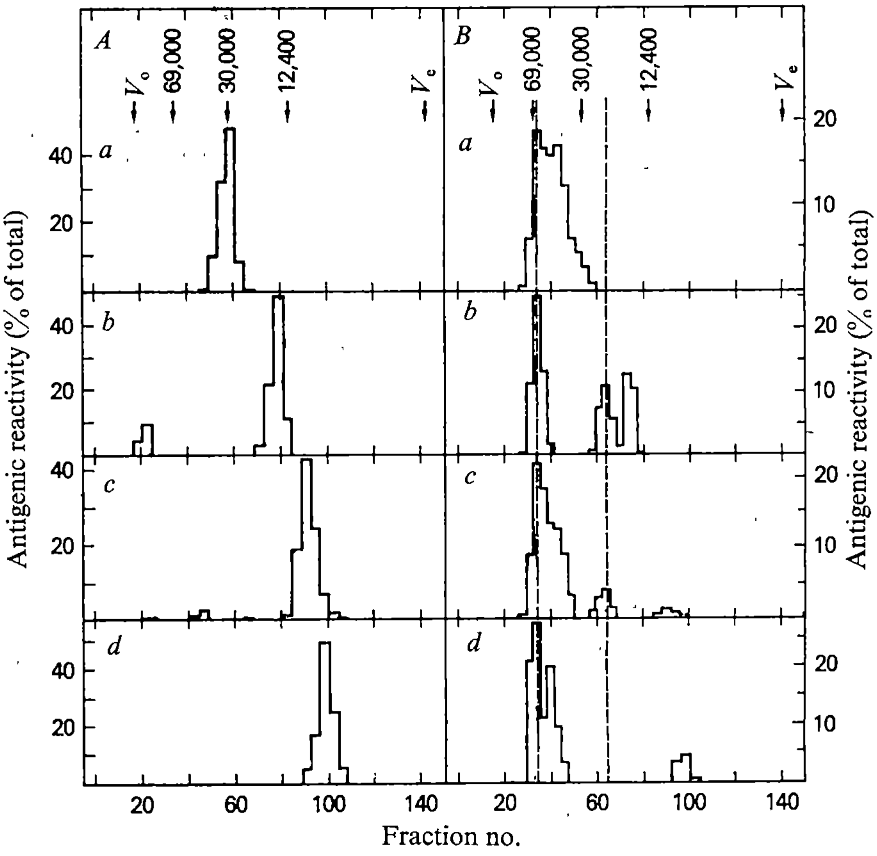

Fig. 1 Molecular sizing chromatography of Rauscher-MuLV, *ts*25 mutant, grown in NIH/3T3 mouse cells at: *A*, the permissive temperature (31 °C), and, *B*, the restrictive temperature (39 °C). Twenty milligrams of the post-microsomal fraction of *ts*25-infected NIH/3T3 cells were lyophilised and resuspended in a 50 mM Tris-HCl *p*H 8.0 buffer containing 8 M guanidine-HCl (GuHCl), 1 mM EDTA and 20 mM of freshly prepared dithiothreitol. After 30 min incubation at 37 °C, the sample was applied to an A-5 Agarose (100–200 mesh, BioRad) 1.5 × 90 cm column equilibrated with a 6 M GuHCl solution containing 20 mM dithiothreitol, adjusted to a final *p*H of 6.5 units. The sample was chromatographed at room temperature at a flow rate of 1.6 ml h^{-1} with a head pressure of 15 cm. Fractions (0.5 ml) were collected, and exhaustively dialysed at 4 °C for 36 h against a 10 mM Tris-HCl *p*H 7.8 buffer containing 100 mM NaCl, 0.5 mM EDTA and 0.1 % Triton X-100. Samples were tested at twofold serial dilutions in homologous competition radioimmunoassays for Rauscher-MuLV: *a*, p30; *b*, p15; *c*, p12; and *d*, p10 proteins, as described in Table 2. Results are expressed as the percentage of total antigenic reactivity. Molecular weight standards, chromatographed along with the sample, included ^{125}I-labelled bovine serum albumin (69,000), ^{125}I-labelled Rauscher p30 (30,000), cytochrome *c* (12,400) and ^{125}iodine (125). The vertical dotted lines indicate the chromatographic positions of Pr65 and Pr25 precursor polypeptides.

p15, p12, and p10, migrated as a 65,000–68,000 molecular weight precursor polypeptide termed Pr65 (Fig. 1*B*). No reactivity corresponding to any of these proteins was detectable at any higher molecular weight, indicating that if Pr65 is initially synthesised as a precursor polypeptide with a molecular weight greater than 65,000, it must be efficiently cleaved. The size of Pr65 would seem to account for not more than the entire translational information of the four viral proteins coded for by the *gag* gene of Rauscher-MuLV.

The results in Fig. 1*B* also indicate the existence of polypeptides containing p30, p15, p12 and p10 antigenic determinants, and possessing molecular weights less than 65,000. These results suggest that even at the restrictive temperature some precursor cleavage takes place in cultures infected with *ts*25 mutant. It was reasoned that systematic analysis of such intermediate cleavage products should provide information concerning the virus maturation process. More importantly, this approach might also provide evidence needed for mapping of individual proteins within the viral genome. For example, the detection of a 23,000–26,000 molecular weight polypeptide containing p15 and p12 antigenic determinants (Fig. 1*Bb* and *c*), suggested that these proteins were located at adjacent positions within the Pr65 precursor polypeptide. Further, antigenic reactivities of p30, p12 and p10 but not of p15 were found in polypeptides eluting in the 40,000 to 60,000 molecular weight region of the guanidine HCl column. In combination with findings of relatively higher levels of mature p15 compared with the other viral proteins, the above data suggested that p15 might be located at a terminal position in the *gag* gene translational product.

Use of mammalian sarcoma virus-transformed cells in sequencing type-C viral genes

Mammalian sarcoma viruses are defective in functions needed for their replication as infectious viruses (for review, see ref. 12). Helper functions including the viral envelope and reverse transcriptase are conferred by a type-C helper leukaemia virus, invariably present in sarcoma virus stocks. Molecular hybridisation studies have indicated that mammalian sarcoma viruses do contain some helper virus genetic sequences[25,26]. In fact, several sarcoma viruses express specific helper viral proteins immunologically detectable in transformed cells[16,18]. That these properties are genetically stable[18,27,28] provides independent evidence of the association of helper viral sequences with these transforming viral genomes. The viruses analysed here included the S$^+$L$^-$ (ref. 16) variant of Moloney-murine sarcoma virus (MSV), a natural sarcoma virus isolate from the BALB/c mouse[29], designated BALB-MSV, and a sarcoma virus isolated from the woolly monkey[30], designated woolly monkey sarcoma virus (WSV). Another virus, the Abelson-murine leukaemia virus (Abelson-MuLV), which induces lymphomas rather than sarcomas[31], was also examined Like the S$^+$L$^-$ Moloney-MSV, this virus transforms fibroblasts in culture and is defective for replication[32] The origins and designations of cell lines transformed by each virus are summarised in Table 2.

The specific antigenic determinants of viral proteins expressed by S$^+$L$^-$ Moloney-MSV and Abelson-MuLV-transformed cells were found to be those of Moloney-MuLV by analysis in radioimmunoassays for type-specific antigenic determinants of p12 and p15 viral proteins, while BALB-MSV transformants expressed antigens specific for a mouse cell tropic helper leukaemia virus indistinguishable from AKR-MuLV by these techniques (data not shown). WSV-transformants contained antigens specific for the woolly monkey helper virus[18]. Thus, each transformed cell line and its appropriate uninfected parental line were compared for reactivity in immunoassays for proteins of the specific helper virus in question (Table 2). Uninfected human and rat cells showed no detectable reactivity in any of the assays used (<10 ng of viral antigen per mg cellular protein) Mouse cells that are known to express antigens of their endogenous viruses[33–35] were, however, cross

Table 2 Patterns of type-C viral antigen expression in cells infected with different mammalian transforming viruses

Viral structural proteins of Rauscher-, Moloney- and AKR-MuLV as well as from the woolly monkey helper virus isolate were purified to apparent homogeneity by a combination of ion exchange and molecular sizing chromatographic techniques as described[20,24]. These included the gp70, p30, p12 and p10 viral proteins of all the four viruses as well as the p15 protein of Rauscher- and Moloney-MuLV. High specific activity ^{125}I-labelling of these proteins was achieved by the chloramine T method[45]. After three cycles of freezing and thawing cells were sonicated for 1 min (Biosonic II sonic oscillator) in a 10 mM Tris-HCl *p*H 7.8 buffer containing 100 mM NaCl, 0.5 mM EDTA and 0.5% Triton X-100, and centrifuged for 2 h at 100,000*g*. The final supernatant was divided into aliquots and stored at −70 °C. These post-microsomal fractions were tested at twofold serial dilutions in the appropriate competition radioimmunoassays for their ability to displace the ^{125}I-labelled viral antigen for binding limiting amounts of goat antiserum raised against homologous virus purified on sucrose gradients. Antiserum and unlabelled competing antigen were incubated at 37 °C for 1 h in a 0.15 ml reaction mixture containing 10 mM Tris-HCl *p*H 7.8, 10 mM EDTA, 0.4% Triton X-100, 1% bovine serum albumin, 0.1% normal goat serum and 10 mM NaCl (p30, p12 assays) or 300 mM NaCl (gp70, p15 and p10 sasays). Around 10,000 c.p.m. of ^{125}I-labelled antigen contained in 0.05 ml of the same buffer were added and incubation continued for 3 h at 37 °C and a further 18 h at 4 °C. Following the addition of 0.025 ml of undiluted swine anti-goat immunoglobulin G to each tube to precipitate the antigen–antibody complexes, reaction mixtures were incubated for 1 h at 37 °C and 3 h at 4 °C. Finally, 1 ml of cold 10 mM Tris-HCl *p*H 7.8 buffer containing 100 mM NaCl and 0.1% Triton X-100 was added to each tube, samples were centrifuged (2,500 r p m for 15 min), supernatants were aspirated, and the radioactivity in the precipitates measured in a Searle gamma counter Model 1285. The results were calculated on the basis of the displacement of the complete competition curve for the unknown relative to that achieved with the corresponding purified viral antigen. Protein concentrations were determined according to Lowry *et al.*[46] using bovine serum albumin as standard.

*Moloney sarcoma- and Abelson leukaemia virus-transformed cells were tested in homologous immunoassays for Moloney-MuLV proteins. MAI 3206 was assayed in the AKR-MuLV homologous assays except for p15, where anti-AKR-MuLV: ^{125}I-Rauscher p15 was utilised. Finally, woolly monkey sarcoma virus-transformed cells were tested in immunoassays for woolly monkey helper virus proteins. Controls for the specificity of each immunoassay included homologous assays for the analogous protein of at least one immunologically distinct type-C virus as well as for the p30s of avian myeloblastosis and RD114 viruses

†Slightly raised levels of gp70 were observed only in $\mathrm{S^+L^-}$ Moloney-MSV-transformed mouse cells. This gp70 was, however, found to contain type-specific antigenic determinants of an endogenous mouse type-C virus[47] (data not shown). These findings together with the lack of detectable gp70 in $\mathrm{S^+L^-}$ NRK rat cells indicate that this gp70 is not coded for by the $\mathrm{S^+L^-}$ Moloney-MSV genome.

‡N.T., Not tested.

reactive at low levels (<50 ng of viral antigen per mg cellular protein) in assays for Moloney-MuLV gp70 and p10 proteins. Therefore, these were subtracted from values obtained with each virus-transformed mouse cell line. As a positive control, virus-transformed cells productively infected with the appropriate helper virus produced high levels of each of the five viral antigens tested.

As shown in Table 2, none of the transformants analysed produced significant amounts of the envelope glycoprotein. gp70. In the analysis of *gag* gene products, several different patterns of expression were observed. For example, cells transformed by the non-producer (NP) variant of Moloney-MSV and by one genetically stable variant of WSV (WSV Cl 9), demonstrated no antigen expression above the levels observed in uninfected parental cells. In contrast, mouse, rat or human cells transformed by the $\mathrm{S^+L^-}$ variant of Moloney-MSV expressed high levels of three Moloney-MuLV proteins, p30, p15 and p12. The production of the same antigens in cells of different species strongly indicates that they are coded by the virus. The fact that p10 was the only missing protein among the Moloney-MuLV *gag* gene products expressed by $\mathrm{S^+L^-}$ Moloney-MSV-transformed cells suggested that this low molecular weight protein might be located at the carboxy-terminal end of the *gag* gene precursor polypeptide.

BALB-MSV and Abelson-MuLV transformants demonstrated high levels of p15 and p12 viral proteins in the absence of p30 or p10, indicating that p30 is the viral protein in closest proximity to p10 These results do not establish the positions of p15 and p12 viral proteins with respect to each other. The presence of *ts*25 Rauscher-MuLV-infected cells of a 23,000–26,000 molecular weight intermediate cleavage product containing both antigens, along with the results presented in Table 2, suggests, however, that p15 and p12 occupy adjacent positions at the amino-terminal region of the *gag* gene translational product.

Transformants of one WSV variant (WSV Cl 11) expressed readily detectable levels of p10 in addition to p30 and p12 woolly monkey helper virus proteins. The unavailability of a radioimmunoassay for woolly monkey viral p15 made it difficult to establish directly the presence of this antigen. The cells were, however, found to express a 65,000–68,000 molecular weight polypeptide containing p30, p12 and p10 and another of 23,000–26,000 molecular weight, possessing p12 but not p30 or p10 (data not shown). Their sizes are evidence that these polypeptides are analogous to those found in Rauscher-MuLV-infected cells and, therefore that p15 is present in both polypeptides. Thus, the WSV Cl 11 transforming virus seems to contain sequences accounting for the entire helper viral *gag* gene.

p15 is the amino-terminal protein of the *gag* gene translational product

In an attempt to determine the relative position of p15 and p12 within the *gag* gene Pr65 product, the molecular size distribution of individual viral antigens was examined in cell extracts of certain of the mouse virus-transformed cell lines described above. The results presented in Figs 2–4 demonstrate the existence of high molecular weight precursor polypeptides as well as several intermediate cleavage products containing *gag* gene-coded structural proteins. Each transformant exhibited a 23,000–

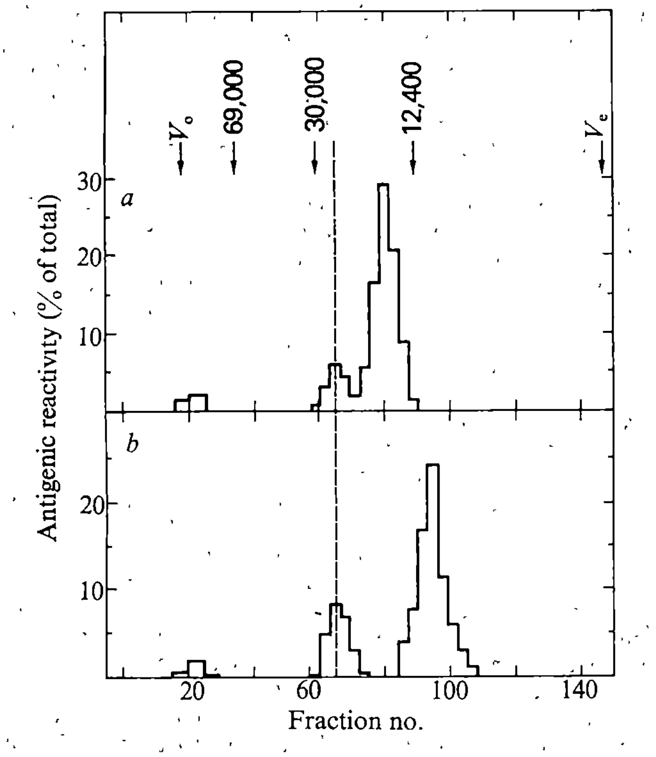

Fig. 2 Molecular sizing chromatographic analysis of helper leukaemia virus-specific antigens expressed in BALB-MSV-transformed rat cells. Twenty-five milligrams of a post-microsomal fraction were submitted to gel filtration chromatography under denaturing conditions as described in the legend to Fig. 1. Dialysed fractions were tested at twofold serial dilutions in the following competition radioimmunoassays: *a*, anti-AKR-MuLV ^{125}I-Rauscher-MuLV p15 assay; and *b*, anti-AKR-MuLV: ^{125}I-AKR-MuLV p12 assay. Results are expressed as percentages of total antigenic reactivity. Molecular weight standards are those described in the legend to Fig. 1. The vertical dotted line represents the chromatographic position of the Pr25 precursor polypeptide.

26,000 molecular weight precursor polypeptide (Pr25) containing p15 and p12 viral proteins analogous to the intermediate cleavage product of the Rauscher-MuLV *ts*25 mutant (Fig. 1*B b* and *c*) The identification of this polypeptide as a precursor to p15 and p12 was particularly obvious in BALB-MSV (Fig. 2) and Abelson-MuLV (data not shown) transformed cells that lacked either p30 or p10. These findings indicate that sequences coding for p15 and p12 occupy adjacent positions within the viral genome.

Analysis of S$^+$L$^-$ Moloney-MSV-transformed mouse cells revealed the presence of additional intermediate cleavage products involved in the synthesis of viral antigens (Fig. 3). These included a 58,000–62,000 molecular weight precursor polypeptide (Pr60) containing p30, p15, and p12 but not p10 and a 43,000–47,000 molecular weight precursor polypeptide (Pr45) containing p30 and p12 antigens in the absence of p15 or p10. The finding that Pr60 lacks only p10 provides further evidence that this low molecular weight protein occupies the carboxy-terminal position in the complete *gag* gene-coded precursor polypeptide. Moreover, the detection of a precursor containing p30 and p12 (Pr 45), but lacking p15, argues for the adjacent location of p30 and p12 within the *gag* gene product. As shown in Fig. 4, the results obtained with S$^+$L$^-$ Moloney-MSV-transformed human cells provide additional evidence supporting this possibility. Cell extracts of this transformant contained proportionally less Pr60 but demonstrated considerably increased amounts of the Pr45 intermediate cleavage product containing p30 and p12, but not p15.

The identification of the intermediate cleavage products, Pr25 and Pr45, led to the establishment of two pairs of adjacent proteins, p15–p12 and p12–p30, respectively. These findings imply that p12 is located between p15 and p30. Moreover, since p30 is missing in BALB-MSV- and Abelson-MuLV-transformed cells that express p15 and p12, the location of p15 must be at the amino terminal end of the *gag* gene translational product.

Sequence and tentative mapping of the *gag* gene

The present evidence utilising a Rauscher-MuLV *ts* mutant blocked in precursor polypeptide cleavage indicates that the *gag* gene translational product (Pr65) contains the major internal protein, p30, as well as the low molecular weight proteins, p15, p12, and p10 (Fig. 1). Moreover, analysis of the expression of helper virus-coded proteins in cells infected with replication-defective transforming viruses revealed that p10 is the carboxy-terminal protein of the *gag* gene-coded precursor polypeptide, and that p30 is adjacent to it (Table 2). Analysis of intermediate cleavage products of the Pr60 polypeptide provided information necessary for the relative positioning of p15 and p12 (Figs 3 and 4). These results led to the following sequence of the *gag* gene product: NH_2–p15–p12–p30–p10–COOH. Since the viral RNA genome is the positive strand[36], the genetic information contained in the *gag* gene would then be arranged in an identical manner from the 5′ to 3′ end of the RNA molecule. A summary of these findings is presented in Fig. 5.

The sequence of the mammalian type-C viral *gag* gene was deduced from analysis of a conditional lethal mutant of mouse leukaemia virus defective in precursor polypeptide

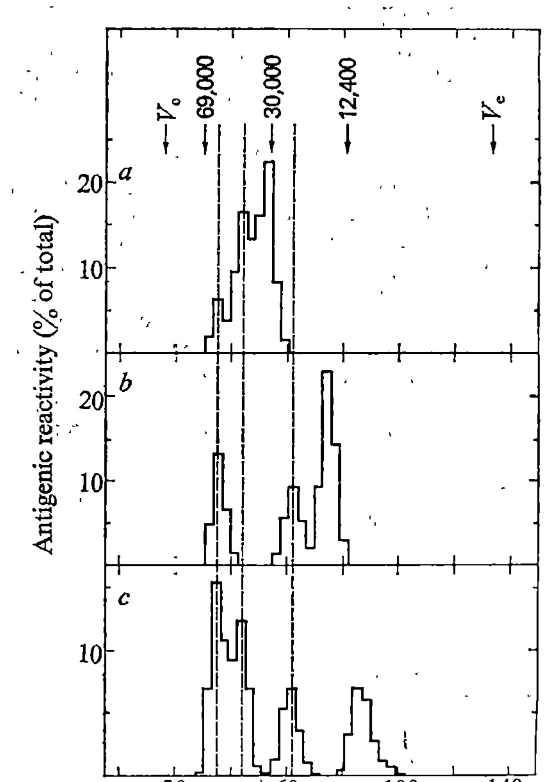

Fig. 3 Molecular sizing chromatographic analysis of helper leukaemia virus-specific antigens expressed in S$^+$L$^-$ Moloney-MSV transformed mouse cells. Twenty mg of a post-microsomal fraction were submitted to gel filtration chromatography under denaturing conditions as described in the legend to Fig. 1. Samples were tested in homologous competition radioimmunoassays for Moloney-MuLV: *a*, p30; *b*, p15; *c*, p12; proteins as described in Table 2. Results are expressed as the percentage of total antigenic reactivity. Molecular weight standards are those described in Fig. 1. The vertical dotted line indicates the elution positions of Pr60, Pr45, and Pr25 *gag* gene-coded precursor polypeptides.

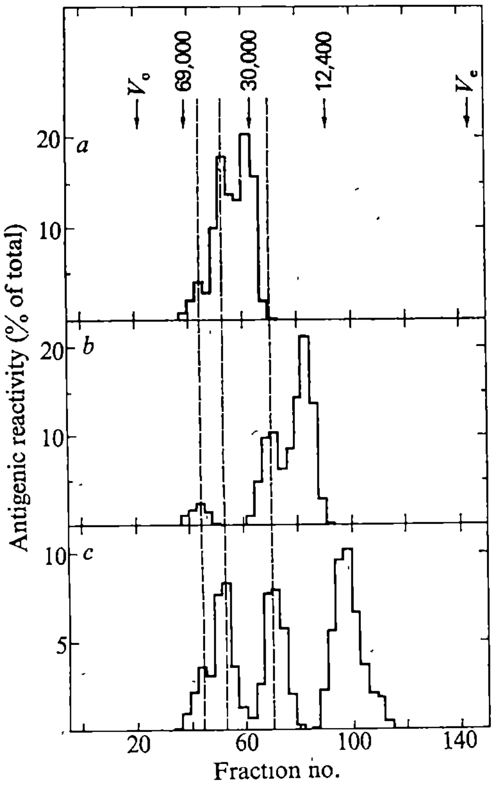

Fig. 4 Molecular sizing chromatographic analysis of S^+L^- Moloney-MSV-transformed human cells. The analysis of Moloney-MuLV helper antigens was performed as indicated in Fig. 3. Vertical dotted lines represent the elution positions of Pr60, Pr45 and Pr25 *gag* gene-coded precursor polypeptides.

cleavage and several independent isolates of replication-defective transforming viruses. These viruses contain stably-associated genetic information of their respective helper leukaemia viruses. Specific patterns of expression of *gag* gene helper viral proteins were demonstrated in cells infected with these transforming viruses. In each case, the size of the highest molecular weight precursor polypeptide corresponded to that expected for a helper leukaemia viral precursor containing only those *gag* gene translational products. Furthermore, the intermediate cleavage products detected in cells infected with each transforming virus were analogous to those detected in cells infected with the conditional lethal mutant of MuLV. The final cleavage products were also identical in sizes and immunological properties to the mature viral proteins of the helper leukaemia virus. These findings all argue against any drastic rearrangement of *gag* gene sequences in sarcoma as opposed to helper leukaemia viruses.

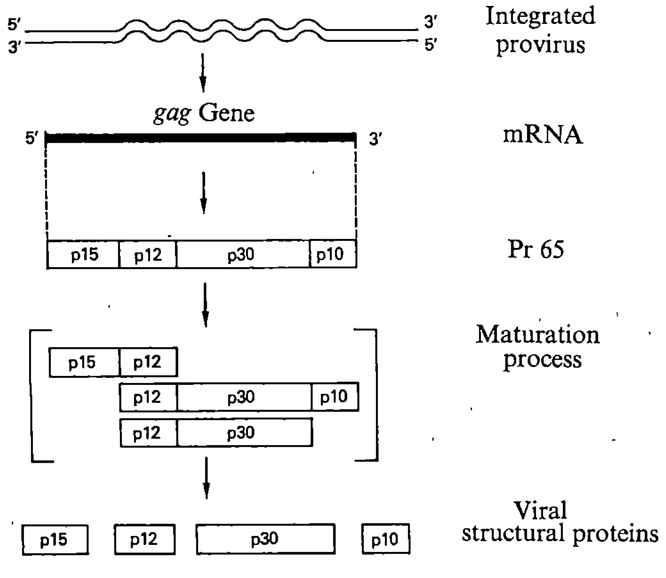

Fig. 5 The sequence and maturation process of the *gag* gene translational product of mammalian type-C RNA viruses.

Our studies of several independent isolates of transforming viruses were consistent with only one possible ordering of *gag* gene sequences on the basis of the above reasoning. Thus, if this gene order were to result from some alteration of the *gag* gene normally present in the helper leukaemia virus, this alteration must be highly specific The ability of different genetic variants of the same transforming virus to transform cells does not seem to be affected by whether they express particular *gag* gene products[18,27]. Thus, the possibility of a specific genetic rearrangement of *gag* gene sequences having any functional significance in the transforming virus seems highly unlikely. Instead, the evidence strongly argues that the *gag* gene sequence as deduced from studies of defective mammalian transforming viruses represents the *gag* gene sequence of the helper leukaemia virus.

With avian type-C viruses, a different experimental approach has led to the following partial sequence of the avian *gag* gene 76,000 molecular weight translational product: NH_2–p19–(p12–p27)–p15–COOH (ref. 14). The position of p12 with respect to p27 is not resolved. Moreover, another low molecular weight protein, p10 (ref. 37) has not been identified within this precursor. Mapping studies of *gag* gene may make it possible to assign similar functions to viral proteins of avian and mammalian type-C viruses on the basis of their positions within their respective viral RNA genomes.

Genetic mapping of *env* and *src* genes at the 3′ end of the avian sarcoma viral genome[9,15] leaves only the *gag* and *pol* genes among the known viral genes that may exist at the 5′ end of the genome. The present evidence does not make it possible to assign the position of the *gag* gene within the mammalian type-C viral RNA molecule. When helper leukaemia viral translational products were detected in the virus transformed cells studied here, however, they invariably included *gag* gene products in the absence of detectable glycoprotein (Table 2). Moreover, one cell line tested, a S^+L^- Moloney MSV transformant of human origin, has been shown to lack detectable viral reverse transcriptase as well[48]. These findings, together with recent reports concerning *in vitro* synthesis of *gag* gene products directed by 35S viral RNA[3,7] indicate that an initiation codon must exist at (or close to) the 5′ end of the *gag* gene. Thus, if the viral genome were to contain a single protein synthesis initiation site, the above information would be sufficient to map the *gag* gene at the 5′ end of the viral genome Reports concerning the size of the viral mRNA[38,39] as well as its translational products[6], taken together would argue for a single initiation site. This possibility remains speculative, however, and awaits further experimental verification.

letters to nature

Solar neutrinos and solar accretion of interstellar matter

McCrea[1] has recalled the suggestions[2,3] that the gravitational energy released by material accreted by the Sun from interstellar clouds could trigger the onset of terrestrial Ice Ages. The purpose of this communication is to point out that if the Hoyle–Lyttleton mass accretion rate applies, this accretion is sufficient to enhance the surface heavy element abundances of the Sun and other solar-type stars. The enhancement may be sufficient to allow the construction of consistent solar models with an interior heavy element abundance significantly lower than the observed surface abundance. This condition lowers the predicted solar neutrino flux[4]. Joss[5] has suggested that a similar enhancement of surface abundances might occur by accretion of planetesimals left over after formation of the Solar System. Both mechanisms may occur, thereby increasing the effect.

In the simple accretion model of Hoyle and Lyttleton[3] a body of mass M accretes matter at a rate

$$\dot{M} = 2.4\times 10^{22}(M/M_{\odot})^{2} n(\mathrm{H}_2) V^{-3}\,\mathrm{g\ yr}^{-1} \qquad (1)$$

where $n(\mathrm{H}_2)$ is the equivalent number of hydrogen molecules cm^{-3} and V is the velocity relative to the cloud in $\mathrm{km\ s}^{-1}$.

If the clouds with internal densities of $n_c(\mathrm{H}_2)$ are distributed randomly with N_c clouds pc^{-3}, and if they may be characterised by spheres of radius, R_c pc, then the fraction of the volume of the galactic disk occupied by cloud material will be $f_c = N_c(4\pi/3)R_c^{3}$. For the age, A, of the Sun, the fraction of time spent inside such clouds will be f_c, and consequently the total mass accreted will be

$$\delta M \simeq \langle \dot{M} f_c\rangle A = 8.2\times 10^{-2} M_{\odot}\langle f_c n_c(\mathrm{H}_2) V^{-3}\rangle \qquad (2)$$

The product $f_c n_c(\mathrm{H}_2)$ is the density of H_2 which would result from smoothing out clouds into a uniform density disk. It is important to note that to compute δM one should include only those clouds for which the internal cloud densities are large enough to choke off the solar wind flow and allow material to accrete on to the stellar surface. As pointed out below, this is approximately $n_c(\mathrm{H}_2) = 10^{4}\ \mathrm{cm}^{-3}$. From Gordon and Burton[6] we adopt the smoothed out density at 10 kpc from the galactic centre of $\langle n(\mathrm{H}_2)\rangle = f_c n_c(\mathrm{H}_2) = 0.5\ \mathrm{cm}^{-3}$. This figure is based on H_2 deduced from CO molecular lines, which require $n_c(\mathrm{H}_2) \gtrsim 10^{4}\ \mathrm{cm}^{-3}$, and consequently it includes the type of clouds which will cause accretion. Consequently, we obtain

$$\delta M \simeq 4\times 10^{-2} M_{\odot}\langle V^{-3}\rangle \qquad (3)$$

Interstellar H I clouds have a turbulent velocity dispersion of $\sim 6.4\ \mathrm{km\ s}^{-1}$ (ref. 7), the mean gas velocity changes by several $\mathrm{km\ s}^{-1}$ during the full cycle of a galactic spiral density wave[8], and the velocity of the Sun oscillates $\sim 20\ \mathrm{km\ s}^{-1}$ around its mean motion about the galactic centre. Thus one expects the relative velocity of the Sun and interstellar clouds to vary over the range 0–$\sim 30\ \mathrm{km\ s}^{-1}$. For any reasonable distribution function of cloud velocities $\langle V^{-3}\rangle$ diverges; consequently the figure to use in equation (3) is dominated by rare, low velocity encounters.

To illustrate this sensitivity, consider the 37 clouds studied by Hobbs[9]. The velocity dispersion of the clouds relative to the Sun was $\langle V^{2}\rangle^{1/2} = 15.7\ \mathrm{km\ s}^{-1}$ (note that this figure includes the systematic motions as well as what would be called turbulent motions about the mean cloud motions observed towards each star). In contrast, the quantity appropriate for use in equation (3) is $\langle V^{-3}\rangle^{-1/3} = 3.1\ \mathrm{km\ s}^{-1}$. To emphasise the sensitivity to rare encounters of low relative velocity, if the one cloud towards ε Aur with velocity $1\ \mathrm{km\ s}^{-1}$ is dropped from the mean, then $\langle V^{-3}\rangle^{-1/3} = 5.4\ \mathrm{km\ s}^{-1}$.

It is not clear whether this sample of clouds is broad enough to determine the appropriate figure to use in equation (3), especially since these clouds are not the same type of objects which have densities of $n_c(\mathrm{H}_2) \gtrsim 10^{4}\ \mathrm{cm}^{-3}$. Nevertheless, we expect that the appropriate mean velocity is likely to be in the range 2–5 $\mathrm{km\ s}^{-1}$ and this gives

$$\delta M \simeq 5\times 10^{-3}\ \text{to}\ 3\times 10^{-4} M_{\odot} \qquad (4)$$

A crucial question which must be answered by future research is whether or not accretion on to the solar surface will actually occur. One of the most obvious obstacles is the outward flowing solar wind. A simple computation may be done by setting the dynamic pressure of the solar wind flow equal to the dynamic pressure of the dense interstellar gas[10]. It is easy to show that for interstellar cloud densities of $n(\mathrm{H}_2) \simeq 10^{2}\ \mathrm{cm}^{-3}$ the solar wind terminates at ~ 1 AU. For larger densities the heliosphere is compressed further and for densities of a few $10^3\ \mathrm{cm}^{-3}$ the termination is within a few solar radii of the Sun. To decide what occurs for higher densities requires knowledge of the mechanisms which affect the solar wind within its critical sonic point at a few solar radii. It appears that the outward flow can be reversed to an inward flow for cloud densities which characterise the dense H_2 clouds used for the estimate in equation (5).

If the accreted mass contains a heavy element abundance by mass $Z_g(t)$ and it has been continually mixed into a surface convection zone of mass ΔM, then the surface abundance of heavy elements will be

$$Z_S(t) = e^{-y(t)}\left[Z_0 + \int_{t_0}^{t} e^{y(t')} Z_g(t') \frac{\dot{M}\,\mathrm{d}t'}{\Delta M}\right] \qquad (5)$$

where Z_0 is the heavy element abundance of the star at its time of formation t_0, and

$$y(t) = \int_{t_0}^{t} \frac{\dot{M}\,\mathrm{d}t'}{\Delta M}$$

The presently observed solar Z_S is $\sim 1.5 \times 10^{-2}$. The heavy element abundance of the interstellar gas at the present time, T, deduced from young stars and H II regions is about the same. If the heavy element abundance in the gas has increased with time and therefore $Z_g(t) > Z_0$, then equation (5) is satisfied providing $y(T) \gtrsim 1$. Standard solar models give surface convection zones with $\Delta M \simeq 10^{-2} M_\odot$. This together with the predicted range for δM given in equation (4) seems to indicate $y(T)$ somewhat <1. Ulrich (personal communication) has, however, shown that ΔM is even smaller if the interior abundance Z_0 is smaller than the surface abundance Z_S. Therefore for sufficiently low values of Z_0 it seems that equation (5) will be satisfied.

The initial solar value Z_0 is difficult to estimate. It is most likely substantially greater than zero. Simple models for the evolution of the Galaxy (for example ref. 11) suggest that 4.5×10^9 yr ago the interstellar gas may have had a value of Z at least as great as $\frac{1}{2}$–$\frac{2}{3}$ the present value Z_g. If these values for Z_0 reduce ΔM to approximately the size of δM, then the solar neutrino counting rate is reduced by a factor of $\sim (Z_0/Z_S)^{1\ 1}$ (ref. 12) to 2 6–3.6 SNU.

Although the precise magnitude of the effect is still uncertain, it seems probable that some enhancement of the solar surface heavy element abundance must occur. Hence, it appears that this mechanism could significantly reduce the discrepancy between the observations and predictions of solar models.

Solar neutrinos and galactic contamination of the Sun

ONLY recently-published observations permit a useful estimate of the total accretion of interstellar matter (ISM) by the Sun since it became a main sequence star. Using measurements from the OAO-2 satellite, Jenkins and Savage[1] conclude that " . . . possibly the most secure estimate of the amount of hydrogen within 1 kpc of the Sun is . . . an overall density n_H (total) = 1.5 atoms cm^{-3} (in the form of protons, atoms and molecules)". Using this number we suggest here a possible explanation of the low observed solar neutrino rate.

Taking hydrogen to be 70% by mass gives for the density of ISM in units of the atomic mass of hydrogen

$$n \simeq 2\ \mathrm{cm}^{-3} \qquad (1)$$

If the Sun of mass 2×10^{33} g traverses ISM of density n at speed V km s^{-1} the mass $m(L)$ accreted in travelling L pc is

$$m(L) = 1\ 2 \times 10^{28} L n V^{-4}\ \mathrm{g} \qquad (2)$$

and the total mass $m(T)$ accreted in time $1T$ (in units of 10^{10} yr) is

$$m(T) = 1.2 \times 10^{32} T \langle n \rangle \langle V^{-3} \rangle\ \mathrm{g} \qquad (3)$$

assuming n, V to be uncorrelated[2,3]. Now a region of radius 1 kpc around the Sun seems to be quite typical along the path of the Sun in present conditions in the Galaxy. Also the amount of ISM was presumably somewhat greater in the past. So from equation (1) we infer that it is not an overestimate to use in equation (3)

$$\langle n \rangle \simeq 2 \qquad (4)$$

If the Sun is in a cloud of ISM the relative speed V is usually taken to be in the range 5–25 km s^{-1}. In equation (3) smaller values are weighted more strongly, so we take

$$\langle V^{-3} \rangle \simeq 10^{-3} \qquad (5)$$

According to standard estimates, the Sun reached the main sequence about 5×10^9 yr ago. The total mass $m(T = 0.5)$ accreted since then is estimated from equations (3), (4) and (5) as

$$m \simeq 10^{29}\ \mathrm{g} \qquad (6)$$

This is an underestimate because it takes no account of the densest parts of the ISM that produce so much obscuration that no stars can be seen through them. Indeed, if the Sun traverses even a single 'very dense' cloud it can accrete between 10^{29} and 10^{31} g, as follows from equation (2) using appropriate values of L, n, V. The Sun must have had a good chance of accreting some such amount each of the $\sim$ 50 times it has crossed a dust-lane associated with a spiral arm of the Galaxy. From all this we may safely take m to be in the range

$$10^{29} < m < 10^{30}\ \mathrm{g} \qquad (7)$$

and we should not exclude still higher values.

On current models, the Sun has an outer convective zone that, along with a region of convective overshooting immediately beneath it comprising altogether a mass M_{conv}, is itself kept mixed but undergoes no mixing with material from the interior. Quoting R. K. Ulrich, Joss[4] gives for two models

$$Z_0 \lesssim 0.002 \quad M_{\text{conv}} \simeq 10^{29}\ \text{g} \qquad (8)$$

$$Z_0 \simeq 0.02 \quad M_{\text{conv}} \simeq 5\times10^{31}\ \text{g} \qquad (9)$$

Z_0 is the initial heavy-element abundance by mass, here assumed to have the same value throughout a model.

Amongst general conclusions from the literature[5] on the chemical composition of the stars are: (a) Clouds from which stars are being formed at the present time have Z-values on average 1.5–2 times higher than those from which stars were formed when the Sun was born. (b) There is an intrinsic spread in the Z_0-values of stars born about any particular time; this is seen especially in the work of Clegg and Bell[6] who find, for stars younger than the Sun, a sixfold range of Z_0. At present IMS has $\langle Z \rangle \simeq 0.02$. Allowing a factor 2 on account of (a) and 2 either way on account of (b) would give a range

$$0.005 \lesssim Z_0 \lesssim 0.02$$

for the Sun at birth, and would not exaggerate the possible range.

These bounds for Z_0 give two possible interpretations of the fact that the observed spectrum of the Sun gives $Z \simeq 0.02$:

(A) $Z_0 \simeq 0.005$. Here M_{conv} is near the low value in model (8) and this can be exceeded by $\dot{m}$ in condition (7). In that case the convective zone is composed of accreted matter for which $Z \simeq 0.02$.

(B) $Z_0 \simeq 0.02$. Here M_{conv} having the high value in model (9) is unlikely to be significantly affected by accretion, and accretion of ISM having $Z \simeq 0.02$ would not in any case affect the composition.

Case (B) is the usual standard uniform model. But from the present standpoint, apart from accretion, a uniform model with $Z_0 \simeq 0.005$ is about as likely as one with $Z_0 \simeq 0.02$; accretion would, however, cause (A) to show the same spectrum as (B). There could be intermediate cases, but we are concerned to demonstrate the plausibility of quite widely different cases.

Bahcall *et al.*[7] predict for uniform solar models

$$Z_0 = 0.002,\ \text{neutrino detection rate} \simeq 1.4\ \text{SNU} \qquad (10)$$

$$Z_0 = 0.02,\ \text{neutrino detection rate} \simeq 5.6\ \text{SNU} \qquad (11)$$

A roughly linear dependence of detection rate upon Z_0 near $Z_0 = 0.015$ inferred earlier[8] would have required it to go from 5.6 to 1.4 SNU if Z_0 goes from $Z_0 = 0.02$ to $Z_0 = 0.005$. In view of result (10) this may not be quite correct, but it shows the predicted rate to be not much above 1.4 SNU if $Z_0 = 0.05$, that is, for case (A). The result (11) predicts 5.6 SNU in case (B).

As their most up-to-date determination, R. Davis, Jr, and J. C. Evans (private communication) find 1.5 SNU as the 1σ upper bound on the solar neutrino detection rate (see also ref. 9). We suggest as the simplest explanation of this low value the possibility that the Sun actually has a low heavy-element content, except in its convection zone which has been enriched by accretion.

The phenomenon of a considerable difference between surface and interior Z-values because of accretion is likely only for stars not much different from the Sun. Population II stars will have space velocities that are too high for significant accretion to occur. Stars of smaller mass would have deeper convective zones, while stars of much greater mass would generate H II regions tending to inhibit accretion, and would not be old enough for significant changes in Z to develop in the ISM from the time of formation. Therefore our suggestion would not require any changes in composition (Z) for the ISM from that normally assumed, either for the present period or when the population II stars were being formed.

In a highly suggestive paper, Joss[4] has considered the possible enhancement of the heavy-element abundances in stellar surfaces by the accretion of chemically fractionated matter in the form of comets and planetesimals. It follows fairly conclusively from his discussion, however, that such material in the required quantity is not available in the case of the Sun. Our suggestion differs from his in a simple way, but it is the crucial one that we appeal only to ISM known to exist in the amount needed.

Amongst possible objections is, for instance, any reason for the inapplicability of the simple theory of accretion; in particular the solar wind might combat accretion, though this seems unlikely to be important since heavy accretion would occur mainly in relatively short intense bursts. Anyhow, little is known about the cause of the solar wind or its time dependence. Again there is the question as to whether the mere addition of material of relatively high Z-value might automatically increase the extent of the convective zone, thereby rendering our process self-defeating. There are also known problems regarding particular abundances (lithium in the Sun, planetary compositions, to name but two) that are still unresolved in any theory. On the other hand, were the neutrino observations accepted as demanding a low Z-value inside the Sun, this would clarify these other problems.

Climatic effects during passage of the Solar System through interstellar clouds

IT seems likely that the Solar System passes through regions where there are a large number of dense interstellar clouds as the compression zone of the galactic spiral density wave passes the Sun. When this occurs, several processes may cause significant changes in the climate of the Earth and other planets. We discuss here the influences of compression of the solar wind cavity, accretion by the Sun, and particulate input into the Earth's atmosphere. The first two may produce radiation hazards for life in addition to causing climate stress.

Shapely[1] and Hoyle and Lyttleton[2] have discussed the idea that gravitational energy released by the accretion of interstellar material to the Sun at a rate $\dot{M}$ would enhance the solar luminosity. The Hoyle–Lyttleton mechanism gives an enhancement of $\delta L \approx \dot{M}\ (GM_\odot/R_\odot) \propto n(\text{H}_2)/V^3$, where $n(\text{H}_2)$ is the equivalent number of hydrogen molecules per cm^3 and V is the velocity of the Sun with respect to the interstellar medium. In contrast to the small accretion rates predicted from earlier data, McCrea[3] has pointed out that there exist very dense interstellar clouds with $n(\text{H}_2)$ values as large as 10^6–$10^7\ \text{cm}^{-3}$, which may produce $\delta L \approx 10^{-2}(n(\text{H}_2)/10^6\ \text{cm}^{-3})L_\odot$ using $V = 20\ \text{km s}^{-1}$. Simple arguments about terrestrial heat balance suggest that luminosity enhancements of 1% or greater will produce significant variations in climate.

The spiral pattern in the Galaxy sweeps by the Sun at intervals of about 10^8 yr, and the sharp compression behind a shock front is believed to initiate the collapse of some interstellar clouds and to induce star formation; see, for example, Shu *et al.*[4]. The width of the compression zone corresponds to an interval of about 10^6 yr. McCrea has estimated that within each compression zone the Sun would encounter several dense clouds, and that the traversal of each would last about 5×10^4 yr (McCrea also considered how these varied times may relate to observed time scales for ice ages).

Observational data are sparse, but it seems that most lines of sight from the Sun encounter cloud complexes of CO molecules[5,6] with emission line strengths implying $n(\mathrm{H}_2)\gtrsim10^3\ \mathrm{cm}^{-3}$. Observed clouds probably have lifetimes of about 10^6 yr, so Earth is unlikely to pass through any of those. If the pattern is continuously maintained by cloud compression in the spiral shock, however, then approximately the same number of clouds can be expected in the compression zone when it passes the Sun. This reinforces McCrea's suggestion[3] that the Sun will regularly encounter dense clouds, but the number of such clouds and the probability of encountering very dense clouds with $n(\mathrm{H}_2)\gtrsim10^5\ \mathrm{cm}^{-3}$ is still uncertain. It seems, however, that encounters with clouds of $n(\mathrm{H}_2)\gtrsim10^3\ \mathrm{cm}^{-3}$ are almost inevitable. We have analyses (unpublished) suggesting that during its lifetime the Solar System has passed through at least 45 clouds with $n(\mathrm{H}_2)\gtrsim10^2\ \mathrm{cm}^{-3}$ and at least five clouds with $n(\mathrm{H}_2)\gtrsim10^3\ \mathrm{cm}^{-3}$.

Dennison and Mansfield[7] have discussed some of the observational difficulties of McCrea's suggestion that each individual glaciation is caused by passage through a separate cloud (there is apparently no trace of the cloud which would have caused the last glaciation). Those arguments, however, do not vitiate the general idea that passage through interstellar clouds may influence climate.

When the Solar System moves through a cloud, the dynamic ram pressure will balance the outward flowing solar wind at a stand-off distance R_s on the upstream side. Under most circumstances of interest V will be much greater than the sonic speed of the interstellar gas, so the flow will be supersonic on both sides of R_s, the two flows being separated by a relatively thin subsonic region. The position of R_s may be estimated by balancing the dynamic pressures of the two opposing flows. The solar wind dynamic pressure is approximately $p_E = m_H n_E (R_E/R)^2 V_E^2$, where m_H is the mass of the hydrogen atom, $n_E\simeq7\ \mathrm{cm}^{-3}$ is the average density currently at $R_E = 1$ AU, and $V_E\simeq400\ \mathrm{km\ s}^{-1}$ is the velocity at 1 AU. The dynamic pressure of the interstellar gas after falling into R is approximately given by

$$p_G = 2m_H n(\mathrm{H}_2)\left(V^2+\frac{2GM_\odot}{R}\right) \qquad (1)$$

If R is greater than the 'accretion radius' $r_c=GM_\odot/V^2$, then $n(\mathrm{H}_2)$ remains approximately equal to its value at large distances from the Sun, and therefore $p_G\simeq$ constant. If $R<r_c$, however, the inflowing gas density increases roughly proportionally to $R^{-3/2}$, and $p_G\propto R^{-5/2}$. With that behaviour the stand-off radius is approximately

$$R_s\simeq750\,n(\mathrm{H}_2)^{-1/2}V^{-1}\ \mathrm{AU} \qquad (2)$$

for small $n(\mathrm{H}_2)$, where V is expressed in $\mathrm{km\ s}^{-1}$. If $n(\mathrm{H}_2)$ is greater than a critical value of approximately $0.4V^2\ \mathrm{cm}^{-3}$ pressure balance is no longer possible and the interstellar gas overwhelms the solar wind. When that occurs $R_s\simeq1.2\times10^3V^{-2}$ AU. That is altered only slightly if non-fluid behaviour resulting from the large mean free path of the neutral gas is considered.

As a typical case we here adopt $V = 20\ \mathrm{km\ s}^{-1}$ for the velocity of the Sun relative to clouds. For that value of V the critical values of $n(\mathrm{H}_2)$ and R_s are about $160\ \mathrm{cm}^{-3}$ and 3.0 AU. In this analysis the conditions on the downstream side are not clearly discernible; nevertheless it is clear that for clouds of $n(\mathrm{H}_2)>10^2\ \mathrm{cm}^{-3}$ the Earth will be outside the solar wind cavity for at least part of the year. Furthermore, the flow becomes an accretion flow which may produce a significant alteration of the chemical abundances at the solar surface and, by implication, surface abundances of other stars as well (R.J.T. and M.J.N., unpublished).

Observational evidence suggests that there is some mechanism producing a relationship between solar wind flow and climate[8–11]. One proposed mechanism is that contemporary solar wind modulation of galactic cosmic rays influences climate[12–14]. Consequently, the fact that the Earth would be outside the solar wind cavity for all or part of the year may have an effect on terrestrial climate. Outside the heliosphere the Earth will presumably be exposed to the full galactic cosmic ray flux; furthermore, there may be an enhanced flux in those environments because of the supernova deaths of massive stars which spend their entire lives in the vicinity of the dense interstellar clouds from which they form. Ruderman[15] has discussed the consequences of nearby supernovae explosions for atmospheric ozone and terrestrial life.

One discussion about the relationship between solar wind and weather has focused on the passage of the Earth through sector boundaries of the interplanetary magnetic field[8]. If those magnetic field discontinuities are important, then discontinuities encountered as the Earth moves in and out of the heliosphere should also be important.

McCrea's discussion of the accretion luminosity δL considered only its magnitude. Its spectrum will be largely determined by the temperature of the gas after the bow shock at R_s or the accretion shock at the solar surface. The temperature will reach at least 40,000 K, which is the value the gas would attain by converting the energy of $20\ \mathrm{km\ s}^{-1}$ bulk relative motion into thermal energy. The spectral character of this radiation will be quite different from the normal solar spectrum, for it will be mostly ultraviolet and X-ray radiation.

During quiet solar periods, solar radiation contains about $1.5\times10^{-6}L_\odot$ on the short wavelength side of Lyman α (ref. 16); this portion governs the thermosphere of the Earth. Therefore, $\delta L\approx10^{-6}L_\odot$ will produce changes of order unity both in the properties of the Earth's atmosphere above about 150 km and in the ionsopheric regions of all planets. Solar radiation contains about $1.5\times10^{-2}L_\odot$ between 2,100 and 3,100 Å (ref. 16), the wavelength region influencing the stratosphere.

The suspected relationships between observed, contemporary solar activity and climatic change[12,13,17] suggest that relatively small variations in solar ultraviolet radiation input may have perceptible influences on climate. If a variation of 1% in radiative input to the stratosphere has a significant effect, then an accretion producing $\delta L\simeq10^{-4}L_\odot$ in ultraviolet and X rays may have a large impact on terrestrial conditions, even though the change in the total heat balance is negligible. Thus, moderately dense interstellar clouds with $n(\mathrm{H}_2)\approx10^3\ \mathrm{cm}^{-3}$ may have significant effects. The $\delta L\approx10^{-2}L_\odot$ relationship discussed by McCrea[3] would have a devastating effect on the Earth's upper atmosphere and perhaps cause ultraviolet fluxes hazardous to life[15].

Dense interstellar clouds are well known because of the optical obstruction caused by dust grains about 0.2 μm in radius. Silicate and ice particles will survive solar radiation at distances from the Sun of a few $R_\odot$ and about 2 AU, respectively (see, for example, refs 18 and 19). Using 1% for the mass in grains per unit mass of H_2, we estimate that once in a cloud the Earth will sweep up an average of about $6\times10^6\,n(\mathrm{H}_2)\ \mathrm{g\ yr}^{-1}$ of dust.

Our computations of the dynamics of infalling dust show that it will reach terminal velocity by the time it falls to about 90 km altitude, and that negligible ablation occurs. The residence time above the tropopause is at least 1 yr. This implies a dust loading of the terrestrial atmosphere of about 6×10^6 tonnes when the Solar System is in a cloud with $n(\mathrm{H}_2)\approx10^5\ \mathrm{cm}^{-3}$.

This is about the level produced by volcanic activity, believed by some investigators[20] to produce perceptible climatic changes through alteration of atmospheric transparency and albedo. This dust may also provide nucleation sites and thereby influence precipitation. Both processes suggest that the accretion of interstellar dust by the Earth will lead to global cooling and glaciation. The frequency of passage through such dense clouds is probably very low, so that the significance of this effect is difficult to evaluate.

We estimate that during the lifetime of the Solar System the mass of dust grains (mostly silicon, magnesium, and oxygen) accreted by the Earth should have been about 10^{16}–10^{18} g. Is there any evidence for their presence? These grains may contain freshly created, short-lived radioactive nuclei produced by supernova nucleosynthesis processes, and they may reveal themselves by exhibiting abundances appreciably greater than would be expected if the species had been decaying in isolation since the origin of the Solar System. Clayton[21] has suggested that this may have already been observed in the detection of naturally occurring ^{244}Pu. Lindsay and Srnka[22] have evidence for the accretion of interstellar dust by the Moon.

The processes proposed here have very complex implications for global weather patterns. We cannot at this time evaluate which, if any, will unquestionably affect the Earth's climate; however, astronomical influences upon climate seem to be far more complex and significant than considered previously. Begelman and Rees[23] have also considered some of the ideas discussed here.

Hard X-ray observations of Circinus X-1 during an outburst

WHILE the Ariel V satellite was observing in the Circinus–Norma region an outburst was detected from Cir X-1 on 1976 February 15 by the rotation modulation collimator (RMC) experiment[1]. One day before the outburst began the Imperial College hard X-ray scintillation telescope (ST) experiment (8° FWHM, 26 keV–1.2 MeV) completed a 4-d observation of this source and a strong signal was detected. For the following eight days, 1976 February 14–22, the source remained within the field of view, though at low sensitivity. Consequently only upper limits were obtained for the hard flux during the outburst and only a limited measure of the spectrum immediately afterwards. We have combined our results with the RMC results from reference 1 to obtain an overall view of the spectral behaviour of Cir X-1 during this outburst. We suggest that the large scale low energy X-ray outbursts of the 'super-variable' Cir X-1 may be interpreted as corresponding to the periodic removal of a dense screening gas to expose a relatively stable source with a power law spectrum.

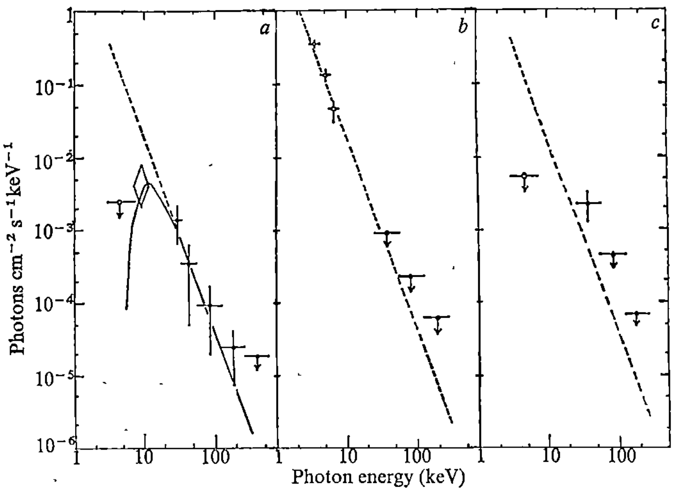

Fig. 1 Observed spectra of Cir X-1 before (*a*, February 10.5–14.5), during (*b*, February 16.5–19.5) and after (*c*, February 19.5–22.5) the outburst of 1976 February. ○, RMC results[1]; ◇, OSO-7 quiet-state result[2]; ●, our ST results.

For the period before the outburst the best fit to our data (see Fig. 1*a*) is found to be the power law

$$\frac{dN}{dE} = 14.6\, E^{-2.7} \text{ photons cm}^{-2}\text{ s}^{-1}\text{ keV}^{-1}$$

Baity *et al.*[2] summarise OSO-7, balloon and rocket results at various times with the law

$$\frac{dN}{dE} = 4.8\, E^{-2.6} \text{ photons cm}^{-2}\text{ s}^{-1}\text{ keV}^{-1}$$

although they have evidence for some spectral hardening as the overall intensity diminishes. Also this data shows intensity variations by a factor of >5 at energies below 10 keV. The power law given by Baity *et al.* also fits our data well. These authors provide a plot of the (7–11) keV flux at various times over the period 1971–1973 and note a relatively steady flux between outbursts of $(2\text{–}8)\times 10^{-3}$ photons cm^{-2} s^{-1} keV^{-1}. We therefore have included this data point in Fig. 1*a*.

During the outburst the soft X-ray flux increased by at least two orders of magnitude but there is no indication of any comparable increase in the flux of hard X-rays (Fig. 1*b*). Our experimental points for the period following the outburst, although less precise, indicate that the spectrum has not greatly changed (Fig. 1*c*). The ST results in Fig. 1*a* and the balloon data of Guo *et al.*[3] from an earlier epoch do not fit a single temperature thermal spectrum. Wilson and Carpenter[1] suggest an absorption column density of 10^{22} atoms cm^{-2} to explain their low energy data during the outburst. Margon *et al.*[4] during a previous outburst find a sharp spectral cutoff, approximately consistent with this value.

Recently Kaluzienski *et al.*[5] have reported that this source has a 16.5-d period with a phase consistent with the time of this outburst, though we note that an earlier event reported by Buff *et al.*[6] does not fall on this period.

We interpret the totality of the data by assuming that there is an intrinsic power law source extending to $\lesssim 1$ keV and that varying amounts of cold gas change the cutoff from 2 keV to 12 keV thereby producing the outburst. A 12-keV cutoff requires a column density of 2.5×10^{24} atoms cm^{-2} of 'typical' interstellar matter and the resulting spectrum is shown as a solid line in Fig. 1*a*. One could imagine a compact object source immersed for most of the time in a dense, cold stellar wind or other 'cloud' of cold material which periodically thins to allow out the soft radiation. An eccentric orbit binary pair is an obvious model for the source.

Our results do not exclude the possibility that the absorbing cloud of gas could radiate by the blackbody mechanism with $kT \lesssim 7$ keV and the emerging spectrum at times of low intensity could be a superposition of this thermal radiation and intrinsic source spectra. The cold cloud is, however, more plausible because to prevent violation of the Eddington limit the hot cloud would have to be no larger than a neutron star. Cir X-1 may thus provide an extreme example of a source where large variations in the amount of surrounding material dramatically changes the spectral shape up to 10 keV or more.

We acknowledge the help of Terence Wyatt in much of the data analysis and the Appleton Laboratory for satellite operations.

New H_2O maser near NGC7538

A NEW, strong, water vapour maser has appeared at the position of a very compact radio and infrared source near the H II region NGC7538. The radio source is NGC7538-B (infrared source IRS-1), the most intense of a group of three compact H II regions[1–4] at a distance of ~ 3 kpc from the Earth. The continuum source is optically thick below 20 GHz (ref. 5), and thus has one of the highest emission measures yet observed in a compact H II region. At 10 μm, it has one of the strongest silicate absorption features known[6], and this source and the KL nebula in Orion are the only sources in the Galaxy which show formaldehyde in emission at 4.8 GHz (ref. 7). The area has been searched many times during the past 5 yr without the detection of this particular H_2O maser. Its sudden appearance may be related to the dynamics of the high-density shell surrounding the compact ionised region.

The observations were made on May 1 and 2, 1976, with the Effelsberg 100-m telescope, which at 22 GHz has a half-power beamwidth (HPBW) of $40'' \times 43''$ and, in the zenith, beam and aperture efficiencies of 35% and 15%, respectively, of the entire 100-m surface. The primary calibration source, NGC7027, had a zenith antenna temperature of 2.1 K and an assumed flux density of 5.9 Jy. The telescope pointing was determined relative to 3C84, 3C273, NRAO530 and 3C454.3, to an accuracy of $\pm 3''$. The mixer receiver had a system temperature of 1,000 K, single sideband, and was followed by a 384-channel autocorrelation spectrometer. With typical spectral resolution of 32 kHz (0.43 km s^{-1}) and integration time of 3 min, the root mean square (r.m.s.) noise was 0.6 K. The rest frequency of the H_2O transition was assumed to be 22.23507985 GHz, and the atmospheric extinction to be 15% in the zenith. All of the observations were made at night, in clear weather.

An area slightly larger than that shown in Fig. 1 was mapped with a grid of 36 points, separated by 20″. Table 1 summarises the properties of the H_2O sources found in this map, and the inset in Fig. 1 shows their spectra. The southern H_2O source has been under observation since 1972 (refs 8–12), and it coincides with a 1,665-MHz OH maser[13] for which no corresponding radio continuum or infrared source has yet been found. The newly discovered H_2O source coincides in position with the more northern OH source[13–15] and with the very compact radio and infrared source. Although some previous workers using larger beamwidths than ours have listed the position of the northern OH source for their observations, it seems clear from the radial velocities that they were actually observing the southern H_2O maser. Two groups[11,12] report limits of 3 Jy for any H_2O emission from the northern position. We conclude that the northern H_2O source has only recently appeared, or that it has reappeared after a long, quiet period.

The main component of this new H_2O source has a radial velocity of -60.8 ± 0.2 km s^{-1} and a width to half-power of 0.6 km s^{-1}. Like many other H_2O sources, it has weaker components at other velocities. On our map, these components coincide in position to within $\pm 5''$ with the main feature at -60.8 km s^{-1}. Similarly, all of the velocity features in the spectrum of the southern H_2O source come from the same, southern position. Nowhere in the map could we find, to a limit of 6 Jy, the components at -112 km s^{-1} reported by Cato *et al.*[11].

The sudden appearance of the northern H_2O source may be related to other unusual properties of the compact H II region. A schematic model of the source (Fig. 2) is as follows.

(1) The exciting star is probably of spectral type O6, since both the far infrared spectrum[16] and the near infrared measurements[6] correspond to a luminosity of $3 \times 10^5 L_\odot$. In contrast, the luminosity of the new H_2O maser is $< 10^{-4} L_\odot$.

(2) Surrounding the exciting star is a compact H II region with an angular size of ~ 1″. Its unusually high turnover frequency of 15–20 GHz (ref. 5) means that it is one of the most compact H II regions known, with an emission measure $> 10^8$ cm^{-6} pc, and an electron density $> 10^5$ cm^{-3}. At 15 GHz (ref. 5), the H II region is 100 times weaker (0.5 Jy) than would be expected from its infrared luminosity. This may be evidence for a high density of dust within the H II region, which absorbs most of the ionising photons. An alternative explanation is that the exciting star has not yet reached the main sequence.

Table 1 Parameters of the H_2O masers near NGC7538

Source	Position (1950)			Radial velocity (line *a*) and line flux density (*b*)							
New H_2O maser	23 h 11 min 36.6	± 0.4 s	*a*	−89.4,	−84.4,	−70.7,	−60.8	(± 0.2)	(km s^{-1})		
	61° 11′ 49	± 3″	*b*	13,	14,	10,	204	(± 4)	(Jy)		
Previously known H_2O maser	23 h 11 min 36.4	± 0.4 s	*a*	−61.3,	−58.6,	−56.1,	−54.1,	−53.1,	−46.6	(± 0.2)	(km s^{-1})
	61° 10′ 28	± 3″	*b*	133,	48,	12,	124,	41,	24	(± 4)	(Jy)

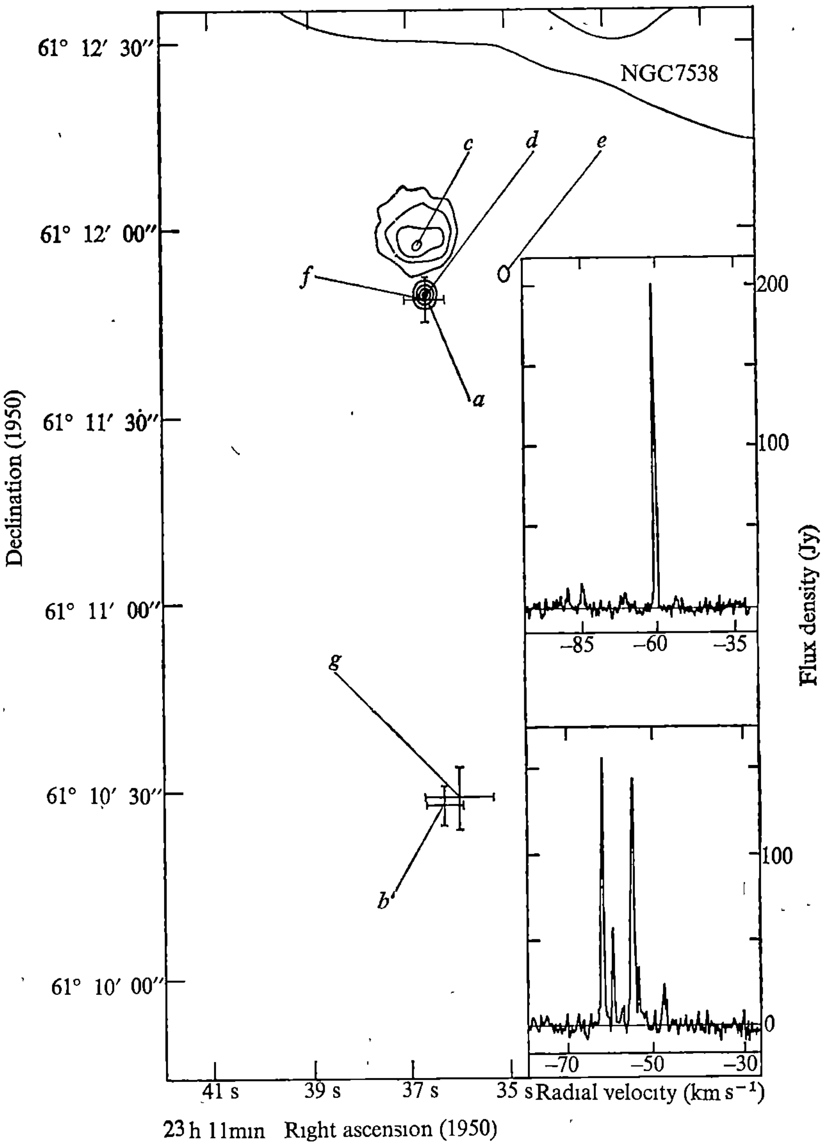

Fig. 1 Location of H_2O and OH masers and continuum sources in the vicinity of NGC7538: *a*, New H_2O source; *b*, previously known H_2O source; *c*, infrared source (IRS) 2; *d*, IRS 1; *e*, IRS 3; *f*, OH 1665/1720 MHz; *g*, OH 1665 MHz. The positions and error bars for the northern H_2O and OH sources are the same. Radio contours are taken from Martin[1]. Inset: Spectra of the northern (upper profile) and southern (lower profile) H_2O masers, obtained with a resolution of 0.43 km s^{-1}.

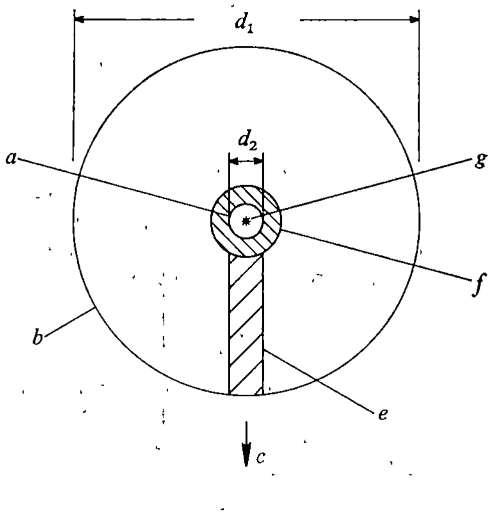
(3) Around the ionised region is a dense shell of dust and neutral gas of angular size < 10″. The visual extinction through this shell is mag 90, and the silicate absorption at 10 μm is one of the strongest known[6]. From the silicate absorption, Willner[6] has derived a hydrogen column density of 1.3×10^{23} cm^{-2}, which with his size limit of 10″ for the dust shell, implies a number density $n_{H_2} > 2\times10^5$ cm^{-3}. This density is high enough to destroy the anomalous refrigeration of formaldehyde, and to explain why H_2CO is seen in emission from this source at 4.8 GHz (ref. 7). The agreement of density estimates from the silicate absorption, the H_2CO emission, and the radio continuum emission indicates that the compact H II region is ionisation bounded.

Fig. 2 Schematic model of the radio source NGC7538-B (= infrared source IRS 1). *a*, Compact H II region, $n_e > 10^5$ cm^{-3}; *b*, shell of dust and neutral gas, $n_{H_2} > 10^5$ cm^{-3}; *c*, ~3 kpc to Earth; d_1, θ < 10″, diameter < 0.1 pc; d_2, θ = 1″, diameter = 10^{-2} pc; *e*, zone of silicate absorption at 10 μm (visual extinction mag 90); *f*, transition zone between ionisation and shock fronts (location of H_2O masers); *g*, O6 star, $L = 3\times10^5 L_\odot$.



According to current ideas[17,18] the ionisation front of the compact H II region is moving into the neutral material at a velocity of ~ 10 km s^{-1}. The radius of the ionisation front is now 5×10^{-3} pc, and the age of the source is ⩽ 10^3 yr. Ahead of the ionisation front, by perhaps 1″ on the sky, is a shock front, moving through the surrounding, dense, neutral matter. The H_2O maser features may arise in the heated region which has a kinetic temperature of 500–1,000 K between the ionisation front and the shock front. The velocity range of 30 km s^{-1} observed in the new H_2O source may correspond roughly to the difference between the radial velocities of the shock front and the exciting star. The H_2CO emission at 4.8 GHz and the OH masers at 1,665 and 1,720 MHz would come from somewhat cooler regions in the dense, neutral shell.

A fair amount of radio continuum, radio line and infrared data are now available for this source. Its geometry seems to be relatively simple, with a single exciting star surrounded by a compact H II region and a dense shell of dust. The object may therefore be a useful prototype for the study of newly formed O stars and H_2O masers in general.

The identity of lunar hydrolysable carbon

LUNAR soils treated with deuterated acid release a variety of deuterocarbon gases including CD_4, C_2D_6, C_2D_4, C_2D_2 and C_3 species[1-3]. We now suggest that the principal hydrolysable carbon phase in lunar samples is carbon in solid solution in body-centred cubic iron (α-Fe). The yield of deuterocarbons (excluding C_2D_2) from a lunar soil is probably a quantitative estimate of this carbon.

The iron–carbon–oxygen system provides a useful basis for the evaluation of the iron phases in lunar samples although this does not mean that iron in lunar soil is necessarily formed by equilibrium gas phase reduction. We have examined synthetic alloys of carbon in α-Fe, together with some samples of cementite (Fe_3C), prepared by reduction of pure Fe_2O_3 in mixtures of CO and CO_2 at selected temperatures and 1 atm total pressure. The gases released by treatment with 38% DCl in D_2O were analysed by gas chromatography[1]. The conditions of sample preparation, together with X-ray diffraction (XRD) data and the yields of deuterocarbons, are listed in Table 1

The yields of deuterocarbons were low from samples which have been shown by XRD to contain cementite (A3, A5, 8224) and also from sample A1 which, according to the phase diagram, should contain this material. The majority of samples, indicated by XRD to be α-Fe, release considerable quantities of deuterocarbons (up to 0.6% by weight is hydrolysable carbon) the largest amounts being evolved from specimens prepared in conditions of high carbon solubility. An α-Fe (8225) prepared in non-carburising gases (H_2–CO_2 mixtures) had only a minimal amount of reactive carbon.

Our results were unexpected for two reasons. first, we obtained α-Fe samples in conditions which, according to the Fe–C–O phase diagram[4,5], should produce the γ phase; and second, the quantity of carbon present in the α-Fe is greater (up to 0.6 weight %) than the published solubility limit (0.02 weight %) of carbon in α-iron[4,6]. Our starting materials were of much higher purity than those used to establish the phase diagram, and prepared samples were quenched[7] after synthesis, which may allow solubility limits to be exceeded.

From the results, we conclude that iron carbides are unlikely to be the hydrolysable carbon phase in lunar soils. Carbon in solid solution in iron, probably associated with α-Fe, is a more likely candidate. All deuterocarbon gases liberated from lunar soils, with the exception of C_2D_2, can be accounted for by carbon in solid solution in iron phases. None of the synthetic samples released C_2D_2. In the investigation of lunar soils this species presumably results from hydrolysis of groups I and II metal acetylides which are the only carbides shown to release acetylene[8,9]. Since the suggestion[3] that the hydrolysable carbon phase in lunar soil might be the meteoritic carbide, cohenite $(FeNi)_3C$, the iron–carbon phase which is the precursor of the deuterocarbons has been referred to as carbide, "carbide", carbide-like or material reacting as carbide. On the basis of the present results, the use of the term carbide should be discontinued, as iron carbide seems to be essentially inert to acid attack[10]. The only fragments of true carbide to be identified in lunar fines are those recognised by microscopy[11]. As only 1–2% of the carbon in samples of meteoritic cohenite could be converted to deuterocarbons by DCl, it has been suggested that almost all the total carbon present in lunar soils might be associated with iron[12]. If the deuterocarbons released from lunar soil are considered as a quantitative yield of C in α-Fe, then only 15–25% of the total carbon is connected with free metal. The bulk of lunar carbon is presumably implanted solar wind atoms which exist in the silicate matrix of soil grains in an as yet unidentified chemical state.

There is considerable evidence that finely divided submicron-sized iron, which is ubiquitous in lunar soils[13,14] is the α phase. Opaque inclusions $\sim$ 150 Å in diameter in glassy agglutinates, give a diffraction pattern consistent with α-Fe (ref. 15). Ferromagnetic resonance data[16] imply that α-Fe has a low nickel content. The Curie points determined for iron in lunar soils[17,18] ($\sim$ 770 °C) are greater than those for γ-iron and cohenite, which are less than 600 °C and 215 °C respectively[19]. The ratios of C_1 to C_2 deuterocarbons obtained by the Berkeley group[8,20] from lunar soils are similar to the values listed for C in α-Fe in Table 1.

Using data for carbon as CD_4 from 15 lunar soils[1] and values obtained by ferromagnetic resonance spectroscopy[13,21] for the abundance of finely divided metal in aliquots of the same samples, the concentration of carbon in the α-iron in lunar material can be calculated as 0.27–0.77% by weight. The calculated values are in excess of the solid solubility limits of C in α-Fe but are similar to the values obtained for our synthetic α-Fe samples.

The processes of formation of lunar metal and/or the incorporation of carbon evidently allow the normally accepted solid solubility limits to be exceeded. Perhaps iron grains $\sim$ 150 Å in diameter contain insufficient crystal boundaries and defects to promote the crystallisation of carbide. As already stated, it is unlikely that iron in lunar soils was formed in equilibrium conditions. We have tried to reduce silicate glasses of lunar composition in conditions similar to those used for the preparation of α-Fe samples. In all cases, the amounts of CD_4 released from reduced glasses were very small: $<$ 0.05% of the glass had been reduced to Fe metal, even though reaction times of up to 24 h were used. The presence of silicate is known to require more strongly reducing conditions for iron formation[22]. The subsolidus reduction process suggested[17] as the origin of iron in lunar soil may, in fact, be appropriate only to major impacts which produced highly metamorphosed breccias containing coarse grained iron and very little hydrolysable carbon[23].

Of the mechanisms which have been suggested for the formation of metallic iron in the lunar regolith, only preferential sputtering by the solar wind has been shown to be both theoretically feasible[24] and practically possible[25].

Carbon could form solid solutions in surface layers of α-iron produced by sputtering in one or more of the following ways: (1) direct implantation of solar wind carbon into metal—this process is capable of producing solid solutions of carbon in α-iron in excess of solubility limits[26]; (2) under the influence of sputtering, the particle surface will be eroded and iron at the surface will gradually reach carbon previously implanted by the solar wind[27]; (3) thermal events associated with agglutination could induce migration of solar wind carbon from implantation sites to the surface iron[27], and micrometeorite impacts may release carbon species which carburise metal on the surfaces of adjacent grains[10]. All of these suggested processes for carbon could be applicable to the accumulation of chemically bound nitrogen in lunar samples[28]. The increased solubility of nitrogen in iron[6] would account for the greater retentivity of nitrogen[28,29].

We thank the SRC for support and for fellowships to C.T.P. and A.J.T.J. Work in Edinburgh (G.M.B.) was supported by the NERC. B.D.B. thanks Macquarie University for leave of absence. We are also grateful to Dr A. K. Galwey, Queen's University Belfast, for samples of cementite and Hägg carbide, which were used in preliminary investigations.

Implications of metal dispersion from submarine hydrothermal systems for mineral exploration on mid-ocean ridges and in island arcs

METAL enrichments in sediments on open ocean mid-ocean ridge segments and in island arcs have been known for some time[1–4], but, to date, no deposits have been found which are rich in copper, zinc and other heavy metal sulphides to a degree comparable to those in the Red Sea. The fact that concentrated brines were thought to have played an essential role in the formation of the Red Sea metalliferous sediments may have inhibited the search for similar deposits elsewhere, because brines of the Red Sea type are unlikely to occur in the open ocean. The discovery at Matupi Harbour, New Britain, however, that high salinity is not a prerequisite for metal enrichment in hydrothermal solutions[5], indicates that any area of submarine volcanic activity has a potential for high grade metalliferous sediment formation given suitable depositional conditions. In this report the dispersion of metals from submarine hydrothermal sources

Fig. 1 Hypothetical vertical sequence of precipitates on mixing of ascending metal-bearing hydrothermal solution with seawater beneath mid-ocean ridge crests in the open ocean. This sequence occurs horizontally on the sea floor around hydrothermal centres in restricted environments like the Atlantis II Deep in the Red Sea and in shallow water volcanic areas, indicating that the nature of the environment of deposition controls the initiation of the depositional process.

is discussed, and its usefulness in developing guidelines for undersea mineral exploration in volcanic areas is considered.

Metalliferous sediments on mid-ocean ridges and in island arcs are thought to form largely as a result of hydrothermal leaching of the oceanic crust by circulating seawater, which in turn becomes both acid and reduced[6,7]. Precipitation of the metals so derived gives rise to deposits which are characteristically rich in iron oxides and sometimes in a variety of other metals such as manganese, copper, zinc and lead; and occasionally, as in the Red Sea, include metal sulphides of localised distribution and very variable composition. It is the latter which are of potential economic value.

Evidence that mid-ocean ridge sediments vary in composition over short distances in the open ocean, and thus may locally be of high grade has been obtained on the Mid-Atlantic Ridge at 45°N (ref. 8). The chemical variations, particularly in the relative dispersion of iron and manganese, were thought to be related partly to the proximity of the samples analysed to submarine hydrothermal sources of the metals and partly to their selective precipitation on mixing with seawater. Unfortunately, the implications of these variations, in terms of geochemical exploration, for metalliferous sediments could not be evaluated because the location of the presumed hydrothermal outlets on the sea floor were not known. More recently, the selective dispersion and precipitation of iron and manganese from a known hydrothermal source has been noted in the FAMOUS area on the Mid-Atlantic Ridge (X. Le Pichon, personal communication), and hydrothermal manganese deposits have been found on the Mid-Atlantic Ridge at 26°N (ref. 9). Nevertheless, there has been no systematic study published to date of metal dispersion from a submarine hydrothermal source in the deep ocean. Fortunately, however, the likely nature of deep-sea hydrothermal metal dispersion can be deduced from studies of submarine hydrothermal systems in the Red Sea and off Santorini. On this basis a model has been constructed which attempts both to predict the most favourable environments for high grade metalliferous sediment formation on the ocean floor and to aid in the location of the sediments.

Metalliferous sediments of hydrothermal origin have been studied in both the Red Sea, and off the volcano of Santorini in the Cyclades Volcanic Arc in the eastern Mediterranean Sea. In each case there is a dispersion halo of metals around the hydrothermal source, showing, among other things, the selective dispersion of manganese from iron[10,11] (Fig. 1). A similar sequence has been observed around hydrothermal springs debouching into Matupi Harbour, New Britain[12]. These variations probably reflect the well known separation of manganese from iron with changing *p*H and *E*h (ref. 13). Poorly oxidised or reduced acid hydrothermal solutions precipitate the metals selectively on mixing with more alkaline oxidising seawater. Metals other than manganese and iron also exhibit a fractional precipitation in submarine hydrothermal systems. In the Atlantis II Deep of the Red Sea, for example, the first formed precipitates on discharge of the hydrothermal solutions are heavy metal sulphides which occupy a restricted area of the Deep adjacent to the hydrothermal vents[14]. Similarly, sulphides occur underneath the sediments rich in iron oxides near the hydrothermal vents in the caldera of Santorini[15], and immediately adjacent to fumaroles off the Island of Vulcano in the Eolian Archipelago, Western Mediterranean[16]. It seems, therefore, that a model for the complete sequence of precipitates on mixing of hydrothermal solutions with seawater would include the fractional dispersion and precipitation of metal sulphides, followed by iron silicates and/or iron oxides, and finally manganese oxides.

This complete sequence of precipitates has not been reported to date on mid-ocean ridges in the open ocean. The iron- and manganese-rich metalliferous sediments characteristic of such ridges, however, are compositionally similar to the widely dispersed iron and manganese oxides around the Atlantis II Deep where the complete sequence is observed. This suggests that the former may be the equivalent of the sediment in the outer zone of the Atlantis II dispersion halo. If this is so, the sulphide deposits which the model predicts should be present in association with the iron and manganese oxides may occur either in restricted locations near to the hydrothermal vents or within the oceanic crust below the oxide deposits. The general physicochemical nature of seawater over mid-ocean ridge crests in the open ocean would favour the latter alternative in most cases. Oxidising seawater can be expected to penetrate fractures and fissures in the upper part of the oceanic crust leading to mixing with ascending hydrothermal solutions and the precipitation of metal sulphides before the solutions reach the surface (Fig. 1). Disseminated sulphides within rocks of the oceanic crust have been reported by several authors[17–19]. Special conditions leading to a reducing environment at elevated temperature, such as occur in the Atlantis II Deep of the Red Sea, would be required to delay sulphide precipitation until the hydrothermal solutions debouch on to the sea floor.

If sulphides are largely precipitated from submarine hydrothermal solutions within the oceanic crust, where else on the sea floor other than in the Red Sea and in small restricted embayments around volcanic islands might they be expected to form? One obvious locale is within the deep fracture zones which cut mid-ocean ridges in all the oceans and which often expose the oceanic crust to considerable depths. Deep hydrothermal circulation under these fracture zones coupled with the possibility of locally reducing conditions in narrow deep basins, could lead to the precipitation of heavy-metal sulphides. Bonatti *et al.*[20] have explained high heat flow in some fracture zones on the basis of sub-seafloor hydrothermal circulation, and have reported the occurrence of pyrite concretions of supposed hydrothermal origin in the Romanche Fracture Zone, Equatorial Atlantic. In addition, Scott *et al.*[21] have reported the occurrence of manganese deposits of probable hydrothermal origin in the Atlantis II Fracture Zone in the North Atlantic. An additional likely locale for heavy metal sulphide precipitation is in the basins associated with island arcs. These can be both volcanically active[22] and sufficiently topographically diverse to possibly lead to a locally restricted circulation and reducing conditions favourable for sulphide deposition. Ancient marginal seas associated with island arcs are thought to have been the environment of formation of some massive sulphide deposits now exposed on land[23]. Iron- and manganese-rich sediments similar to those on mid-ocean ridges have been found in association with the island arc system in the south-western Pacific Ocean[24], and submarine sulphide deposits may also be present.

It is evident from the above that mid-ocean ridge fracture zones and island arcs warrant more attention in the search for ocean floor metalliferous sediments. The dispersion model discussed here may additionally be of use in locating such deposits. The dispersion halo of manganese around the Atlantis II Deep deposit is up to 20 km in diameter even though the sulphide deposit itself is much smaller[25]. Thus in designing a grid sampling program to locate heavy metal sulphides on the ocean floor, one could look initially for manganese dispersion haloes on a wide-spaced sampling pattern, and, if located, design a smaller grid to search the vicinity for heavy metal sulphides. Tests of the model as an exploration tool are currently being conducted around the TAG hydrothermal field on the Mid-Atlantic Ridge at 26°N, and in a fracture zone transecting the East Pacific Rise at 9°S.

Observation of the interference of neutrons reflected from thin films

DURING measurements of the reflection of neutrons from metallic thin films, we have observed an optical interference phenomenon analogous to the interference of light reflected from plane parallel plates; the experimental arrangement is the neutron analogue of the Lummer–Gehrcke interferometer[1].

A simple application of Snell's Law[2] predicts the essential features of the effect, which is illustrated in Fig. 1. We recall that neutrons of wavelength λ incident at glancing angles θ_1, on a material characterised by a mean coherent scattering length b and with a density of scattering centres N, undergo total reflection when $\theta_1 < Re\,(\theta_c)$ where the critical glancing angle θ_c is given by[3]

$$\theta_c = \lambda\,(Nb/\pi)^{\frac{1}{2}} \tag{1}$$

The refractive index n_2 of the film material may be written as

$$n_2 = 1 - \theta_c^2/2 \tag{2}$$

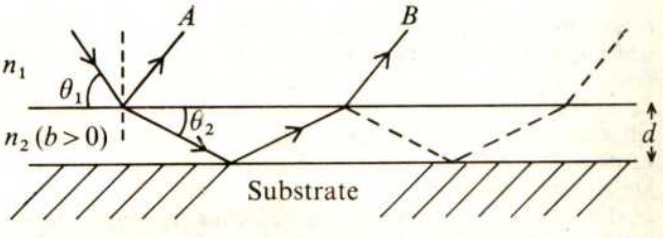

Fig. 1 Reflection of neutrons from a plane parallel plate. n_1 and n_2 are the refractive indices in air and in the thin film respectively. (Note that for neutrons $\theta_2 < \theta_1$, in contrast to the case for light.) Angles are greatly exaggerated for clarity.

Since b may be positive or negative, n_2 may be larger or smaller than 1. From classical optics[1], the path difference for beams A and B can be shown to be

$$\Delta = 2d(\theta_1^2 - \theta_c^2)^{\frac{1}{2}} \tag{3}$$

As there is no phase change for the reflection of neutrons, the condition for constructive interference is given by

$$\Delta = m\lambda \qquad (\text{where } m = 0, 1, 2 \ldots) \tag{4}$$

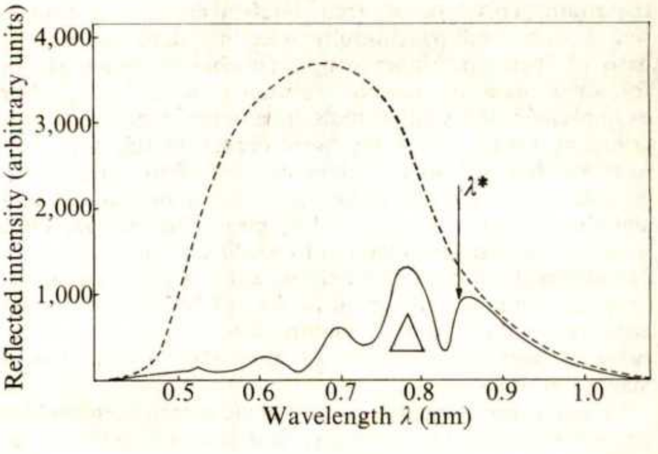
For positive values of b, $m = 0$ corresponds to the limit for total reflection, and interference fringes will only be observed when $\theta_1 > \theta_c$; for negative values of b, interference is possible at all glancing angles. From equations (3) and (4) we see that at a given angle of reflection θ_1, intensity maxima will occur when

$$\lambda = \frac{2d}{m}(\theta_1^2 - \theta_c^2)^{\frac{1}{2}} \tag{5}$$

This analysis determines only the relation between θ_1 and λ at the intensity maxima, and is unaffected by multiple reflection effects.

Interference fringes were observed by reflecting a narrow (1-mm wide), well collimated (divergence $= 1.5 \times 10^{-4}$ rad) neutron beam from thin metallic films evaporated on to plane glass substrates. The film materials used (Be and a magnetised $Co_{0.5}Fe_{0.5}$ alloy) have critical glancing angles greater than that of glass, thus ensuring that substrate reflections do not contribute to the interference peaks. At angles of incidence $\theta_1 > \theta_c$ interference fringes will be observed at wavelengths which satisfy equation (5). For the magnetised material

Fig. 2 Interference fringes measured for neutron reflection from a magnetised $Co_{0.5}\,Fe_{0.5}$ thin film. The wavelength spectrum of the incident beam is shown dashed (not to scale) for comparison. λ^* is the critical wavelength (equation (1)) above which all neutrons are totally reflected at this incident angle ($\theta_1 = 1.5 \times 10^{-2}$ rad). △ represents the wavelength resolution.



b (equation (1)) is replaced by $(b+p)$ and $(b-p)$ for the two neutron spin states in the incident beam, where p is a magnetic scattering length, and where $|b| \simeq |p|$ it is only for the $(+)$ neutron spin state that n_2 differs significantly from unity. This situation exists for the magnetised alloy we used, therefore the neutrons detected in the interference peaks for this thin film are also spin polarised.

The experiment consisted of reflecting a polychromatic incident beam (mean wavelength $\lambda_0 = 0.7$ nm) at a fixed angle θ_1, and analysing the wavelength spectrum of the reflected beam by the neutron time of flight method. The measurements were carried out on the IN11 instrument at the High Flux Reactor, Institut Laue–Langevin, Grenoble; the angular resolution $\delta\theta/\theta_1$ was 1% and the wavelength resolution $\delta\lambda/\lambda_0$ was 5%.

Figure 2 shows the time of flight data observed for a magnetised $Co_{0.5}Fe_{0.5}$ film of thickness 100 ± 15 nm (as measured by a quartz crystal thickness monitor) at $\theta_1 = 1.5 \times 10^{-2}$ rad. Fitting equation (5) to the measured fringe positions gave a 'best-fit' thickness $d = 88 \pm 5$ nm, in agreement with the thickness measured during the evaporation of the film.

The wavelength spectrum of the incident beam (see Fig. 2) limited our observation to four orders of interference. For the beam divergence used, and assuming that the film thickness is completely uniform, the Heisenberg Uncertainty Principle requires the neutron coherence length in this example to be at least 70 nm; it should therefore be possible to observe interference fringes to much higher orders than are reported here.

Optical methods to select diamonds of very high lattice perfection

WE describe here recent developments which permit the selection of diamonds very free from strain by purely optical inspection. Figure 1*a* shows the edge of a diamond slab which chipped while being polished, and Fig. 1*b* the same slab viewed between crossed polars[1]. The birefringent pattern indicates a region of strain centred near the crack, and a dark area where the chip has come away relieving the strain. This type of strain birefringence is, of course, well known, and by carefully selecting diamonds on the basis of their birefringence it is possible to obtain stones for tools with a superior resistance to chipping. For example, the six similar tools in a wear experiment described by Casey and Wilks[2] were chosen in this way, and wore steadily without any chipping. Bell, Wilks and Wilks[3] have described how the resistance of a diamond to cracking and chipping may be estimated by measuring the load on a small diamond sphere required to produce a ring crack on a flat diamond surface. In these experiments, measurements on a diamond slab chosen to be free of birefringence gave consistent values of the fracture load which were about twice as high as those on another slab which showed marked birefringence.

Minimal birefringence is an obvious requirement for strain free stones, but a more critical selection can be made by inspecting the natural octahedron surfaces of a diamond using phase contrast or Nomarski interference techniques. This method had its genesis in an observation[4] of a good quality gem octahedron which exhibited a small group of very shallow pyramidal depressions, or trigons, situated somewhat away from the centre of each face. The fact that the three lines joining the centres of opposite groups of trigons met approximately in the same internal region of the diamond, suggested the presence of an inclusion, from which dislocations spread out to the surface, where they gave rise to the trigon etch features. This interpretation was subsequently confirmed by Frank and Lang[5] using X-ray topography. The presence of trigons on a natural face is thus a further indication of internal strain, and subsequent experiments by Wilks and Wilks[6] showed a marked correlation between the density of trigons and the degree of birefringence. A third indication of lattice imperfection is that carefully polished cube faces of diamond containing impurities deposited on octahedral planes during growth often exhibit rectangular markings or traces where these planes of impurities intersect the surface[7]. In fact, we have never observed any such traces on diamonds selected to have minimum birefringence and freedom from trigons[6].

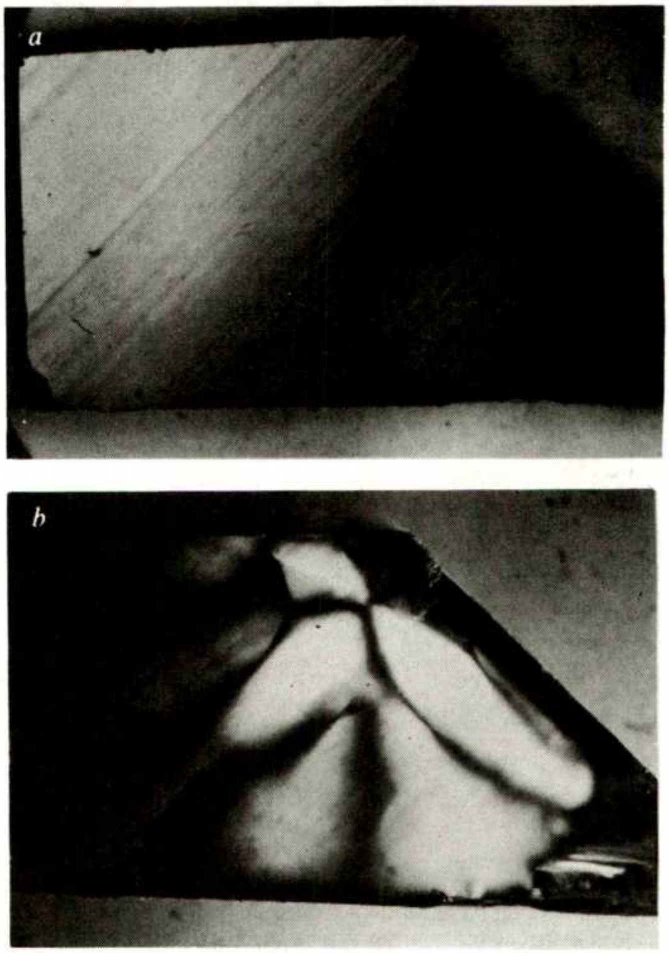

Fig. 1 The polished face of a slab of diamond viewed *a* in incident light, *b* between crossed polars (×36).

Perhaps the most refined selection of strain free diamonds yet made is our recent selection of diamonds for targets for the production of polarised photons in the 5-GeV electron synchrotron NINA of the SRC Daresbury Laboratory, as described by Jackson[8]. To produce polarised photons, the diamond must be oriented so that the synchrotron beam makes an angle of ~ 2×10^{-3} rad with a set of lattice planes in the diamond, with an accuracy of better than 10^{-4} rad. It follows that any local misorientations of the diamond lattice must be small compared with 2×10^{-3} rad, but natural diamonds frequently show lattice curvature of this order. The first stone selected by our optical inspection had a curvature as indicated by an X-ray rocking curve analysis of $<5\times10^{-5}$ rad, and was the first diamond to give a satisfactory beam of polarised photons at Daresbury[8]. Subsequently two more diamonds selected in the same way have met the same stringent requirement of producing a satisfactory beam of photons. Of course, to obtain such a degree of perfection it is necessary to use high quality optics and to make the selection from a large sample of diamonds.

I thank De Beers Industrial Diamond Division for their support, and Mr W. F. Cotty for discussions.

Ordered states in systems of macroscopic particles

ONE of the most striking observations of systems consisting of macroscopic particles (~ 1 μm in diameter) dispersed in a uniform background, is that in certain circumstances the particles can form themselves into an ordered or solid-like array. The importance and significance of these structures to a wide range of materials, including virus suspensions, soils, lacquers and latices, was recently discussed quite extensively by Efromov[1]. In recent years this has also been the subject of considerable experimentation on well characterised polystyrene latices[2–4]. We have developed a theoretical model for a stable colloidal dispersion[5] in which this disorder–order transition in a system of macroscopic particles is treated as the analogue of the fluid–solid transition in molecular materials. This theoretical approach shows that this ordering is a consequence of the repulsive forces between the particles. We show the more detailed features of the structure of the disordered and ordered phases of systems of colloidal or macroscopic particles.

Briefly, the model replaces an infinite system of interacting particles by a small (32 or 108 particles) periodic system. The interaction[6], consisting of a combination of van der Waals' attraction and double layer repulsion, is assumed to operate between all possible pairs of particles in the system. The properties of the system, such as excess pressures, internal energies and radial distribution functions, are then obtained by Monte Carlo averaging over the likely configurations of the particles. The results obtained are very similar to the measured properties of aqueous polystyrene colloids[5,7]; thus the model is at least qualitatively correct.

One significant advantage of the Monte Carlo model, over perhaps more expedient but less exact approaches[7], is that it enables one to obtain much finer details of the structure of a system than can be obtained experimentally. For example, one cannot only calculate the experimentally accessible radial distribution function, but also the higher order distribution functions[8,9] and, even more interestingly, typical configurations can be displayed with the Monte Carlo model[10].

We have chosen a colloidal system consisting of spherical particles of diameter 595 nm with a surface potential of 60 mV, dispersed in an aqueous electrolyte (relative permittivity of 80) at room temperature[5]. The results of the Monte Carlo model at electrolyte concentrations of 0.5 mol m^{-3} and 0.05 mol m^{-3} will be discussed.

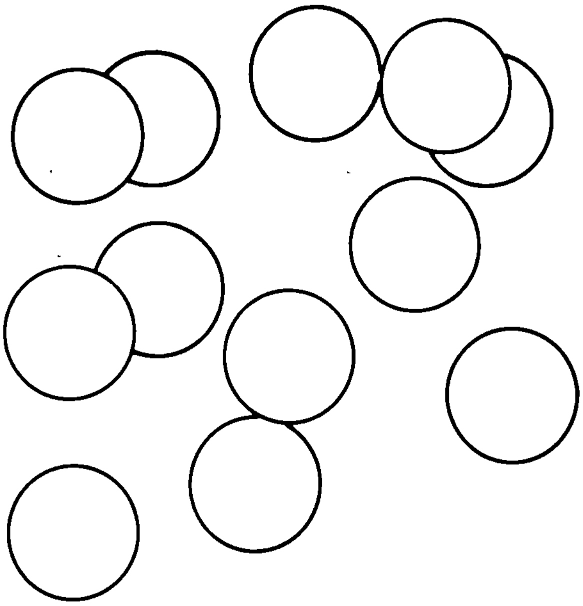

Fig. 1 Two-dimensional projection of a typical Monte Carlo (MC) configuration for a volume fraction φ = 25% and concentration of monovalent 1:1 background electrolyte $n = 0.5$ mol m^{-3}.

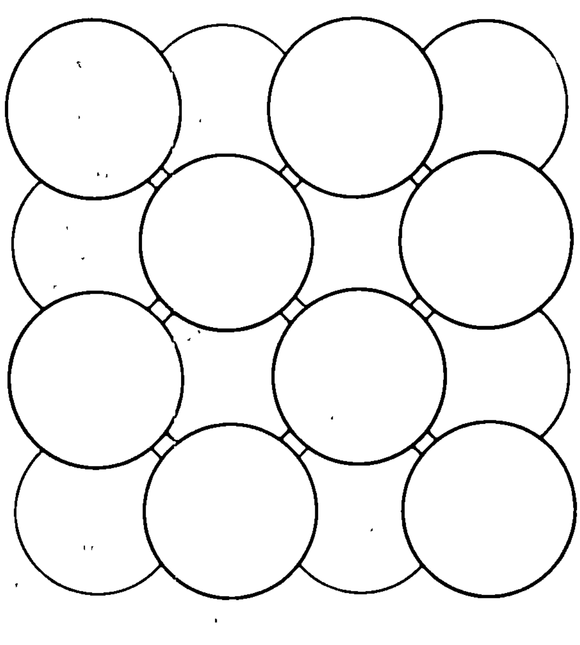
For the higher electrolyte concentration the particles form an ordered array (face-centred cubic (fcc)) for percentage volume fractions, φ, in excess of 43%. This may be seen from the radial distribution functions, $g(r)$, calculated for the respective volume fractions at this electrolyte concentration[5]. To demonstrate what this gross structure indicator, $g(r)$, is showing, we display typical particle configurations for φ=25% and φ=50% in Figs 1 and 2, respectively. (In these diagrams we have drawn only those particles whose centres lie in a slice of thickness approximately equal to one particle diameter.) As may be seen, the system of particles at the higher volume fraction is indeed ordered and nearly conforms to a perfect fcc structure

Fig. 2 Two-dimensional projection of a typical MC configuration for φ = 50% and $n = 0.5$ mol m^{-3}.



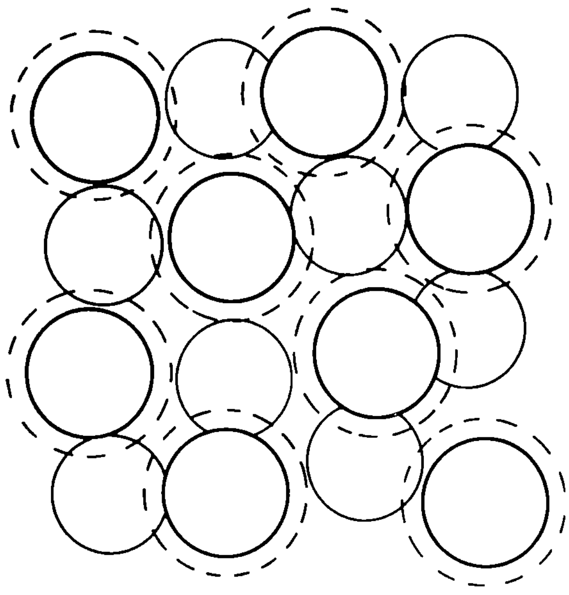


Fig. 3 Two-dimensional projection of a typical MC configuration for $\varphi = 25\%$ and $n = 0.05$ mol m^{-3}. The dashed circles represent the effective particles.

with a particle surface to surface separation as one would expect in a microscopic crystal. On the other hand, no such ordering is evident for the system of particles at the lower volume fraction.

At the lower electrolyte concentration (0.05 mol m^{-3}) the particles change to an ordered state at $\sim \varphi=25\%$. Figure 3 shows the distribution of particles for this case for $\varphi=25\%$. Again, an almost regular fcc arrangement is indicated but now with a particle surface to surface separation of $\sim$ 280 nm. As one lowers the background electrolyte concentration the particles order themselves at progressively lower volume fractions.

The reason for this behaviour is that the bare particle diameter is not a good indicator of the real size of the particle. Rather, the effective size of the particle is that of the particle plus the effective thickness of the attached double layer, the latter being a measure of the range of the repulsive potential acting between the particles. In terms of this effective diameter the properties of the system, including the disorder–order transition, can be very simply accounted for by means of a hard sphere model[11]. Some simple criteria exist for calculating the effective hard sphere diameter and Fig. 3 shows the effective particles superposed on the real particles. The effective volume fraction of the system is $\sim$ 50% with the mean surface to surface separation of the effective particles $\sim$ 25 nm (see Fig. 2).

One final point to be made is that the exact lattice type observed for the ordered phase will depend strongly on the interparticle potential, particularly on its range.

In conclusion, it is hoped that this short article has demonstrated the power of machine methods to explore and display the structure of physical systems in general, and that it will be used more in the future to help visualise and understand the fascinating properties of colloidal dispersions, in particular.

Polymer effects on microjet impact and cavitation erosion

THERE is a growing interest in using high molecular weight polymers as additives in various fluid-engineering systems. These activities are mainly stimulated by the anomalous drag reducing characteristics some high polymers exhibit in turbulent flows[1]. Early experiments also showed that polymeric additives suppress flow-generated cavitations[2,3]. An interesting question may therefore be raised as to the effects of high molecular weight polymers on cavitation erosion. We report here attempts made to examine such effects on static vibration-generated cavitation and flow cavitation.

It is generally accepted that in cavitation erosion the main damage results from the collapse of single cavitation bubbles near the solid surface. In such a collapse an inward moving microjet is always formed against the solid surface[4] and the damaging effect of the microjet with velocity as high as 130 m s^{-1} impinging on the surface[5] has been confirmed[6]. It was proposed earlier[7] that polymer viscoelastic effect might introduce very high stresses by stretching the fluid, and consequently the formation of the microjet might be retarded. It was not, however, realised until recently that the development of such high stresses requires substantial flow time[8]. In the case of a microjet, although the jet velocity increases rapidly to apply a strong stretching to polymer molecules, the flow time involved is only $\sim 10^{-6}$ s, considerably shorter than polymer relaxation times ($\sim 10^{-3}$ s). Therefore one may have to expect that any polymer effect on microjet formation and thus cavitation erosion would be minimal.

Recently, Ashworth and Proctor[9] reported the results of standard vibratory tests in solutions of a hydrolysed polyacrylamide, where the cavitation erosion rate is increased. They also showed that the viscous effect was not responsible for the increased damage because, in a water–glycerol mixture, the cavitation damage was actually decreased greatly. While no indication of the possible mechanism was given, the result of increased damage was considered to be analogous to that of enhanced jet-cutting in polymer solutions[10]. Some remarks will now be offered with regard to this proposed analogy.

First, the high speed liquid jets for jet-cutting operations have very high Reynolds numbers and are therefore turbulent. In these applications fluid momentum is converted into stagnation pressure to erode away the solid material. The effect of polymer in this case is mainly to introduce improved local stability to prevent small scale jet breakup. The result is that the turbulent jet possesses less violent appearance, higher velocity and longer throw[11]. In the case of cavitation microjet, however, because of their extremely short lifetime and small physical size, instability-type disturbances would not have enough time to grow so the laminar flow prevails. The damage caused by the microjets is perhaps of an impact nature, characterised by the water-hammer pressure, estimated[5] to be as high as 600 atm. This most impressive stress is sufficient to crack the solid to initiate subsequent material removal, and is in direct contrast to the gradual 'chew-away' actions in turbulent jet-cutting. This consideration is further shown by the liquid viscous effects. In the case of jet-cutting, Semerchan[12] demonstrated that a systematic increase in viscosity causes the jet forces to increase accordingly. But in the more viscous glycerol–water mixture cavitation erosion rate was lower as compared with the water

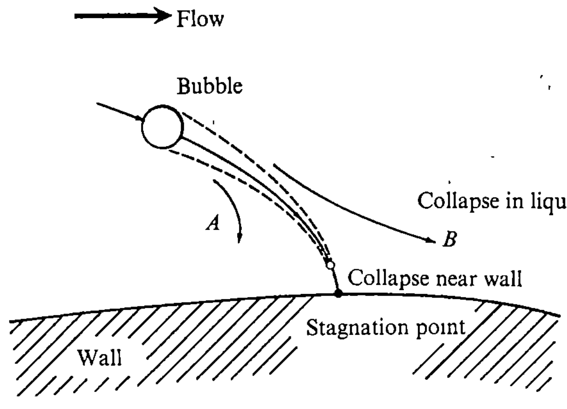

Fig. 1 Schematic representation of collapsing travelling bubbles approaching a stagnation point.

case[9]. This clearly suggested that the nature of the microjet is different from that of the turbulent jets for jet-cutting and the erosive activity of microjets is less intensive in a more viscous environment.

The explanation for the observed increase in cavitation erosion rate in polymer solution may still have its origin in polymer viscoelasticity. A deformational process in polymer solutions may be characterised by the relative scale between the duration of the deformation process and the polymer relaxation time. If the deformation time is sufficiently long, the polymer molecules adjust readily to the new deformed state. But if the duration of the deformation is much shorter than the polymer relaxation time, not enough time is allowed for the polymer molecules to adjust themselves and the material can only respond in a 'solid-like' elastic fashion. Since in the case of cavitation microjet the time scale is only $\sim 10^{-6}$ s and much shorter than polymer relaxation time ($\sim 10^{-3}$ s), it is expected that the polymer jet impinges on the wall with more solid-type impact than the water case. This additional impact stress may be briefly developed.

Consider a simple viscoelastic model for rapid deformation[13] where the total stress τ is

$$\tau = -pI + GB^{(1)}\Delta t + 2K[B^{(1)}\Delta t]^2 + \frac{G}{2}B^{(2)}\Delta t^2 + \ldots$$

where $B^{(n)}$ are deformation tensors defined as

$$B_{ij}^{(1)} = \frac{\partial v_i}{\partial x_j} + \frac{\partial v_j}{\partial x_i}$$

$$B_{ij}^{(n+1)} = \frac{\mathrm{D}B_{ij}^{(n)}}{\mathrm{D}t} - B_{mj}^{(n)}\frac{\partial v_i}{\partial x_m} - B_{im}^{(n)}\frac{\partial v_j}{\partial x_m}$$

G and K are the material moduli, and Δt represents the very short duration of deformation. For an axial motion with velocities

$$v = (\gamma x_1, -\frac{\gamma}{2}x_2, -\frac{\gamma}{2}x_3)$$

it can be readily shown that

$$\tau_{11} = -p + 2G\gamma\Delta t + (8K - 2G)\gamma^2\Delta t^2$$

For extremely small Δt ($\sim 10^{-6}$ for the interest here) as compared with polymer relaxation time ($\sim 10^{-3}$), we may approximate

$$\tau_{11} = -p + G\gamma\Delta t$$

A modified Bernoulli equation may be written as

$$\frac{1}{2}\rho U^2 - \tau_{11} = \frac{1}{2}\rho U^2 + p - 2G\gamma\Delta t = p_\infty$$

where p_∞ is the pressure in a quiescent reference state of uniformity. Compared with the Newtonian case

$$\frac{1}{2}\rho U^2 + p_{\mathrm{N}} = p_\infty$$

one observes that the difference represents an additional impact stress (or pressure)

$$\Delta p = p - p_{\mathrm{N}} = 2G\gamma\Delta t$$

This term, which may be responsible for the increased cavitation erosion effect in polymer solution, is proportional to the elasticity of the liquid represented by an elastic modulus G, which normally scales with polymer concentration c and molecular weight like $c[\eta]$ if $[\eta]$ is the polymer intrinsic viscosity. This is in agreement with the observed result that the cavitation erosion rate is slightly higher in 1,000 p.p.m. solution than in 100 p.p.m. solution[9].

Finally, while the results of Ashworth and Procter were obtained in a static vibratory-test system, it is noted that the cavitation fields occurred in most actual engineering applications are involved in a flow system. It is known[6] that only one out of 10^4–10^{10} cavitation bubbles that are swept into a stagnant flow region seems to collapse adjacent to a solid surface and actually produces a damage pit (Fig. 1). Therefore the effect of flow behaviour is extremely important to this highly selective collapse process in causing damage. The suppression of flow-generated cavitation has been attributed primarily to higher viscoelastic stresses built up near the nose of a blunt body[2]. Similarly, it may be expected that a proper application of the polymer additives may introduce higher stresses in the stagnation region which would lead to the following consequences. First, for a bubble travelling along the stagnation line, a higher external pressure would cause the bubble to collapse faster, and the chance for the cavity to be carried towards the surface is less. Second, for bubbles travelling along paths close to the stagnation line, higher stresses in the stagnation zone cause them to be repelled away from this region to take either path A or B shown in Fig. 1. A cavity that takes path A would be somewhat against the flow and quickly collapse in the liquid, causing practically no surface damage. On the other hand, a cavity following path B would be swept away downstream so that it would never come close enough to the surface to cause damage. Consequently, a reduction in flow-cavitation erosion may be expected. Experiments studying polymer effects on cavitation collapse and erosion in a flow system would be of some interest, and efforts along this line are now under way at this laboratory.

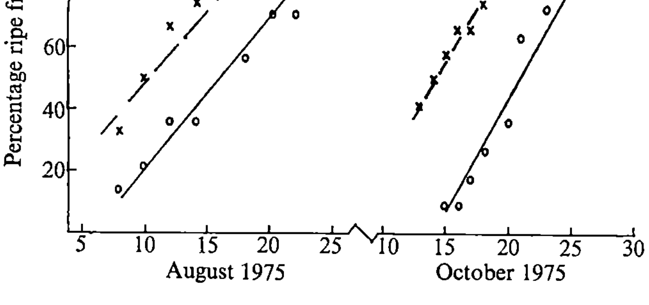
Leaf cultivar influences composition and ripening of apples

POMOLOGICAL literature contains two reports of the influence of grafted scions on the size, colour and ripening season of apples borne on the stock portions of topworked trees[1,2]. The experiment reported here, initiated as part of of a larger study of apple ripening control mechanisms, confirms those reports.

Buds from a Lodi apple tree were grafted into branches of several Golden Delicious apple trees. When the Lodi scions bore fruit, half the scion branches were defoliated in early July, one month before the normal Lodi ripening season. Thereafter, these Lodi fruits received synthates translocated from Golden Delicious leaves. In late July, gas-sampling tubes (8 mm in diameter × 40 mm) were secured with grafting wax to the intact calyx ends of these Lodi fruits; the open end of each tube was fitted with a serum cap. Similar tubes were also secured to Lodi fruits borne on the other scion branches which still had Lodi leaves attached. The atmosphere inside the gas-sampling tubes equilibrated with apple internal atmospheres. A 1-cc syringe was used on alternate days to withdraw gas samples from the tubes and ethylene present in the samples was determined as described previously[3]. The ethylene analyses indicated the Lodi apples fed with synthates translocated from Golden Delicious leaves ripened slightly earlier than Lodi apples fed with synthates translocated from their own leaves.

In the second season, half of the Lodi-fruited branches were girdled in early July to prevent translocation of synthates from Golden Delicious leaves. On the same date, all the leaves were removed from the remainder of the fruited Lodi limbs. Lodi fruits on defoliated limbs received synthates translocated from Golden Delicious leaves. To ensure comparable accumulation of Golden Delicious leaf synthates in Lodi apples on the defoliated scions, bark girdles were located a few side branches below the Lodi graft unions. A similar procedure was followed in mid-September for limbs bearing Golden Delicious fruits.

Fig. 1 Ripening of *a*, Lodi and *b*, Golden Delicious apples borne on limbs fed with synthates from Golden Delicious (×) or from Lodi (○) leaves. In each of the four treatments there was a total of 16 fruits on 6–10 trees.



Lodi fruits were judged to be ripe when the ethylene in the gas-sample tubes reached 10 p.p.m. or higher; or when, in a few cases, the fruits abscised or split open. Golden Delicious fruits, which ripen with lower levels of ethylene, were judged to be ripe when ethylene in the gas-sample tubes was 4.5 p.p.m. or higher. The data (Fig. 1) indicate that Lodi and Golden Delicious apples fed with synthates translocated from Golden Delicious leaves ripened 5–7 d earlier than comparable apples fed with synthates translocated from Lodi leaves. Although the source of the synthates influenced the time of fruit ripening, the source of the synthates did not seem to influence the level of ethylene in the apples once they began to ripen on the tree.

During the Golden Delicious ripening season, red stripes appeared on fruits fed with Lodi leaves. An analysis of skin composition indicated that, in comparison with similar fruit fed with Golden Delicious leaves, fruit fed with Lodi leaves contained higher levels of anthocyanin and flavonols, but similar levels of soluble carbohydrates, starch and flavolans (Table 1).

Table 1 Skin composition of Golden Delicious apples from girdled limbs fed with synthates from Golden Delicious or Lodi leaves

Leaves	Soluble carbohydrate (mg cm^{-2}) (4)	Starch (mg cm^{-2}) (4)	Anthocyanin (nmol cm^{-2}) (5)	Flavonols (nmol cm^{-2}) (6)	Flavolans as monomers (μmol cm^{-2}) (5)
Golden Delicious	3.0	0.69	0.84	47.9	0.95
Lodi	2.9	0.75	4.09	101.0	0.90

Reference numbers in parentheses.

In summary, our analytical study verified orchard observations made in 1880 and 1927 that the cultivar of apple leaves may influence the composition and the time of ripening of apple fruits.

Watering converts a CAM plant to daytime CO_2 uptake

THREE different photosynthetic options have been identified in plants[1,2]: (1) most plants have the reductive pentose phosphate or C_3 pathway, where CO_2 is incorporated into ribulose-1,5-diphosphate (RuDP) to yield two molecules of 3-phosphoglyceric acid, a three-carbon compound; (2) the C_4 mode, where the first photosynthetic products are four-carbon dicarboxylic acids like oxaloacetate and malate formed following CO_2 incorporation into phosphoenolpyruvate (PEP); and (3) crassulacean acid metabolism (CAM), found in many succulent plants growing in arid regions. In the last, stomatal opening and net CO_2 uptake occur at night, CO_2 being incorporated by way of PEP carboxylase into organic acids. The tissue acidity decreases as the organic acids are decarboxylated during the day, when the internally released CO_2 is prevented from leaving by the closed stomata. The water vapour concentration difference between the tissue and ambient air is less at night, and thus the night-time stomatal opening of CAM plants leads to overall water conservation. For example, the water lost per CO_2 fixed averages about sixfold higher for C_4 plants and tenfold higher for C_3 ones than for CAM plants in natural conditions[2]. The net daily CO_2 uptake by CAM plants is less than for C_3 or C_4 plants, so CAM plants tend to be relatively slow growing.

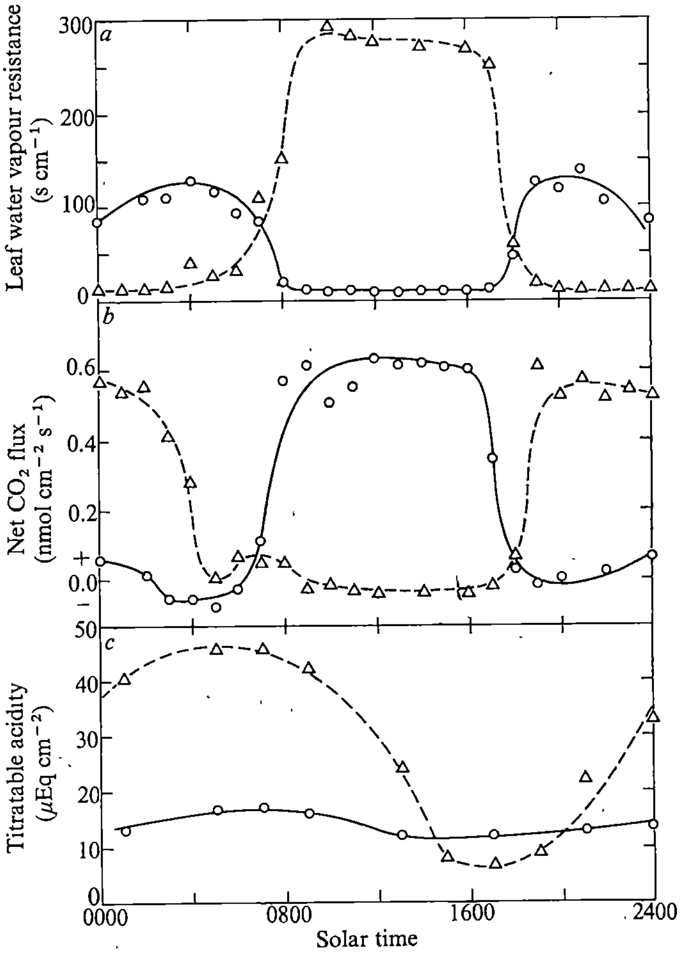
We investigated the results of giving CAM plants an adequate water supply, thereby obviating the need for water conservation and show that this leads to their conversion to daytime CO_2 uptake. We used *Agave deserti* Engelm. (Agavaceae) plants, which are common in the sandy soils of the Colorado, Mojave and Sonoran deserts[3], and experimented on plants maintained in a glasshouse so that the watering regime could be controlled. Gas exchange was measured with a Siemens null-point closed-circuit flow system[4,5] with a Cambridge Systems EG&G 880 dew-point hygrometer for measuring water vapour concentrations and a Beckman 315A infrared gas analyser for CO_2 concentrations. At about weekly intervals, the distal end of an attached leaf representing about 100 cm² of surface area was sealed into the leaf chamber and maintained under natural illumination for a determination of gas exchange over 24 h. The resistance for water vapour diffusion from a leaf (R_{wv}) equals the concentration of water vapour within a leaf (assumed to be the saturation value at the leaf surface temperature) minus the water vapour concentration in the leaf chamber, divided by the measured rate of water vapour loss per unit leaf area. To measure leaf acidity[6,7] approximately 4 g of leaf tissue were removed with a cork borer, ground in 100 ml of distilled water, boiled for 5 min, and then filtered. Two 40-ml aliquots were titrated to an endpoint of *p*H 6.4 using 0.011 N NaOH. For determination of PEP and RuDP carboxylase activities, each gram of freshly removed leaf tissue was ground in 5 ml of 0.2 M HEPES buffer (*p*H 8.0), 1 mM Na-EDTA, 1 mM dithiothreitol, and 40 mg ml^{-1} polyvinyl pyrrolidone; enzyme activities were assayed by following the conversion of $KH^{14}CO_3$ into stable products[8]. Soil water potential (Ψ_{soil}) was measured daily with a Wescor HR 33 dew-point microvoltmeter and PT 51-05 soil thermocouple psychrometers.

Four plants were potted in the field when no natural stomatal opening was occurring ($\Psi_{soil} < -90$ bar, where 1 bar = 10^5 Pa). Ψ_{soil} was then raised to -0.1 ± 0.1 bar, which induced night-time stomatal opening After two weeks in a wet soil, CAM-type stomatal movements (Fig. 1*a*), a night-time CO_2 influx (Fig. 1*b*), and diurnal variations in the tissue acid level (Fig. 1*c*) were clearly evident. After four more weeks with a wet soil, the stomata remained open in the morning; the net CO_2 influx was 0.24 nmol cm^{-2} s^{-1} at 0900 and did not cease until 1130. After a total of 12 weeks with a Ψ_{soil} maintained at -0.1 ± 0.1 bar by daily watering, the night-time stomatal opening was replaced by a daytime opening, characteristic of C_3 and C_4 plants (Fig. 1*a*). Net CO_2 uptake (97% of the daily total) now occurred during illumination (Fig. 1*b*) and there was little diurnal change in tissue acidity (Fig. 1*c*). Allowing the soil to dry for 3 weeks caused the plants to revert to a more-or-less normal CAM mode with night-time stomatal opening and daytime closing.

When the plants were exhibiting photosynthesis primarily during the daylight hours and there was an apparent lack of the circadian fluctuation of organic acids, some form of either the C_3 or C_4 photosynthetic pathway was presumably being followed. The vascular tissue of *A. deserti* seemed to have a bundle sheath containing chloroplasts, but the cells were not as conspicuous as for most C_4 plants. Measurements of PEP carboxylase and RuDP carboxylase indicated a ratio of the activities similar to that observed for C_4 and CAM plants[1]. For samples taken at 1200 from a plant exhibiting daytime stomatal opening, the PEP carboxylase activity was 1.01 μmol CO_2 fixed per g wet weight per min compared with 0.080 for RuDP carboxylase. In the CAM mode (at 0000) there was also high PEP carboxylase activity relative to the RuDP carboxylase activity (0.80 as against 0.078 μmol per g wet weight per min). Whether the CO_2 assimilation in the light involves primarily PEP or RuDP carboxylase remains to be determined. The CO_2 compensation value measured at 1200 during daytime CO_2 uptake for plants at 17 °C in saturating light conditions and 21% O_2 was relatively high (an average of 88 μl l^{-1} for three experiments). This is not characteristic of C_4 plants (CO_2 compensation point generally less than 10 μl l^{-1} (ref. 9)), but is similar to CO_2 compensation points for C_3 plants.

The maximum R_{wv} for *A. deserti* was twofold greater in the CAM mode (~300 s cm^{-1}, Fig. 1*a*) than for the daytime CO_2 uptake, indicating a tighter closing of the stomata when water conservation is more critical. The daytime stomatal opening did not produce a much greater maximum rate of photosynthesis than the CAM night-time opening (0.63 compared with 0.57 nmol cm^{-2} s^{-1}, Fig. 1*b*). These maximum rates are two- to sixfold lower than those for conventional C_3 and C_4 plants[2], primarily because of the rather high resistance for the gas phase part of the pathway for *A. deserti* (minimum R_{wv} of about

Fig. 1 Conversion from crassulacean acid metabolism (CAM, △) to daytime CO_2 uptake (○) after watering *Agave deserti*. Gas exchange data were obtained in identical conditions using attached leaves 2 weeks (CAM) and 12 weeks after raising Ψ_{soil} from < −90 bar to −0.1 bar. Acidity was determined for leaves on a companion plant showing the same stomatal movements. Air in the leaf chamber was maintained at 17.0±0.4 °C and 5.0±0.1 μg H_2O cm^{-3}. Illumination was provided by natural sunlight (supplemented with a xenon arc lamp during brief cloudy periods) and controlled using neutral density screens so that it was representative for a cloudless winter day (for example, January 1, 1976). Illumination had a maximum of 80 klx at 1200 with values of 10 klx at 0730 and 1645, as determined using a Spectra FC 200-TV-B meter. Data are expressed on the basis of total area (both sides) for these succulent leaves.



7 s cm^{-1} for both modes). This succulent arid-region plant would thus still grow relatively slowly if switched to the daytime mode of photosynthesis. For the CAM mode, the net CO_2 fixation was 18.3 μmol cm^{-2} for 24 h (Fig. 1*b*), whereas it was 21.0 μmol cm^{-2} for daytime CO_2 uptake. These values of net daily photosynthesis were obtained in conditions of wintertime illumination. The relative advantage of predominantly daytime photosynthesis would be greater for the longer days (a longer period for daytime CO_2 uptake) and shorter nights (less time for the CAM night-time CO_2 influx) that would occur at other times of the year. The time course of the increase in titratable acidity closely followed the net accumulation of CO_2 in the leaf during the night-time period in the CAM mode and 2 μEq of acidity were produced per μmol CO_2 taken up as expected (Fig. 1*b* and *c*).

When water is readily available, strictly adhering to the water-conserving CAM mode may no longer be beneficial to a CAM plant. At least some supplemental daytime stomatal opening and CO_2 uptake would become advantageous. Indeed, many CAM plants show a net CO_2 uptake during the day when not under water stress; such daytime CO_2 uptake increased as water became more available for *Bryophyllum daigremontianum*[10], *Agave americana*[11], and *Dudleya farinosa*[12]. The shift to daytime photosynthesis was only partial, however, as in all cases the night-time stomatal opening and net CO_2 influx characteristic of CAM plants still occurred. In different experiments, Osmond *et al.*[13] showed that subjecting *Kalanchoe daigremontiana* to 9 weeks of drought caused the carbon isotope discrimination ratio to shift from a value close to that for C_3 plants towards that expected if all CO_2 uptake took place at night in a CAM mode. For *A. deserti*, it seems that watering can cause an essentially complete switch from CAM to daytime photosynthesis (Fig. 1). Such switching did not lead to greater net daily photosynthesis for winter days, but greater photosynthetic productivity would be predicted for the longer daylight periods occurring at other times of the year. Thus, the ability to shift modes of photosynthesis when water is not a limiting factor could be a distinct advantage to this plant.

Memory phases in *Drosophila*

MEMORY in many organisms can be disrupted by anaesthesia or electroconvulsive shock applied shortly after training. Later, if left undisturbed, the memory becomes immune to these agents. This suggests that learned information is stored by the brain in more than one form[1–4]. A population of *Drosophila melanogaster* can be trained to avoid an odorant by presenting the odour in combination with electric shock. When tested later without shock, the flies avoid this odorant specifically (ref. 5 and unpublished results of Y.D.). By anaesthetising the flies briefly with cold at various times between training and testing, we have found two memory components in *Drosophila*.

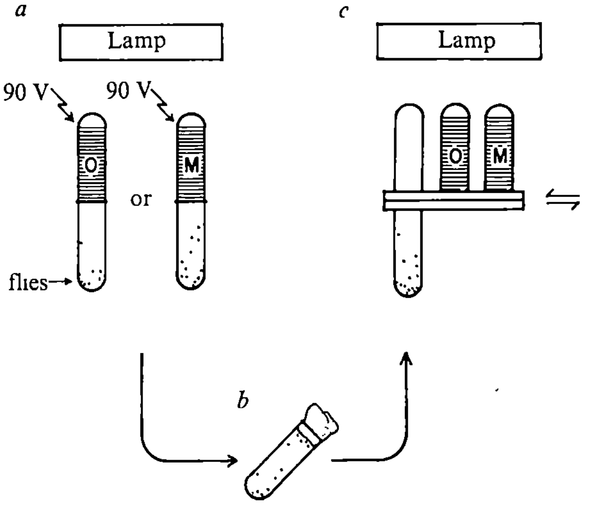

Fig. 1 Procedure for measuring memory retention. *a*, Training: a population of 30–50 flies was trained in two horizontal plastic tubes, joined open end to open end (in a behavioural countercurrent device[5]). The light attracted the flies from a start tube, containing 1 μl of a chemical odorant (either 3-octanol (O) or 4-methyl-cyclohexanol (M)) spread on an electrified grid (60 Hz, 90 V a.c.)[5]. After 60 s, the flies were shaken back into the start tube and another run was begun. This cycle was repeated ten times. By the tenth training cycle fewer than 20% of flies entered the grid tube. *b*, Waiting: flies were left undisturbed in dim illumination at room temperature (22 °C), in a perforated plastic tube closed with a polyurethane foam plug. *c*, Testing: the sliding countercurrent apparatus[5] allowed the start tube, with flies, to be shifted opposite any of several illuminated tubes. Selective odour avoidance of the flies was measured by testing them alternately with two (non-electrified) grids, one spread with O, the other with M. In each test, the flies were shifted opposite a tube containing the grid and odorant and given 15 s to run, after which the flies remaining in the start tube were counted. Before each test, flies were allowed to run to a perforated rest tube for 45 s. The order of odorants was reversed in half the experiments.

D. melanogaster of the Canton-special wild-type strain were used. Culture methods, experimental conditions, chemical odorants and the apparatus for training and testing were as described before[5], except that, to enhance memory retention, we used a more intensive training procedure consisting of ten consecutive exposures to one odorant coupled with shock (Fig. 1*a*). Between training and testing, flies were left undisturbed in ventilated plastic tubes (Fig. 1*b*). They were tested, as before[5], by allowing them to run sequentially into two new grid tubes (non-electrified), each containing one of the odorants above (Fig. 1*c*). The index of learning used was the fraction of the population which avoided the odorant associated with shock during their training, minus the fraction which avoided the novel (control) odorant. Each experiment was run in reciprocal halves; two groups of flies, each trained to avoid one of the odorants, were both tested in the same apparatus to compensate for asymmetries in the apparatus or in the flies' intrinsic reaction to the odorants. The learning index, Λ, for a complete experiment was the average of the indices for the two halves. Learning indices are reported as mean ± s.e. of mean for four experiments. With the training procedure described above, selective avoidance was present immediately after training, $\Lambda = 0.25 \pm 0.02$, and remained high; when tested 45 min after training $\Lambda = 0.34 \pm 0.06$.

Brief cooling induces rapid and reversible anaesthesia in *Drosophila*. Flies to be treated were transferred to a glass test tube (18 × 150 mm), shaken to the bottom, and the tube was placed in a bath of moving water at 4 °C. Within 15 s the flies stopped climbing, fell over and became immobile. After a further 60 s they were transferred back to perforated plastic tubes at room temperature (22 °C). Two minutes later they began to walk, and locomotion appeared normal by 7 min.

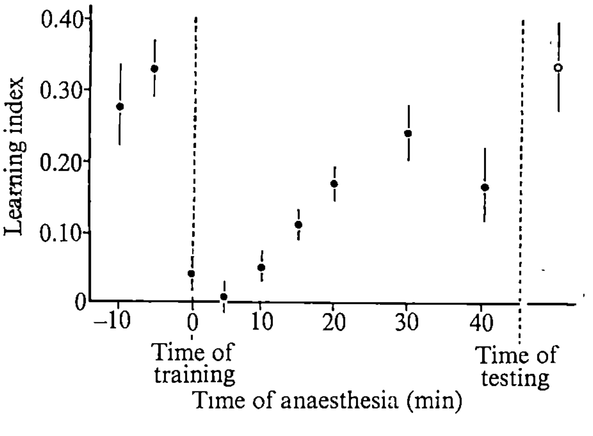
We tried to disrupt the flies' memory by applying this cold treatment at various times before and after training, and in each case measured their retention 45 min after training (Fig. 2). Flies anaesthetised before training (at −10 or −5 min) perform as well as untreated flies, indicating that the cooling *per se* does not interfere with subsequent neural function, sensory perception or capacity to learn and remember. Flies anaesthetised 0 or 5 min after training, on the other hand, showed almost no selective avoidance when tested at 45 min. Apparently cold-induced anaesthesia can disrupt recently acquired memory in *Drosophila*. From 10 to 30 min after training, the memory became progressively more resistant to anaesthesia. This time-dependent increase suggests the onset of a second memory phase. The following experiments examine alternatives to this interpretation.

Populations of flies were trained as above, immediately anaesthetised, maintained at room temperature and tested at 5, 15, 30, 45 or 60 min. In all cases they showed little retention, with values of Λ less than 0.10. This indicates that in *Drosophila* cold-induced anaesthesia after training either eradicates learned information or permanently interferes with its normal expression. The amnestic effect of cold anaesthesia is not an artefact of the time chosen for testing.

Memory-disruption experiments are complicated by the possibility that the disruptive agent, applied shortly after training, itself acts as a reinforcement, causing gratuitous learning which cancels the effect of previous training[6]. In our case, the learning task is aversive, and anaesthesia decreases avoidance of the shock-associated odorant. Therefore, the anaesthesia cannot act as a negative reinforcement. Positive reinforcement effects were excluded by a separate control: populations of flies were cold-anaesthetised in the presence of either 3-octanol or 4-methylcyclohexanol, at the concentrations used above. When tested later they showed the same slight aversion to both odorants as did naive control flies.

Time-dependent sensitivity of memory to cold anaesthesia has also been demonstrated using the original paradigm of Quinn *et al.*[5], which contains an internal control of sensitisation. Flies were trained by alternate exposure to two odorants, one of which was associated with shock. Testing was as above. Cold anaesthesia disrupted memory if applied 5 min after training (Λ = 0.05±0.04), but not if applied at 30 min (Λ = 0.18±0.04) (unpublished results of Y.D.).

Fig. 2 Effect of cold anaesthesia on memory. Populations of 30–50 flies were trained and tested 45 min later as described in Fig. 1. Populations were anaesthetised at the times shown, by cooling them for 60 s at 4 °C. (The decreased learning performance of flies anaesthetised at 40 min may be due to incomplete recovery by testing time.) The abscissa shows time between training and cold anaesthesia. Negative times indicate anaesthetisation before training; positive values indicate anaesthetisation between training and testing. The point shown after testing (hollow circle) represents unanaesthetised control flies. The ordinate shows Λ, the selective avoidance due to learning.



The extent to which the mechanisms underlying memory storage are shared among species is unknown. Nevertheless, analogous techniques can be used to resolve memory phases in creatures ranging from dipterans to primates. Among the insects, multiple memory components have been shown in cockroaches by use of lesions[7], and in honey bees by use of anaesthesia and electroconvulsive shock[8]. The demonstration of two forms of memory in *Drosophila* may be useful because of the suitability of this organism for behaviour-genetic analyses[9]. At present, work on memory phases is limited to phenomenology, and fundamental questions remain unanswered. Short and long term memory storage could proceed by different physiological processes, or the second phase could represent merely a saturation or intensification of the first. Information may proceed serially through short term to consolidated memory, or the two forms may have parallel inputs. These questions could be studied if mutations affecting different memory components were obtained. In this respect, it is interesting that a single-gene mutant deficient in learning has been isolated recently[10].

We thank many friends for help with the manuscript, especially Seymour Benzer, Yuh Nung Jan and Donald Ready. This work was supported by grants from the NSF to W.G.Q. and Seymour Benzer. Y.D. is a fellow of EMBO.

Maintenance of fluid volume in the starfish water vascular system

LOCOMOTION in the starfish *Asterias forbesi* involves many tube feet, each functioning independently as a hydrostatic skeleton; the circular muscles of the ampulla acting antagonistically to the longitudinal muscles of the tube foot itself through the constant volume of fluid contained in the ampulla–foot unit[1]. The fluid for each tube foot comes from the water vascular system to which each foot is connected through its own lateral canal. The water vascular system in *Asterias* consists of three interconnecting series of canals: (1) radial canals running the length of each arm; (2) a circular canal running around the gut at the base of the arms, and (3) the stone canal which runs from the radial canal up to the aboral ("dorsal") surface, terminating in the madreporite. The madreporite, an orange disk, is porous and associated with several sets of cilia. For some time it has been presumed, and is still presented or indicated in some textbooks, that the fluid contained within the starfish water vascular system is pumped by ciliary activity through the madreporite into the canal system, although it has been pointed out that no experimental evidence supports this assumption[2]. Ionically, the fluid within the water vascular system is nearly identical to the external seawater with the exception of internal K^+, which is present in a concentration up to 60% higher than that of the seawater[3,4]. On the basis of this difference, it was suggested that K^+ accumulation by the water vascular system is responsible for water uptake by this system, either by creating a slight osmotic gradient within the tube feet or by direct movement of water with hydrated K^+ ions, as opposed to direct uptake of seawater through the madreporite[5]. We have investigated the generation of the fluid in the water vascular system more thoroughly by determining the osmotic and ionic characteristics of the fluid within the tube feet and the ionic transport characteristics of the isolated tube foot epithelium.

We used *A. forbesi* collected in Jamestown, Rhode Island and maintained for up to 1 week before use in tanks of artificial seawater at 7 °C. Fluid from the water vascular system was obtained from an intact starfish by placing it on its aboral surface and tying off individual tube feet close to their base with silk thread. The foot was then isolated from the animal, washed quickly in distilled water, blotted dry and cut open. The released fluid was taken up into a micropipette. Na^+ and K^+ concentrations in the tube foot fluid were determined by flame photometry, and Cl^- was measured by a modified microelectrometric titration technique[6], and the total osmolality of the fluid was obtained with a Clifton nanolitre osmometer. These determinations are summarised in Table 1. The Na^+ concentration of the tube foot fluid was identical to that of the external medium, while internal Cl^- was slightly but significantly higher than environmental Cl^-. In agreement with earlier measurements on other echinoderms[3,4], the K^+ concentration of the tube foot fluid from *A. forbesi* was considerably higher than that of the external seawater. In addition, the tube foot fluid was distinctly hyperosmotic to the surrounding seawater, by up to 22 mosM. The perivisceral (coelomic) fluid was osmotically and ionically (Na^+, K^+ and Cl^- ion concentrations) identical with the external seawater.

To investigate whether or not the tube foot epithelium itself is in part responsible for K^+ secretion, individual tube feet were cut off at the base, filled with fresh seawater and tied off with silk thread. Thus initially identical ion concentrations were present on both sides of the isolated tube foot epithelium. The tube foot–sac preparation was allowed to equilibrate in aerated seawater for 90 min. Analysis then showed that, as in the intact tube foot, the K^+ concentration of the fluid in the isolated tube foot was higher than that of the surrounding medium. The internal K^+ concentration was 16.8 mM, while that in the external seawater was 9.5 mM. The secretion of K^+ by the isolated tube foot epithelium could be inhibited by addition of CN^- (1×10^{-4} M) to the external medium. The isolated tube foot could also be set up as a tubular system and perfused[7]; in this manner unidirectional K^+ fluxes, using ^{42}K (New England Nuclear), could be measured. Unidirectional K^+ influx was 4.2×10^{-9} mol cm^{-2} min^{-1} and unidirectional K^+ efflux was 3.4×10^{-9} mol cm^{-2} min^{-1}.

Table 1 Osmotic and ionic characteristics of fluid from intact starfish tube feet and of surrounding seawater

Ion concentration (mmol kg^{-1})	Seawater	Tube feet fluid
Na^+	469±2.9 (17)	471.4±2.6 (17)
K^+	9.5±0.8 (21)	17.3±1.8 (21)
Cl^-	543.3±2.6 (19)	551.7±3.1 (19)
Total osmolality mosmol l^{-1}	1,095±3.3 (25)	1,117±3.8 (25)

Figures are mean±s.e.m., with number of determinations in parentheses.

Connection of the tube feet with the outside medium through the canals of the water vascular system and the madreporite was investigated by equilibrating intact starfish for 24 h in seawater with ^{14}C-polyethylene glycol (New England Nuclear); molecular weight 4,000. Samples of fluid were then removed from the tube feet as before and counted in a liquid scintillation counter. Negligible amounts of label were found inside the tube feet, indicating that no direct connection exists between the fluid in the tube feet and the outside medium across the madreporite, an observation consistent with studies performed with dyes[5].

None of these observations supports the assumption that the fluid in the tube feet of the starfish is simply seawater pumped into the water vascular system through the madreporite by the action of cilia. The fluid in the tube feet, as well as that in the connecting water vascular system, is higher in K^+ and Cl^-, and is hyperosmotic with respect to the external seawater. This hyperosmotic condition is probably brought about by the active secretion of K^+, with Cl^- following passively, across the tube foot epithelium. Other epithelial structures in addition to the tube foot epithelium itself in the starfish may contribute to total K^+ secretion into the water vascular system, for example, the ampulla epithelium. The generation of a slightly hyperosmotic condition in the tube foot lumen by solute secretion would create a driving force for water across the tube foot epithelium into the tube foot lumen. This water provides the fluid through which the circular muscles of the ampulla and the longitudinal muscles of the foot are antagonised. In addition, water uptake in this fashion could make up for water losses through ultrafiltration across contracted tube feet and through damaged tube feet.

The lack of any direct connection of the madreporite with the more distal portions of the water vascular system in the starfish does not rule out any exchange whatsoever between different parts of the water vascular system and the external seawater through the madreporite. The water vascular system in some echinoderms is probably connected entirely to the outside environment through the madreporite. Water movements which do occur through the madreporite in asteroids may serve either a sensory role or could serve to equalise pressure differentials[8] between the water vascular system and the outside environment.

Evolution of responses to relative homozygosity

ACCORDING to the theory of kin selection first elaborated by Hamilton[1,2], all individual behaviour is selected to maximise the increment to inclusive fitness $\Delta W_i + \Sigma \Delta W_j r_{ij}$, where ΔW_i is the effect of an act on the fitness of the actor, ΔW_j is the effect of the same act on the fitness of a conspecific, and r_{ij} is the coefficient of relationship between the actor and the conspecific. Acts that lower an individual's direct fitness can thus be favoured by natural selection if, by conferring benefits on relatives of the actor, they cause a positive increment to the actor's inclusive fitness[3,4]. Since the average r_{ij} between an individual and the targets of its behaviour varies because of fluctuations in local population structure, an individual is most likely to secure a positive increment if its behaviour is conditioned on as accurate an estimate as possible of the particular local distribution of r_{ij}. I describe here a mechanism by which this estimate could be improved on the basis of information derived from the relative homozygosity of the individual's own genotype, in species with certain kinds of life histories.

A geographically viscous, sexually reproducing population is locally inbred, reflecting the fact that the parents of a typical individual are more highly related to each other than are two adults taken from the population at large[5]. Since relative homozygosity correlates with the extent of inbreeding, an individual that is homozygous at an unusually high proportion of its population's polymorphic loci is almost certain to be one whose ancestors for several preceding generations were closely related. In a viscous population, neighbouring individuals tend to share largely overlapping sets of ancestors. Thus given any mating system, characteristic pattern of dispersal, and level of genetic polymorphism, an individual more (or less) homozygous than its population's recent average expects a larger (or smaller) than average coefficient of relationship to conspecific near neighbours[6]. In many species these neighbours are likely to be its principal ecological competitors.

Particular developmental and behavioural responses to homozygosity could be favoured by natural selection, if the relationship between individual fitness and some limiting resource can be described by an increasing function that becomes concave downwards above a level of use commonly reached by members of the population. The summed fitness of two individuals who divide a given resource may then exceed the fitness either of them would attain by taking all of that resource. Given sufficiently high r_{ij} and a sufficiently large shareable resource, each individual is selected to take less than all of that resource and so attain less than the direct fitness it might. An unusually homozygous individual may, on average, increase its inclusive fitness by being relatively small and reproductively efficient. A very heterozygous conspecific may be selected to exhibit greater competitiveness over the shareable limiting resource because its inclusive fitness is less likely to be increased by any benefits (positive ΔW_j) it bestows on neighbours.

The logic of this argument has been tested in a series of numerical experiments. The model species is monoecious, semelparous and synchronously breeding. Each site on a 24×24 stepping-stone array accommodates, at most, one individual, who may be more or less 'competitive'. This phenotypic variance in competitiveness has two selective effects. First, the risk of juvenile mortality is a positive linear function of the competitiveness (and the number) of an individual's immediate neighbours. Second, more competitive individuals draw resources from less competitive neighbours, and fertility is an increasing sigmoid function of resource accrued. Competitiveness is controlled by two alleles at each of four independently assorting loci. One allele at each locus is dominant for maximum competitiveness; the other is recessive for reduced competitiveness. Phenotypic effects of the four loci are multiplicative. Symmetrical binomial probabilities govern the dispersal of male gametes and of zygotes, which experience average migrations of slightly more than one step and slightly less than one step, respectively.

Each experiment simulated one hundred generations of selection and reproduction. The recessive allele was strongly favoured at rates of self-fertilisation ranging between zero and 0.975. Gene frequencies changed very little during corresponding control runs in which all genotypes produced the same intermediate level of competitiveness. Individual fertility in experimental runs was observed to correlate positively with competitiveness. Thus, the success of the allele that responded to homozygosity by lowering the competitiveness of its phenotype could have been due only to benefits it conferred on replica copies occurring in neighbours.

Predictions derived from this model have been tested on published hybridisation experiments from a number of species. Embryos *in utero* stand in competition for a bounded set of resources. Relatively homozygous embryos, with high coefficients of relationship to each other, should compete less strongly than relatively heterozygous embryos. Not only should they be smaller than the heterozygotes, they should also be less variable at birth if competition tends to increase the variance of resource accrual. Where crosses are made between completely inbred lines there exists among F_1 littermates no genotypic variance to which their phenotypic variance might be attributed. Taketomi and Matsuo reported a large and well controlled hybridisation experiment with mice[7], where the coefficient of variation of weight at 10 d of age was significantly larger for F_1 hybrid than for inbred litters ($P < 0.01$). This difference is unlikely to have been caused by some special incompatibility between inbred females and their hybrid embryos, because backcross litters on inbred females were less variable than backcross litters on F_1 females ($P < 0.01$).

For another series of hybridisation studies on mice, there is a strong and significant positive correlation between the hybrid litters' heterosis for birth weight and their 'heterosis' for variability[8]. This supports the assumption that intrauterine competition for resources tends to increase the variance of birth weight.

Barley is a predominantly self-fertilising species with very low rates of pollen and seed dispersal. In several hybrid populations synthesised from parents of diverse origin, yields per unit area and average homozygosities both increased during early generations[9,10], although barley is strongly heterotic for individual yield[11]. Available evidence does not permit an unequivocal rejection of the possibility that selection produced late generation plants that were as large as early generation plants and even higher yielding. But since late generation plants were very homozygous, it seems likely that they were also smaller and individually less fit than their more heterozygous ancestors. Their greater yields per unit area are then assumed to reflect higher densities and greater efficiency in the utilisation of resources such as light. The response of individual yield to plant spacing in barley is smoothly asymptotic[12], so selection in a viscous population would seem to favour a response to homozygosity like that modelled in the numerical experiments.

In these barley populations, however, the seeds used to initiate each generation were a large and thoroughly randomised sample produced the previous generation. Therefore differentiated neighbourhoods could not actually develop. Close relatives would seldom have received the benefits dispensed by uncompetitive individuals. In such unusually heterogeneous and chaotically arrayed populations, selection should favour those homozygous genotypes that lead to relatively unreduced competitiveness. Electrophoretic surveys on one of these populations revealed an apparent narrowing of the difference between single-locus homozygous and heterozygous fitnesses within the first twenty-eight generations[13], in spite of a marked increase of gametic phase disequilibrium[10]. During the same series of generations, highly significant increases in the rate of outcrossing also occurred[14]. Both of these changes can be interpreted as evolutionary responses to a situation in which direct fitness and inclusive fitness have become nearly synonymous.

The accuracy of an estimate of average genetic relationship to near neighbours that is derived from homozygosity must depend on the number of loci entering into the estimate, and on the independence with which those loci assort. Traits whose expression depends heavily on the amount of fitness-limiting resources accrued are thus expected to show low additive genetic variance, relatively high non-additive genetic variance and strong heterosis, and this pattern is widely observed[15,16]. Much of the inbreeding depression seen in normally outbred species must result from the expresion of truly deleterious recessive alleles. But such alleles should be relatively rare in species that inbreed to any considerable extent; particularly in such species, the loss of direct fitness that accompanies inbreeding may result in part from mechanisms favoured by natural selection.

Published observations seem to satisfy many predictions derived from the hypothesis, but plausible alternative explanations can be advanced for most and none constitutes a clear critical test. An important and largely unexamined general implication of the model is that particular features of the mating and genetic systems of species to which it applies, should seem designed to facilitate the proposed responses to relative homozygosity.

For many helpful criticisms I thank F. Benford, S. Blaffer Hrdy, J. Coyne, I. DeVore, R. Lande, N. A. Nicolson, O. T. Solbrig, E. O. Wilson, and especially M. A. Etter and R. L. Trivers. This work was supported in part by a USPHS training grant from the NIGMS.

Non-random inactivation of X chromosome in the rat yolk sac

THE Lyon hypothesis postulates that the mammalian female is a natural mosaic for clones of cells with either the maternally derived X chromosome (X^m) or the paternally derived one (X^p) which is randomly inactivated early in development[1,2]. We have presented evidence for the dominance of the inactive X^p in extraembryonic regions of 7.5- and 8.5-d mouse embryos heterozygous for Cattanach's translocation[3] in which the two X chromosomes could be readily identified[4]. Though we presumed that this might not be an exceptional phenomenon restricted to mice bearing this X-autosome translocation, this has been difficult to confirm because of the lack of a system suitable for experiments. Here we report further cytological evidence that the inactive X is predominantly paternal in the yolk sac of the laboratory rat.

We used X^t-X^{st} dimorphism in the laboratory rat[5]; the X chromosome is telocentric (X^t) in F344 and ACI strains, whereas it is subtelocentric (X^{st}) in the WKA strain bred at our laboratory (I. Hayata, unpublished). X^tX^{st} heterozygotes were obtained from the cross ACI(X^tX^t) × WKA($X^{st}Y$) and WKA($X^{st}X^{st}$) × F344(X^tY). The X chromosome transmitted from the father is X^{st} in the former cross, whereas it is X^t in the latter. Embryos were recovered from the decidual swelling at 10.5 d gestation when the yolk sac had enveloped the amnion, and the allantois had fused with the chorion. Mosaic composition was studied only in the embryo proper, and in the yolk sac, by means of a technique essentially similar to the one described elsewhere[6,7].

Distinction between X^{st} and X^t was unequivocal and an asynchronously replicating X was identified as the palest red element in the great majority of metaphase spreads with banded chromosomes (Fig. 1). It should be mentioned, however, that the short arm of the isocyclic X^{st} failed to show up in occasional black and white photographs. Cytogenetic examination was carried out in 8 and 7 embryos from the cross $X^{st}X^{st} \times X^tY$ and $X^tX^t \times X^{st}Y$, respectively. In the former 8 embryos the percentage of cells with the X^p allocyclic ranged from 82.1% to 97.8% with an average of 94.7% in the yolk sac, whereas it ranged from 46.7% to 71.4% with an average of 55.3% in the embryo proper. The difference between the two was highly significant ($P < 0.001$). The results were similar in the latter 7 embryos; the average for the yolk sac, although slightly lower

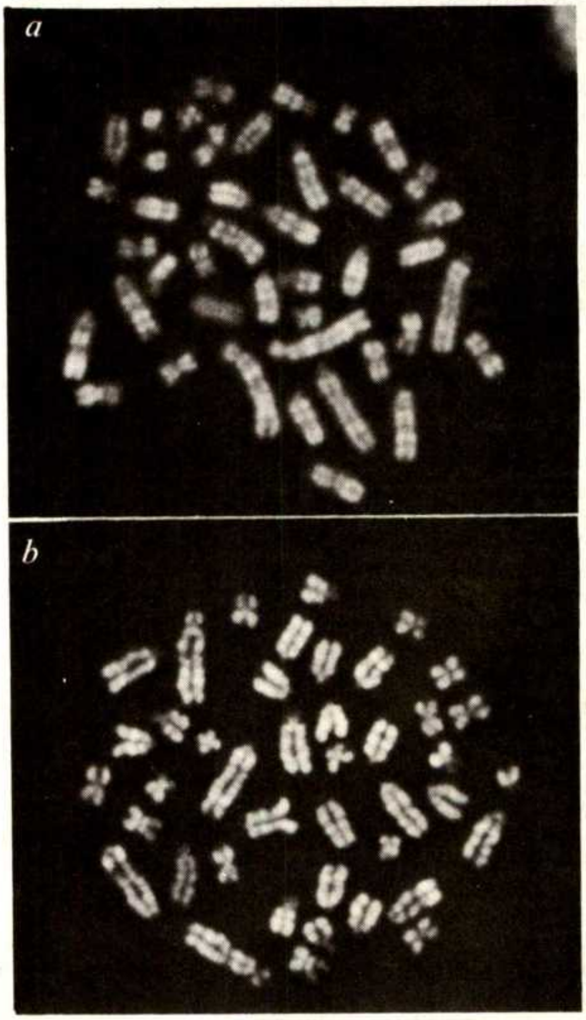

Fig. 1 BUdR–AO differential staining of the allocyclic X chromosome in cells of a 10.5-d-old X^tX^{st} embryo from the cross $X^tX^t \times X^{st}Y$. The allocyclic X which fluoresced faintly is maternal (X^t) in *a*, whereas it is paternal (X^{st}) in *b*. Embryos were taken out of the uterine cavity, incubated at 37 °C for 10 h in Eagle's medium supplemented with foetal calf serum (20%) and bromodeoxyuridine (100 μg ml^{-1}). Colcemid (1 μg ml^{-1}) was added 1 h before collection. Air-dried slides were prepared according to a modified method of Wroblewska and Dyban[6] as described by Takagi and Oshimura[7], and stained with acridine orange (0.5 mg ml^{-1}) in 0.15 M Sörensen's phosphate buffer (*p*H 7.0).

Table 1 Parental influence on X-inactivation mosaic composition in 10.5-d-old female rat embryos

Embryo	Area examined	No. of cells examined	No. of cells with allocyclic X^p (%)

Table 2 Comparison of average percentages and standard deviations of cells with an allocyclic X^p in the yolk sac and embryo proper

Cross type	Yolk sac	Embryo proper
$X^{st}X^{st} \times X^{t}Y$	94.1* ± 4.9	57.5 ± 8.3
$X^{t}X^{t} \times X^{st}Y$	90.9* ± 2.4†	57.0 ± 6.9
Combined	92.6* ± 4.2†	57.3 ± 7.3

*$P < 0.001$.
†$P < 0.05$ (compared with the embryo proper).

compared with that in the former embryos, was not statistically significant ($0.1 < P < 0.2$). It seemed that there was more variation in mosaic composition among embryos themselves than yolk sacs, as indicated by a significantly higher standard deviation ($P < 0.05$). It should also be mentioned that there was no correlation in the proportions of the two cell types between these structures within an embryo ($r = 0.33$, $0.2 < P < 0.3$). Thus the present study substantiated the previous observation made in the mouse heterozygous for Cattanach's translocation. Another aspect in common with the mouse embryo was a slight excess of cells with the X^p inactive in the embryo proper. But the source of departure from the equal representation expected on random basis is not known.

We have already discussed elsewhere[3] possible ways to bring about the extreme mosaicism and its potential significance. A salient feature may be mentioned in connection with the recent findings. There are at least three possible ways of explaining the apparently preferential inactivation of the paternal X chromosome: (1) reactivation of the inactive X^m with simultaneous inactivation of the active X^p; (2) selective growth of cells with the X^m active after random inactivation; (3) preferential inactivation of the X^p. Takagi (in preparation), by means of a double labelling method with ^{3}H-thymidine and 5-bromodeoxyuridine, could exclude the first possibility in mouse embryos. Which of the remaining two is more likely? Isozyme activities of glucose-6-phosphate dehydrogenase in various organs from mules[8] strongly suggest *in vivo* selection for cells with the horse X active in certain organs. Extra-embryonic regions in mouse and rat might also be under strict selective pressure which favours the cell having the X^m active. Our recent observation (N.W. and N.T., unpublished) in 3.5-d mouse embryos, on the contrary, suggests that the initial event may not be random, in that the X^p was allocyclic in more than 90% of informative metaphases. Resolution of this problem will require fuller cytological studies of embryos in early development.

The result reported here implies that the overwhelming excess of the X^p inactive in the yolk sac and probably in some other extraembryonic tissues may hold at least in the family *Muridae*. Further studies will disclose whether it is an evolutionary specialisation in a small group of species, or a widespread phenomenon among eutherian mammals. In either case, it seems highly unlikely that the specific pattern of inactivation has been retained without any advantage. Cells having the active X^m may somehow be advantageous for the interaction between mother and embryo after implantation. We may assume that the majority of primordial germ cells, arising in the yolk sac, would possibly have the active X^m. If this is the case, it is tempting to consider the extreme mosaic composition in the yolk sac as a mechanism controlling X chromosome activity in female germ cells.

This study was supported in part by grants from the Ministry of Education, Science and Culture, and the Ministry of Health and Welfare of Japan.

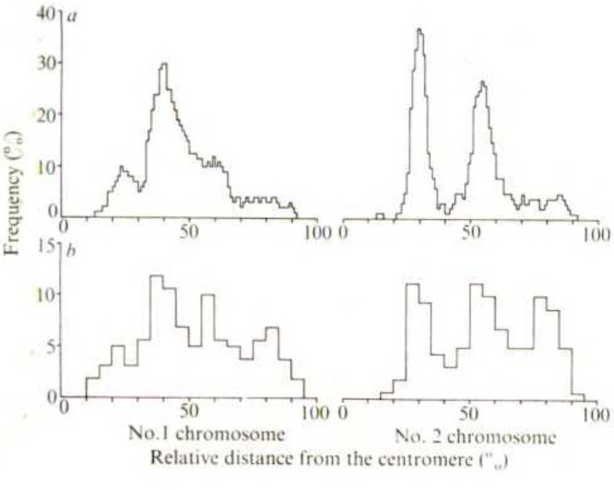
Parallel distribution of sister chromatid exchanges and chromosome aberrations

THE role of chromatid exchange in the origin of chromosome aberrations has been a subject of research since the chromatid exchange hypothesis of chromosome aberrations was proposed[1]. Which of the breakage-reunion hypothesis[2] and the exchange hypothesis better explains the origin of chromosome aberrations is still disputed[3,4]. The part played by DNA repair in aberration and exchange formation has been identified[5,6], and there is much evidence for non-random distribution of chromosome aberrations, especially in the heterochromatic regions[7,8]. We have shown previously by autoradiography, that sister chromatid exchanges (SCEs) induced by 7,12-dimethylbenz(*a*)anthracene (DMBA) are frequently associated with aberrations[8]. Newly introduced 5-bromodeoxyuridine(BUdR)–33258 Hoechst methods for SCEs[9,10] have made it possible to reanalyse these problems in more detail and with considerable accuracy. The results presented here indicate that two different hydrocarbon carcinogens, DMBA and 7,8,12-trimethylbenz(*a*)-

anthracene (TMBA), induce aberrations localised in the same chromosomal regions of the rat bone marrow cells and that the targets for chromosome aberrations and for SCE are identical; in other words, both phenomena are related.

Two of the largest chromosomes (Nos 1 and 2) of the rat have extremely vulnerable regions to DMBA, especially when the carcinogen is administered shortly before cell collection, probably because of late DNA replication in these regions[8]. These vulnerable sites were therefore used to study the relationship between chromosome aberration and SCE. Male Long–Evans rats (30 d old) were used and were injected intravenously with a lipid emulsion of DMBA or TMBA (Upjohn) at 50 mg per kg body weight, 6 h before killing. Colchicine (0.3 mg) was administered intraperitoneally 1 h before killing and chromosome specimens were prepared from femur bone marrow by the standard air-drying method and stained with Giemsa. Chromosome aberrations observed consisted of gaps and breaks. Gaps were defined by a clear achromatic lesion with continuity, and breaks by displacement of the distal segment. Both ends of a break, or a gap from the centromere projected on the chromosome axis, were measured as accurately as possible in photographic prints and expressed by the percentage in the length of these chromosome arms. Distribution curves were plotted of the relative location of 100 breaks and gaps along both chromosomes. For SCE, an *in vitro* system was used, because *in vivo* BUdR-labelling of rat bone marrow cells was unsuccessful. The bone marrow cells from femur were suspended in 5 ml of thymidine-free F-12 medium containing 15% foetal calf serum and $2\ \mu g\ ml^{-1}$ of BUdR and were cultured for 26 h, or two rounds of the cell cycle[8]. DMBA or TMBA (5×10^{-4} mM) was dissolved in 0.1 ml of dimethylsulphoxide, and $0.2\ \mu g\ ml^{-1}$ of colchicine were added to the medium 6 and 2 h respectively before collecting the cells. Chromosome specimens were prepared and differential staining of sister chromatids was carried out using the modified 33258 Hoechst–Giemsa method[11]. One hundred SCEs in the long arms of both chromosomes were located in photographic prints by measuring the relative distance from the centromere. The distribution curves of SCEs were made by plotting the relative site of each exchange along the chromosome axis divided into 20 segments.

Fig. 1 Distribution of DMBA-induced chromosome aberrations (*a*) and sister chromatid exchanges (*b*) along the long arms of No. 1 and No. 2 chromosomes. The graphs are a combination of results from several samples. Numbers on the abscissa represent percentage distance from the centromere; 0, centromere; 100, telomere. The ordinate indicates the frequency per 100 aberrations in each chromosome. Six hours after DMBA (50 mg kg^{-1}, intravenously), 23.4% of metaphase bone marrow cells had aberrations. The mean number of aberrations per cell was 0.27; 13.7% were in No. 1; 17.9% in No. 2; and 68.4% in the remaining chromosomes. Of the aberrations 14% were breaks as defined by chromatid displacement and the rest were gaps. On the other hand, 289 SCEs were found in 26 metaphases (11.5 per cell) 6 h after addition of DMBA (5×10^{-4} mM) *in vitro*; 9.7% were in No. 1; 11.7% in No. 2; and 78.5% in the remaining chromosomes.



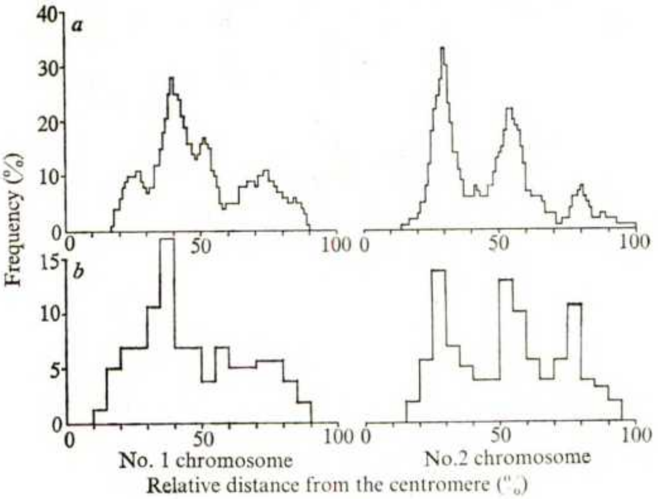


Fig. 2 Distribution of TMBA-induced aberrations (*a*) and sister chromatid exchanges (*b*) along the long arms of No. 1 and No. 2 chromosomes. At 6 h, 17.7% of metaphase bone marrow cells revealed aberrations. The mean aberration per cell was 0.20; 18.6% were in No. 1; 22.9% in No. 2; and 58.6% in the remaining chromosomes. Of the aberrations 14.5% were breaks and the rest were gaps. 253 sister chromatid exchanges were found in 26 metaphase cells (9.7 per cell) 6 h after addition of TMBA (5×10^{-4} mM) *in vitro*; 10.2% were in No. 1; 9.0% in No. 2; and 76.7% in the remaining chromosomes.

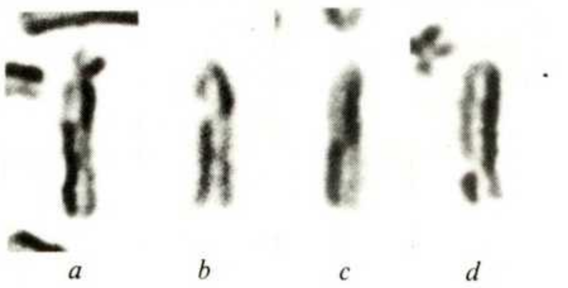
The DMBA- and TMBA-induced breaks and gaps were shown to distribute along the chromosomes non-randomly and reproducibly (Figs 1 and 2). The No. 1 chromosome had a susceptible site 40% of the distance along the long arm. In the No. 2 chromosome, there were three target sites for breaks and gaps; they were about 30, 55, and 80% along the chromosome from the centromere, although the last peak was not evident in the animals referred to in Fig. 1 treated with DMBA. SCEs were, however, also distributed non-randomly. The distribution curves of exchanges in No. 1 chromosome were similar to those for aberrations. There were also three susceptible regions for exchanges in the No. 2 chromosome. They coincided completely with the target sites for aberrations although the third susceptible region was far more susceptible to exchanges than to aberrations. Some SCEs were associated with aberrations (Fig. 3).

These results indicate that aberrations and SCEs are correlated. From this correlation, it is possible that aberrations represent incomplete SCEs that were not repaired.

Fig. 3 Sister chromatid exchanges in the susceptible regions of No. 1 chromosome (*a*) and No. 2 chromosome (*b*, *c* and *d*). *b* and *d*, Exchanges are incomplete, but are associated with a gap.



Whether SCEs comprise 25% of the total chromosome lesions as expected from Revell's hypothesis[1] is unknown from the present studies. Because late DNA replication in and the late vulnerability of these susceptible regions to DMBA have been suggested[8], it is possible that DNA replication is important in the induction and non-random distribution of these changes, although the part played by other factors such as repetitious DNA, intranuclear distribution of carcinogens, and chromosome association in the interphase nuclei[7] cannot be excluded. These non-random actions of chemical carcinogens need further studies in relation to carcinogenesis, because they parallel carcinogenicity of the chemicals[5,12] and the chemical carcinogens with a completely different chemical structure such as 4-nitroquinoline-1-oxide and *N*-nitroso-*N*-butylurea also induce the same genetic effects (unpublished data).

We thank the Ministry of Education, Science, and Culture, Ministry of Health and Welfare, and Princess Takamatsu Cancer Research Foundation for financial support. TMBA and DMBA were gifts from Professor C. Huggins, University of Chicago.

Communication through fimbriae during conjugation in a fungus

LONG fine hairs, termed fimbriae[1] or pili[2], have been observed in many bacteria and in fungi[3–5]. Bacterial sex pili transfer chromosomal and plasmid DNA during conjugation[6]. This paper describes evidence that the fimbriae of the smut fungus *Ustilago violacea* also transfer sex-specific molecules between the two conjugants.

The cells of this fungus may mate while they are touching (contact mating) or at distances of up to 20 μm on water agar (distant mating)[5,7]. During distant mating a tube grows from the a_2 mating type to the other cell (a_1 mating type; Fig. 1). Fimbriae up to 15 μm long are found on both mating types and are therefore long enough to account for distant mating, if it is assumed that the fimbriae of the two mating cells may attach end-on. The evidence that such fimbrial contacts between cells are formed and that they are essential for conjugation is as follows:

The behaviour of the cells, as observed under the light microscope, provides very strong evidence for the existence of an invisible connecting fibre at distances of more than 5 μm apart. Such cells floated together in water suspensions, rotating in unison and maintaining a constant maximum distance apart. The axis of rotation indicated that the cells were connected by a fibre that was laterally flexible but torsionally rigid, and was attached to the cell surface at a discrete site. They therefore rotated very similarly to two balloons fixed together with thin wire. The connection was fragile and could be broken by pressure on the cover slip. When water suspensions of cells were made carefully, such attached cells were found in mating cultures, but not in pure cultures or in mixed cultures of opposite mating type kept in conditions unsuitable for mating. Fimbriae are the only structures on the cell wall which could act as these invisible fibres.

The conjugation tube in cells mating at a distance seemed to grow along the line of the fimbrial connection. On nine occasions to date cells were observed similar to those in Fig. 1*a*, in which one mating partner produced a conjugation peg that had grown part way towards the other cell. The cells remained connected by an invisible thread and in every case their rotation as a pair clearly showed that the invisible fibre connected the tip of the conjugation tube to the other cell. The distance covered by the fibre varied

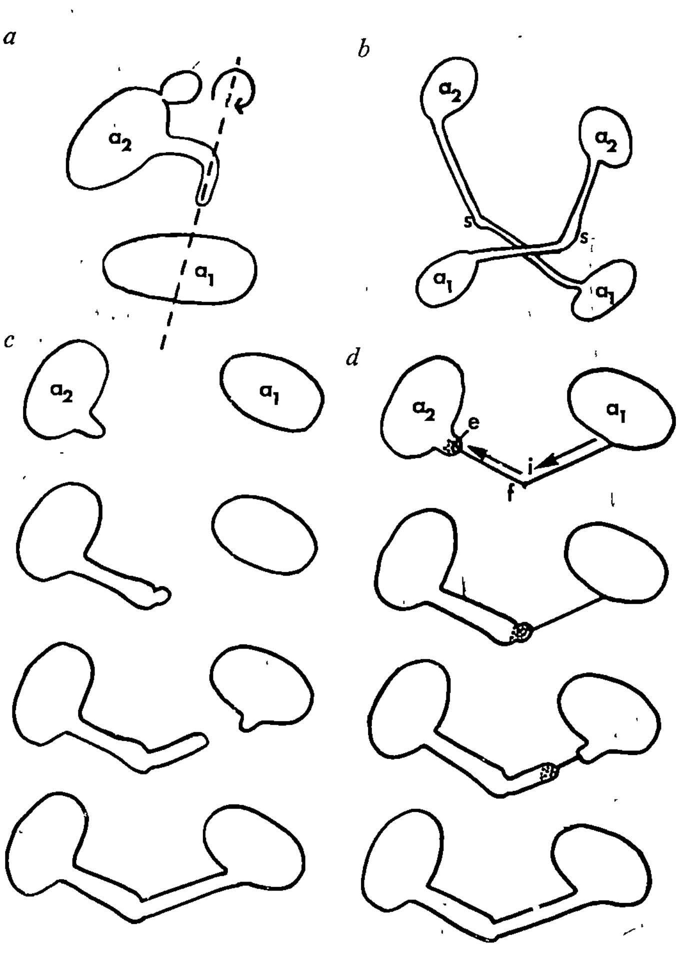

Fig. 1 *a*, Pair of mating cells attached by an 'invisible' fibre as observed under the light microscope in a water suspension. Dotted line represents axis of rotation of the pair of cells. *b*, Route taken by conjugation tubes from a pair of a_2 cells to two a_1 cells. Note that the tubes do not necessarily contact the nearest partner, and that they may swell before changing direction. *c*, Pair of cells during distant mating, showing the development of the conjugation tube from the a_2 cell, the swelling at the point where the direction changes and the growth of a small peg on the a_1 cell opposite the tube. *d*, Interpretation of the stages in *c*. The cells are considered to be connected by end-to-end joining of fimbriae *f*, from each partner. An inducer (i) is transported along this fimbrial connection from the a_1 cell to the a_2 cell. The inducer stimulates local production of wall-softening enzyme (e), at the a_2 terminus of the fimbrium, causing development of a peg. Further transport of inducer along the fimbriae results in continued growth of the tube along this path. As the growing tube nears the other cell transport of enzyme or of an inducer from a_2 may occur in a reverse direction causing some tube development on the a_1 cell.

from 1 to 5 μm; probably longer fimbrial connections tend to break in water suspension.

During distant mating the tube frequently did not grow directly across to the other cell but curved or turned at a sharp angle. Frequently the tip of the tube swelled before resuming growth in a new direction (Fig. 1*b–d*). The tube sometimes passed by a nearby cell of opposite mating type to reach one further away (Fig. 1*b*). The nearer cell later mated with another cell. These observations are difficult to explain if chemical diffusion is the cause of tube growth, but are readily explained if the tube follows the line of a previously established fimbrial connection.

Observations of several closely related species of *Ustilago* have established that only fimbriated strains can conjugate. Thus Kniep[9] showed that strains of *U. scabiosae*, *U cardui*, *U. vinosa*, *U. utriculosae* and *U. violacea* will conjugate with each other. Modern strains of these species that have become afimbriate have also lost the ability to conjugate, whereas strains that still produce fimbriae have full mating activity.

In an earlier report[5] it was shown that fimbriation and conjugation both have the same maximum temperature[2,5], the same response to temperature shifts, the same response to enzyme treatments, and are both blocked before translation by high temperatures. The cells still grow in conditions which limit both conjugation and fimbriation.

Electron microscopy of thin section and freeze-etched preparations demonstrated that fibres of similar appearance to fimbriae connect cells that are very close together[5,7,8]. These fibres were also found on the ends of the conjugation tubes[5,7]. Unfortunately, the fragility of the connection in distantly mating cells has so far frustrated attempts to demonstrate it by shadow casting.

Although these results establish that fimbriae are essential for conjugation, their exact function is not yet known. It is possible that there are both common fimbriae and sex fimbriae as in bacteria, since one or two fimbriae may differ from the others in having a terminal knob[5], just as frequently occurs with the sex pili of bacteria[6], and since only one or two conjugation tubes are produced per haploid cell, although there are hundreds of fimbriae on most cells.

The growth of the conjugation tube along the line of the fimbrial connection suggests that this fibre may be used to provide chemical communication between the cells[5]. It is suggested that 'inducer' molecules are transmitted along the fimbrial connection mainly from the a_1 cell to the a_2 cell, and that these molecules stimulate production of a wall-softening enzyme locally near the a_2 terminus of the fimbrial connection. This would cause bulging of the cell wall at the fimbrial terminus and initiate development of the conjugation tube. Further transmission of inducer together with continued growth in the a_2 cell would cause the tube to grow at its tip along the line of the fimbrium. If the connection between the two fimbriae is a poor one, inducer may accumulate at the junction resulting in swelling of the tip of the conjugation tube before growth along the fimbrium is resumed. The tendency of the a_1 cell to produce a conjugation peg as the conjugation tube approaches (Fig. 1*c* and *d*) may be due to movement of the enzyme itself along the fimbrium, or to the slow transport of inducer molecules from a_2 to a_1.

The inducer is perhaps most likely to be an enzyme subunit or coeffector, but it could also be a regulatory protein, messenger RNA or perhaps even DNA. The ability of fimbriae to transmit such large molecules was doubted for a while but has received strong support from recent work with bacteria[6], including the decisive experiments of Ou and Anderson[10] who showed that *E. coli* cells could complete conjugation and undergo recombination while remaining separated by distances of up to 3 μm and connected only by an 'invisible' thread. The similarity between the ultrastructural features of conjugation in bacteria and in *Ustilago* is very striking in view of the differences in nuclear organisation. It remains to be seen to what extent this similarity extends to the biochemical, genetical and regulatory levels.

Induction of "natural killer" cells by BCG

THE past decade has witnessed numerous attempts to suppress tumour growth by the administration of immune stimulants. Notable successes have been achieved, particularly following the intralesional injection of Bacille Calmette-Guérin (BCG) which has been observed to cause the regression of local tumour nodules in both experimental animals[1,2] and man[3–5]. Although there is some controversy as to the mode of action of BCG, it has become widely accepted that its anti-tumour effects are principally mediated through host macrophages, "activated" by the immunostimulant[6–8]. Observations we have recently made in studies of the peritoneal exudates of BCG-infected mice suggest an alternative possibility: that tumour destruction is caused by a non-macrophage population of cytotoxic cells which is induced by BCG immunisation.

Young adult (6–8 weeks) C57BL/6 mice were immunised intraperitoneally with 10^7 viable BCG organisms (Pasteur Strain, Trudeau Institute, New York). Peritoneal exudates were harvested at frequent intervals thereafter and the lytic activity of washed cells assessed against a variety of ^{51}Cr-labelled target cells using a 4-h microcytotoxicity assay[9]. Exudates from unimmunised animals were not cytotoxic under these assay conditions. In contrast, peritoneal cells obtained 2–15 d after

Table 1 Lytic activity of murine peritoneal exudates

Treatment used to induce exudate	% Specific cytolysis P815-X2*	EL-4 (G-)†

*A methylcholanthrene-induced mastocytoma of DBA/2 origin, maintained in ascites form.

†A methylcholanthrene-induced thymoma of C57BL/6 origin, maintained in ascites form.

Young adult C57BL/6 mice were immunised intraperitoneally with 10^7 viable BCG organisms (Pasteur strain, Trudeau Institute, New York), with 2 ml 3% (w/v) thioglycollate medium or with 1.5 ml 10% (w/v) proteose peptone. Peritoneal exudates were collected 3 d later and lytic activity of 1.5×10^6 cells assayed against 10^4 ^{51}Cr targets. A 4-h microcytotoxicity assay was performed in RPMI 1640 containing 10% foetal calf serum. Specific cytolysis was calculated relative to target cells in the absence of any effector cells. The standard deviation of quadruplicate cultures was ±2% of the mean We have also observed extensive lysis of Chang (human liver cell line) cells by BCG exudates and, to a much reduced extent, by exudates induced by thioglycollate and proteose peptone (data not shown).

Table 2 Characteristics of the peritoneal exudate killer cell

Peritoneal exudates were collected from C57BL/6 mice 3–6 d after immunisation with 10^7 viable BCG organisms. The following fractionation procedures were performed in attempts to identify the cytotoxic cell. (1) Exudates were centrifuged (300*g*, 3 min) on to a tissue culture dish (Falcon Plastics) and were then incubated for 40 min at 37 °C. Non-adherent cells were decanted, adherent cells removed with 5 mm EDTA in ice-cold Ca^{2+}-free HEPES buffer. (2) Carbonyl iron depletion was carried out by method of Lundgren[14]. (3) The anti-θ serum used was an AKR anti-C3H thymus previously described[15]. Normal rabbit serum was used as the source of complement (C). (4) A rabbit anti-mouse Fab serum was a gift from Dr Keith James, University of Edinburgh. Rabbit serum was again used as a complement source. The cytolytic activity of the fractionated populations was in each case assessed in a 4-h assay using 5×10^5 effector cells and 10^4 ^{51}Cr-labelled P815 target cells.

immunisation invariably caused target cell destruction. While there was considerable animal to animal variation in the amount of cytotoxicity exhibited, peak lytic activity was observed in exudate populations harvested 4–8 d after immunisation. The decline in reactivity was gradual, and some lytic activity was noted in populations harvested up to 3 weeks after BCG administration.

Several features of the lysis observed deserve comment: (1) the amount of lysis occurring in a 4-h period was directly proportional to the number of exudate cells added to the cultures (range used: 2×10^5–2×10^6 exudate cells per 10^4 target cells); (2) lysis, over a 3-h incubation period, was a linear function of time; and (3) C57BL/6-derived peritoneal exudates were capable of lysing syngeneic EL-4 thymoma targets as well as allogeneic P815 mastocytoma targets. Data from a typical experiment are shown in Table 1. The lytic effect noted was not confined to the C57BL/6 mouse; similar cytolysis has been observed with BCG induced exudates in the DBA/2 mouse. Interestingly, while thioglycollate and proteose peptone induced more copious, macrophage-rich, peritoneal exudates than did BCG, such cell populations were only minimally lytic (Table 1).

Attempts were made to characterise the nature of the cytotoxic cell present in BCG-induced exudates. The cytotoxic cell did not adhere to tissue culture plates (Table 2) nor was it phagocytic. Depletion of phagocytes by treatment of 2×10^7 peritoneal exudate cells with 200 mg carbonyl iron for 40 min at 37 °C, followed by application of magnetic field, removed 60% of the total cells. There was a concomitant increase in the lytic activity of the residual population (Table 2). It thus seems extremely unlikely that the cytotoxic cell in the exudates is a macrophage.

The lytic activity of BCG-induced peritoneal exudates was not affected by treatment with an AKR-antiserum directed against θ-alloantigen in the presence of a source of rabbit complement (Table 2). Identical treatment removed 91% of the T cell-mediated cytotoxic activity of spleen populations obtained from C57BL/6 mice immunised with P815 (DBA/2) alloantigen (data not shown). We conclude therefore that the killer cell in BCG exudates is not a thymus-derived lymphocyte.

Cells bearing surface immunoglobulin were quantitated by the use of a flouresceinated goat IgG with anti-mouse Fab activity. Treatment of exudates with a rabbit antiserum to the Fab portion of mouse IgG in the presence of rabbit complement diminished the number of flourescent cells from 12% to 2.4%. This treatment was without effect on the lytic activity of the exudates (Table 2). We conclude that the killer cell lacks surface immunoglobulin.

Soluble immune complexes were without effect on cytolysis by BCG-induced exudate cells under conditions which readily inhibited antibody-dependent K cell-mediated cytolysis (Table 3). This suggests that the BCG exudate cytolytic cell is not dependent on an Fc receptor for its activity. Furthermore, although K cells are notably trypsin resistant[10], cytolysis by BCG exudates was inhibited by trypsinisation of the effector cells before the assay (Table 3).

The effector cell present in BCG-induced peritoneal exudates therefore lacks: (1) the adherent and phagocytic characteristics of macrophages, (2) the surface characteristics of both T and B lymphocytes, and (3) the Fc-dependency and trypsin resistance of the K cell. By these criteria the cell is comparable to the "natural killer" cell described by Herberman *et al.*[11,12] and by Kiessling *et al.*[10,13].

To further this comparison, we investigated whether the exudate cell possessed an additional feature which has been reported to be peculiar to the natural cytotoxic cell: namely, a marked lability at 37 °C in culture[11].

Peritoneal exudate cells harvested 5 d after BCG infection were cultured at 37 °C at a concentration of 5×10^6 cells ml^{-1} in RPMI 1640 containing 10% foetal calf serum. After incubation for varying periods of time at 37 °C, the cells were held at 4 °C until a total time of 4 h had elapsed. At this time ^{51}Cr-labelled P815 cells were added, the cultures transferred to an incubator at 37 °C and the lysis of target cells evaluated 4 h later. As can be seen from Table 4, the lytic activity of exudate cells was extremely labile, a 50% reduction in lytic activity being observed within 7 h (3 h incubation + 4 h assay) at 37 °C. In contrast, T cell-mediated cytotoxic activity of alloimmune

Table 3 Inhibition of cytotoxicity by immune complexes or trypsinisation of effector cells

Effector cells	Target cells	Immune complex inhibition Antibody control	Complex	Inhibition (%)	Trypsin sensitivity Control	Trypsin	Inhibition (%)
Alloimmune spleen	P815	16	17	0	8.7	0.2	98
Normal spleen	Antibody coated CRBCs	14	3.6	74	4.5	5.0	0
BCG exudate	P815	20	23	0	23	12	48

Alloimmune spleen cells were obtained by culturing normal C57BL/6 mouse spleen cells with DBA/2 stimulating cells for 4 d in the condition described by Cerottini *et al.*[16]. Normal spleen cells were from C57BL/6 mice, and peritoneal exudate cells were obtained from the same strain 4 d following BCG inoculation. Both alloimmune spleen and BCG-induced peritoneal exudates were assayed against 10^4 ^{51}Cr-P815 target cells, the former at a 5:1, and the latter at a 50:1 effector–target cell ratio. Antibody-dependent cytolytic (K cell) activity was measured by culturing 10^6 normal spleen cells with 5×10^4 ^{51}Cr-labelled chicken erythrocytes (CRBCs) which had been coated with a 10^4 dilution of a mouse anti-CRBC serum. Soluble immune complexes were prepared by incubating a rabbit anti-DNP antiserum (40 μg ml^{-1}) with DNP-BSA (4 μg ml^{-1}) for 1 h at 37 °C. A 0.05-ml volume of this mixture was then added to 0.1 ml of effector cells and incubated 30 min at 37 °C, followed by addition of target cells in an 0.05-ml volume. Trypsin treatment of effector cells was carried out for 45 min at 37 °C using a cell concentration of 2×10^7 cells ml^{-1}, and either 0.25% trypsin (Sigma) or medium alone. Cells were washed and adjusted for viable cell recovery before assay. All cultures were in the presence of target cells for 4 h at 37 °C.

spleen (or peritoneal exudate cells) did not fall during identical culture conditions (Table 4 and unpublished observations).

In summary we have observed a cytotoxic cell population in the peritoneal exudates of mice 2–15 d after infection with viable BCG organisms. The cell population lacks those characteristics that are associated with B and T lymphocytes, macrophages and K cells. The BCG exudate cytotoxic cell shows a marked lability to temperature that the directly cytotoxic T cell does not. Additionally, in agreement with Kiessling *et al.*[10], it shows a susceptibility to trypsin treatment similar to the cytotoxic T cell, but in contrast to cytotoxic K cells. The exudate killer cell we describe here thus seems similar, if not identical, to the natural cytotoxic cell previously described[10–13].

It is interesting to note therefore that Herberman's studies[11] have shown that the mouse strain used here (C57BL/6), and specifically its peritoneal exudate, has a very low incidence of natural cytotoxic cells. This is presumably reflected in an inability to detect lytic activity in our assay system using normal exudate populations. It is not yet clear which of several alternatives is responsible for the vastly augmented activity seen in exudates after BCG administration. The principal possibilities seem to be: (1) that BCG induces a cytotoxic population *ab initio*; (2) that BCG causes the expansion of a population of cytotoxic cells which is initially present at an incidence below detection; (3) that BCG recruits into the peritoneal cavity cells which normally reside in other compartments or (4) that BCG "activates" an exudate cell population, rendering it cytotoxic.

Table 4 Lability of the cytotoxic cell

Cell	Time (h) 37 °C	Time (h) 4 °C	Specific cytolysis (%)	Inhibition (%)
BCG peritoneal exudate	0	4	27	0
	1	3	30	0
	2	2	21	21
	3	1	13	52
	4	0	6.4	76
Alloimmune spleen	0	4	68	0
	1	3	67	2
	2	2	69	0
	3	1	74	0
	4	0	78	0

Peritoneal exudates were harvested 5 d after immunisation of 6-week-old C57BL/6 mice with 10^7 viable BCG organisms. Alloimmunised spleens were obtained from C57BL/6 mice 10 d after immunisation with 3×10^7 P815 cells. Effector cells were incubated alone at 37 °C for various periods of time and then placed in an ice water bath at 4 °C until a total time of 4 h had elapsed. At this time 5×10^5 effector cells were incubated for 4 h at 37 °C with 10^4 ^{51}Cr-P815 cells and the degree of target cell destruction evaluated. Inhibition following culture at 37 °C was calculated relative to the activity of effector cells stored continuously at 4°C.

Further investigations will clearly be needed to define the nature of the inductive process, to delineate the lineage of the cytolytic cell, and to see whether other bacterial products with anti-tumour reactivity (for example *C. parvum;* MER) also produce cytotoxic cells. It may not be coincidental that of the three agents we have used to induce peritoneal exudates only BCG substantially augments natural cytotoxicity and only BCG shows anti-tumour activity *in vivo*.

The induction of cytotoxic cells following BCG administration suggests to us that this population might be at least partially responsible for the tumour regression associated with BCG therapy. Furthermore, these observations imply that measurement of the natural cytotoxic cell population might prove to be a useful adjunct to studies aimed at optimising therapy with bacterial adjuvants.

We thank Drs Keith James and John Cebra for their gifts of rabbit anti-Fab serum and the flouresceinated Ig reagents.

Spleen cells from *Schistosoma mansoni*-infected mice produce diffusible stimulator of eosinophilopoiesis *in vivo*

WE have previously demonstrated that a diffusible stimulator of eosinophilopoiesis is produced in mice after secondary injection with tetanus toxoid (TT)[1]. Lymphoid cells from TT-primed animals are capable of producing a diffusible eosinophilopoietic stimulator in non-primed hosts on intraperitoneal TT injection[2]. To establish that this is not a unique phenomenon, limited to this antigen, but rather that it is characteristic of antigen-induced eosinophilias and associated eosinophilopoietic responses, we have studied eosinophilopoiesis in a parasite-induced eosinophilia.

Mice with experimental schistosomiasis exhibit marked peripheral eosinophilia[3], also observed in patients with this infection[4]. Spleen cells (SC) from *Schistosoma mansoni*-infected mice were tested for their ability to produce a diffusible stimulator of eosinophilopoiesis in response to an injection of a soluble schistosomal egg antigenic (SEA) preparation[5].

Prospective SC donors were injected intraperitoneally with 125 *S. mansoni* cercariae 8–12 weeks before use; control SC donors were untreated. Peripheral eosinophil levels in infected mice remained at normal levels (<5%) until between weeks 7 and 8 after infection. They then increased to 7–14%, at which level they remained until the last animal was killed at week 12. Liver and lung sections from infected mice contained large eosinophil-containing granulomas surrounding schistosoma ova.

The quadrachamber diffusion assembly[2] was used to culture normal C57BL/6Ja bone marrow cells transfilter *in vivo* from SC from *S. mansoni*-infected, or normal, non-infected, isogeneic mice Chamber assemblies were implanted in the peritoneal cavities of non-infected C57BL/6Ja or B6D2F$_1$ (C57BL/6Ja×DBA/2) mice. One hour after implantation, host mice received an injection of 25 μg protein SEA intraperitoneally. Six days after implantation, chambers were recovered and assayed for total and differential cell counts (see Fig. 1).

After killing and assaying, significantly greater total and

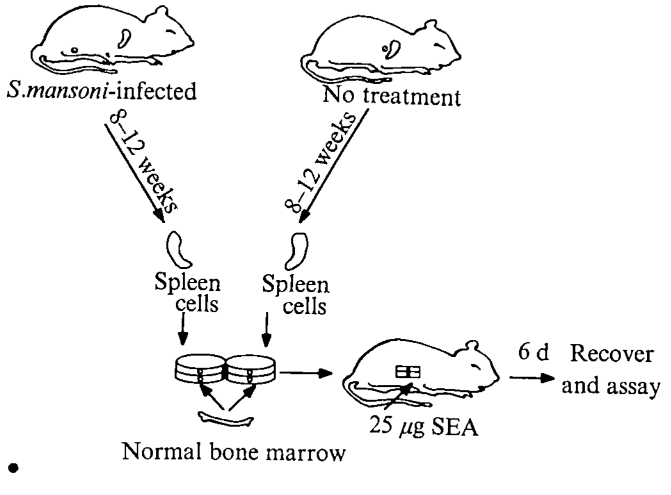
percentage eosinophil granulocyte counts were present in bone marrow populations transfilter from infected SC compared with those transfilter from non-infected SC (Table 1). Total eosinophils were 0.042×10^6 compared with 0.022×10^6 in controls ($P<0.005$), representing a percentage eosinophil granulocytes of 7.01 and 2.95, respectively ($P<0.001$). The difference in eosinophil levels was not attributable to differences in total cell counts, percentage granulocytes or total granulocytes, as no significant differences were seen in these parameters for the two bone marrow cell populations Expression of eosinophils as a percentage of total granulocytes (%E/TG) gives a further indication that increases in eosinophil levels did not correlate with total granulocyte changes. In these studies, the %E/TG was 17.0% transfilter from infected SC compared with 6 5% across from non-infected SC, confirming the specificity of the stimulus for eosinophils.

These results indicate that spleen cells from schistosoma-infected mice are capable of producing a diffusible substance stimulatory for eosinophilopoiesis and are consistent with previous[2] experiments that demonstrated the production of a diffusible eosinophilopoietic factor by TT-primed lymphoid cells on secondary challenge.

Fig. 1 Quadrachamber diffusion assembly assay. SC donors received either 125 *S. mansoni* cercariae intraperitoneally or no treatment 8–12 weeks before quadrachamber diffusion assembly implantation. Chamber assemblies composed of two diffusion chamber doublets with 0.22 Millipore filters on both sides, and between upper and lower chambers, enable diffusion within doublets, and with the peritoneal fluid, but not directly between doublets. Upper chambers received 10^7 spleen cells from either the normal or schistosome-infected donors in 0.1 ml suspending fluid (6 parts M199 : 2 parts buffer : 1 part plasma-EDTA). Lower chambers received 10^6 normal bone marrow cells in 0.1 ml suspending fluid. Chamber assemblies were implanted intraperitoneally in C57BL/6Ja or B6D2F$_1$ mice. Within 1 h after implantation, host mice received an intraperitoneal injection of 25 μg SEA in 0 2 ml saline. Six days later chambers were recovered, shaken in 0 5% protease in 5% Ficoll in PBS, and individual bone marrow chamber contents were assayed for total and differential cell counts.



Increased peripheral eosinophil levels are seen in experimental animals and man during the course of *S. mansoni* infection. It has been shown that eosinophil granulocytes are prime components in the immune response to schistosoma eggs[6], and *in vitro* studies indicate that they may additionally be involved in immune-dependent destruction of schistosomula. It is therefore not surprising that an eosinophilopoietic factor would be produced in schistosomiasis.

Functional lymphoid cells are necessary for eosinophil response to antigens in which this has been tested[8,9]. The lymphoid cells evidently produce the stimulator of eosinophilopoiesis *in vivo* as a part of their response to antigens which elicit eosinophilia and medullary eosinophilopoiesis, as in the case of TT and schistosomiasis. Murine or human lymphoid cells from schistosoma-infected individuals produce a lymphokine-termed eosinophil stimulation promotor (ESP) on exposure to SEA *in vitro*[10,11]. ESP causes increased eosinophil migration in the *in vitro* assay conditions. Whether the eosinophilopoiesis stimulating factor is identical or distinct from ESP needs to be determined.

Further understanding of the processes regulating eosinophil production may assist our understanding of the reaction to parasitic infection, and the mechanisms of granulopoiesis.

Novel approach to the treatment of hydatid disease

HYDATID disease is a cyclozoonotic infection of man and certain other mammals which results from the cystic intermediate stage of the cestodes *Echinococcus granulosus* and *E. multilocularis*. The growth of these two species of parasites is basically similar except that the latter undergoes tumour-like metastatic dissemination. The present knowledge about immunity to this disease is incomplete; however, recent reports from this laboratory[1-3] have defined certain basic aspects of the immune response to secondary echinococcosis. These studies have demonstrated the rapid *in vitro* lysis of protoscoleces by the complement proteins when these are activated by surface immunoglobulins acquired *in vivo* by the larvae within the cysts. We also have evidence (unpublished data) that host serum proteins, including IgG and IgM immunoglobulins, are found within the cyst tissues of *E. multilocularis*, as previously demonstrated in *E. granulosus*[4]; Rau and Tanner[3] have demonstrated that heat-inactivated serum from infected hosts is cytotoxic to the protoscolices of *E. multilocularis in vitro*. Based on these results, we now hypothesise that anti-*Echinococcus* antibodies in the serum of infected animals can "recognise" antigenic sites on the parasite but are unable to reach these sites in sufficient quantities under the natural conditions of the infection; given the opportunity of contact, these cytotoxic antibodies would subject the parasites to the deleterious effects of the immune response. We now present results which show that cysts of *E. granulosus* are killed when the fluid within these cysts is replaced with the fresh serum of infected animals and suggest this immunotherapy as a novel treatment of hydatid disease. Similar replacement of the fluid of *E. multilocularis* cysts also successfully killed the treated cysts; but the cyst mass continued to grow by surface budding.

In a series of experiments, sterile and fertile free peritoneal cysts of *E. granulosus* from infected A/J mice were transplanted into the peritoneal cavities of normal cotton rats (*Sigmondon hispidus*). Sixty days later, laparotomy was performed and the cysts treated as described in Table 1.

When the fluid was replaced with fresh serum from infected hosts (group 3), the cysts showed signs of regression by day 30 and became opaque, compared with the healthy transparent cysts in the controls (groups 1 and 2). From day 60–150, the laminated membrane of the treated cysts thickened, fluid was lost and the germinal membrane collapsed; the protoscolices within these cysts were degenerated and dead and failed to produce an infection when inoculated into susceptible animals.

Various hypotheses have been proposed to account for the survival of parasites in immunologically competent hosts[5-11]. The data presented in this report confirm our working hypothesis and also offer a practical approach to the biological/medical treatment of *E. granulosus* cysts. Thus, in spite of the claim that hydatid cysts induce an insufficient adverse host response[12], our results indicate that circulating anti-*Echinococcus* antibodies can kill these cysts if they contact the inner surface of the germinal membrane in sufficient quantities. These results raise the possibility that the cyst membrane is either impermeable to cytotoxic antibodies and thus selectively permeable to macromolecules, or that these antibodies pass into the cysts in quantities too small to destroy the parasite. Since macromolecules of host origin have been demonstrated in hydatid cysts[4,13,14], we conclude that the latter mechanism is operative in hydatid infections and would explain the long persistence of hydatid cysts in the immunologically hostile environment of the host. Furthermore, a breakdown in the mechanisms controlling permeability of the membrane and the consequent leakage of cytotoxic antibodies into the cysts could account for dead hydatid cysts found sometimes in infected animals.

Table 1 Effect of the replacement of hydatid fluid by serum on the growth of *Echinococcus granulosus* cysts in cotton rats

Group	No. of animals	Treatment	No. of viable cysts / Total no. of cysts
1	6	None	6/6
2	6	Normal cotton rat serum	6/6
3	6	Infected cotton rat serum	0/6

Adult cotton rats were each surgically transplanted with one cyst (1–3 cm in diameter) of *E. granulosus*. Two months later laparotomy was performed and the following treatments carried out: Group 1: no treatment; groups 2 and 3: the cysts were punctured with a 22 gauge needle and the fluid was aspirated and replaced by an equal volume of 20% ice-cold fresh serum (in Medium 199) from normal or heavily infected cotton rats (>30 g cyst mass), respectively. The needle, an empty syringe and a syringe containing the diluted serum were fitted on to a 3-way valve (Pharmaseal) and used in the above procedure. Cyst growth and survival was determined every 30 d on laparotomy in alternate animals. The experiment was terminated on day 150 after treatment when the viability of the cysts was determined both macroscopically at necropsy as well as by an increase in cyst size and/or by the eventual formation of protoscolices in the sterile cysts after subsequent transplantation into susceptible animals

Although surgery is the commonest treatment for hydatid disease[15,16], it is often unsuccessful since spillage of cystic contents, particularly protoscolices, during surgical resection can result in anaphylactic shock and secondary hydatidosis. Furthermore, surgery is impractical when the cysts are embedded in vital organs, such as heart and brain, or when resection of the parasite also necessitates the excision of tissues that are vital to the host. Our findings suggest the possibility that a hydatid infection with *E. granulosus* can be treated and the parasite killed by replacing the fluid within the cysts with fresh serum from the infected host. Since the need for surgical resection would no longer be necessary, spillage of protoscolices and hydatid fluid is minimised and the host need not be subjected to ethanol, formalin or hypertonic saline which are currently used to kill the parasite before resection. Protoscolices that might escape as a result of this treatment would have been lysed by the complement proteins in the injected fresh serum. This new approach provides, for the first time, a practical immunotherapeutic method to treat and kill surgically non-resectable *E. granulosus* cysts.

This research was supported by grants from the Research Programs Directorate, DNHW, and from the Medical Research Council to C.E.T. Research at the Institute of Parasitology is supported by the National Research Council of Canada.

Identification of breast cancer transcortin and its inhibitory role in cell-mediated immunity

THE successful development and maintenance of a neoplastic malignancy is generally accepted to result from a temporary or lasting suppression of cell-mediated immune mechanisms. Many studies illustrate that whereas lymphocytes of a cancer patient are functionally sound, their participation in cell-mediated immune responses to an antigenic neoplasm is abrogated by factors present in the plasma[1]. Among such factors identified are certain plasma proteins whose concentrations are markedly higher in the plasma of the cancer patient[2]. We have shown that the content of transcortin, the cortisol-binding protein of human plasma, is higher in patients with demonstrable cancer[3], and since transcortin inhibits the response of human lymphocytes to phytohaemagglutinin[4], a test generally accepted as demonstrative of active cell-mediated potential, we have attempted to study the relationship of such elevated levels of plasma transcortin to breast cancer.

The question of whether serum obtained from freshly diagnosed breast cancer cases inhibits the response of normal human lymphocytes to the presence of phytohaemagglutinin is answered by the data presented in Table 1. The inhibition of the incorporation of ^{3}H-thymidine into DNA promoted by such sera remains even after exhaustive dialysis, and therefore the responsible factor must be a species whose molecular weight is in excess of 10,000. In addition, we have tested the suppressive property of these sera on the incorporation of DNA precursors by lymphocytes of the RPM I-1788 cell line, and a similar inhibition was also found with all such sera tested. We also note that transcortin inhibits the incorporation of thymidine by either normal or RPM I-1788 lymphocytes.

Since breast cancer sera have been shown previously to contain two to three times as much transcortin as those of the corresponding normal females (our unpublished work), and since transcortin also inhibits the synthesis of DNA by human lymphocytes[4], we investigated the relationship of increased levels of transcortin to the existence of the breast tumour; of primary concern was the question of the source of the increase in plasma transcortin. Previously, we used a transcortin-specific antibody tagged with fluorescence, which we applied to frozen sections of tissues. This permitted the *in situ* identification of intracellular transcortin in human liver[5] and lymphocytes[6] as well as in the syncytiotrophoblastic cells of the human placenta[4]. In the case of both the liver and the placenta, this molecule seems to be synthesised within the tissues studied and subsequently released to the immediate circulatory supply of the representative tissues. On the basis of the placental transcortin study, we reasoned that breast tissue might also demonstrate the *in situ* presence of a species recognisable by the fluorescein-labelled transcortin-specific antibody.

Table 1 Effect of breast cancer sera and transcortin on the incorporation of ^{3}H-thymidine by normal lymphocytes stimulated with PHA, and by RPM I-1788 lymphocytes

	N	Mean c.p.m. ± s.d.	% Difference
(1)* Normal lymphocytes stimulated with PHA			
Normal sera	5	6,680 ± 180	—
Breast cancer sera	10	4,290 ± 165	−36%
Transcortin	5	3,460 ± 51	−48%
(2)† RPM I-1788 lymphocytes			
Normal sera	5	2,065 ± 82	—
Breast cancer sera	10	842 ± 38	−60%
Transcortin	5	1,386 ± 18	−33%

*5 × 10^5 Normal human lymphocytes were incubated in 2 ml of medium containing PHA with 0.2 ml of sera from normal or breast cancer patients, or with 50 mg of purified human transcortin[4]. At the end of 72 h incubation, 2 μCi of ^{3}H-thymidine was added to each culture and incubation was continued for an additional 2 h.

†5 × 10^5 RPM I-1788 lymphocytes were incubated in 2 ml of media with normal or breast cancer sera, or transcortin as above.

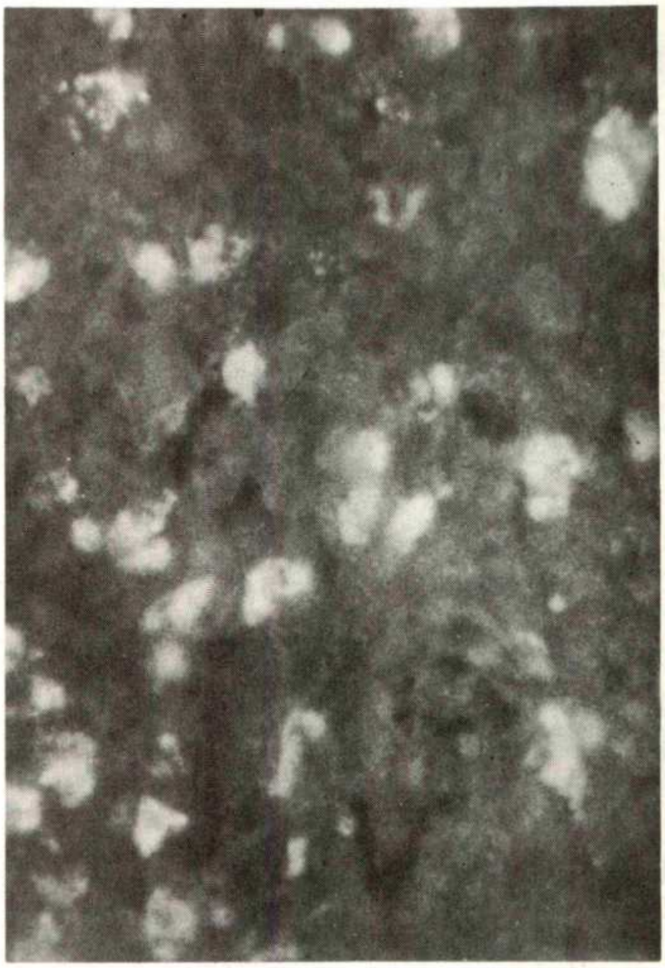

Fig. 1 Fresh biopsy breast tissues frozen rapidly and sectioned at a thickness of 4 μm. The sections were air dried and fixed in ice-cold acetone, and stored at −20 °C. Fluorescein-labelled transcortin antibody was applied as previously described[4].

Figure 1 illustrates that transcortin is present within the sectioned cells of the human breast cancer tissue. No transcortin has been detected by this technique in normal breast tissue. We have also studied other breast diseases in this way and have noted that transcortin almost exclusively occurs in malignancies of the breast. Table 2 shows that whereas 52 normal breast tissues gave negative results, almost 95% of all breast cancers examined contained transcortin. It is interesting to note that the condition of gynocomastia in the male, a benign tumour influenced by

Table 2 Fluorescent localisation of transcortin in breast lesions

excessive oestrogen levels, is also positive for transcortin.

In an effort to define the functional role of breast cancer transcortin, we have tested the possibility that cytosols of breast cancer tissues could, as transcortin and breast cancer sera, limit the response of lymphocytes to PHA stimulation. Table 3 illustrates that only breast cancer cytosol exhibits appreciable inhibitory qualities in the incorporation of thymidine into the DNA of either normal or RPM I-1788 lymphocytes. The inhibitory factor is non-dialysable, and furthermore the inhibition can be obviated if cytosols are stripped of transcortin by previous incubation with the transcortin-specific antibody.

In summary, our studies indicate quite strongly that breast cancer tissue contains a transcortin-like species capable of limiting the response of human lymphocytes to PHA. Since oestrogens are known to induce breast cancer in both females[7] and males[8], and since oestrogen also induces the biosynthesis of transcortin in liver[9], the observation that the oestrogen-induced gynocomastic lesion also contains transcortin lends support to the hypothesis that oestrogen promotes the successful development and maintenance of a breast cancer by inducing the synthesis of transcortin within the abnormal cells. It is the release of this transcortin and its subsequent role in inhibiting the responses of T cells to the antigenic neoplasm which we believe to result in the successful maintenance of the breast cancer.

Table 3 Effect of normal and breast tumour cytosol on the incorporation of ^{3}H-thymidine by PHA-stimulated human lymphocytes and RPM I-1788 lymphocytes

	No. of separate experiments	Average difference from controls (%)
(1) Normal lymphocytes stimulated with PHA

Breast tissues were obtained surgically, homogenised in 0.010 M Tris-phosphate *p*H 7.4, the lipid layer removed and cytosols prepared by centrifugation for 3 h at 105,000*g*. Protein concentrations were adjusted to 10 mg ml^{-1}. All cytosols prepared were used on that same day for all the above experiments. 0.2 ml of breast cytosols were added to cultures containing normal lymphocytes and PHA, or RPM I-1788 lymphocytes. Incubations were for 72 h at 37 °C. At the end of this period, 2 μCi of ^{3}H-thymidine was added. Breast cytosols for some experiments were dialysed against 3 l of buffer for 24 h at 4 °C. In other experiments, breast cytosols were incubated with transcortin-specific antibody for 24 h at 4 °C. The antibody–antigen complexes were removed by centrifugation.

We thank Bennie Denson and Daniel Pina for technical assistance, Gloria Daniti for the preparation of the manuscript and Allan Brown for the preparation of the figure.

Cyclic nucleotide-dependent phosphorylation of intestinal epithelium proteins

THE function of cyclic AMP as an important regulator of ion and fluid transport in the small intestine has been well documented[1]. The non-dividing maturating crypt cells and the differentiated villous cells are the main sources of cyclic AMP-mediated secretion of water and electrolytes during experimental cholera in rats and guinea pigs[2,3]. It has been proposed that cyclic AMP, analogous to its possible mode of action in kidney[4] and toad bladder[5] epithelial cells, controls ion movements across the apical membrane of the intestinal epithelial cell (enterocyte) by changing the state of phosphorylation of some protein(s) in the intestinal brush border[6]. Studies have shown, however, that adenylate cyclase[2,7], the high affinity form of particulate cyclic AMP phosphodiesterase (unpublished observation) and receptor bound cyclic AMP (ref. 8) are localised predominantly in the basal–lateral membranes of the villous cell. In contrast, the luminal membrane is enriched in components of the cyclic GMP system, such as guanylate cyclase[9,10], cyclic GMP phosphodiesterase (unpublished observation) and receptor-bound cyclic GMP (ref. 8). The polarisation of both systems in the enterocyte would be more consistent with a model in which cyclic GMP, rather than cyclic AMP, is involved in the regulation of ion transport across the brush border, whereas cyclic AMP action might be confined to the contraluminal membrane. To test this hypothesis further, we have studied the subcellular distribution of specific substrate proteins for cyclic nucleotide-dependent protein kinases in isolated villous cells from rat small intestine.

Brush borders, microsomal fractions (enriched in basal–lateral membrane markers, compare ref. 11) and a 100,000*g* supernatant fraction (containing the cytosolic proteins) from villous cells were prepared as described previously[2,9,12]. Subcellular fractions were incubated with γ-^{32}P-ATP in the presence of Mg^{2+}, the proteins were separated by sodium dodecyl sulphate (SDS)–polyacrylamide gel electrophoresis and stained with Coomassie blue. Subsequently, the gels were dried and processed for autoradiography.

Protein staining patterns of brush-border preparations (Fig. 1) were characterised by a high content of an actin-like protein (molecular weight ~ 46,000) identified earlier by Tilney and Mooseker in microvillous cores from chicken intestine[13]. Incubation in the absence of cyclic nucleotides revealed a number of ^{32}P-labelled proteins, most of them not coinciding with major protein staining bands. Low concentrations of cyclic GMP (0.05–1.0 μM) or high concentrations of cyclic AMP (1.0–10 μM) caused an additional phosphorylation of a single brush-border protein (hereafter called protein B) with an apparent molecular weight of 86,000. The radioactivity of this band most probably reflects labelled phosphate esterified to serine or threonine residues of the protein because: no radioactive band could be detected using α-^{32}P-ATP; lipid extraction, treatment with hydroxylamine, cold or hot trichloroacetic acid or cold sodium hydroxide before electrophoresis did not influence the extent of labelling; and treatment with 0.4 M NaOH at 37 °C for 15 h removed the label almost completely (results

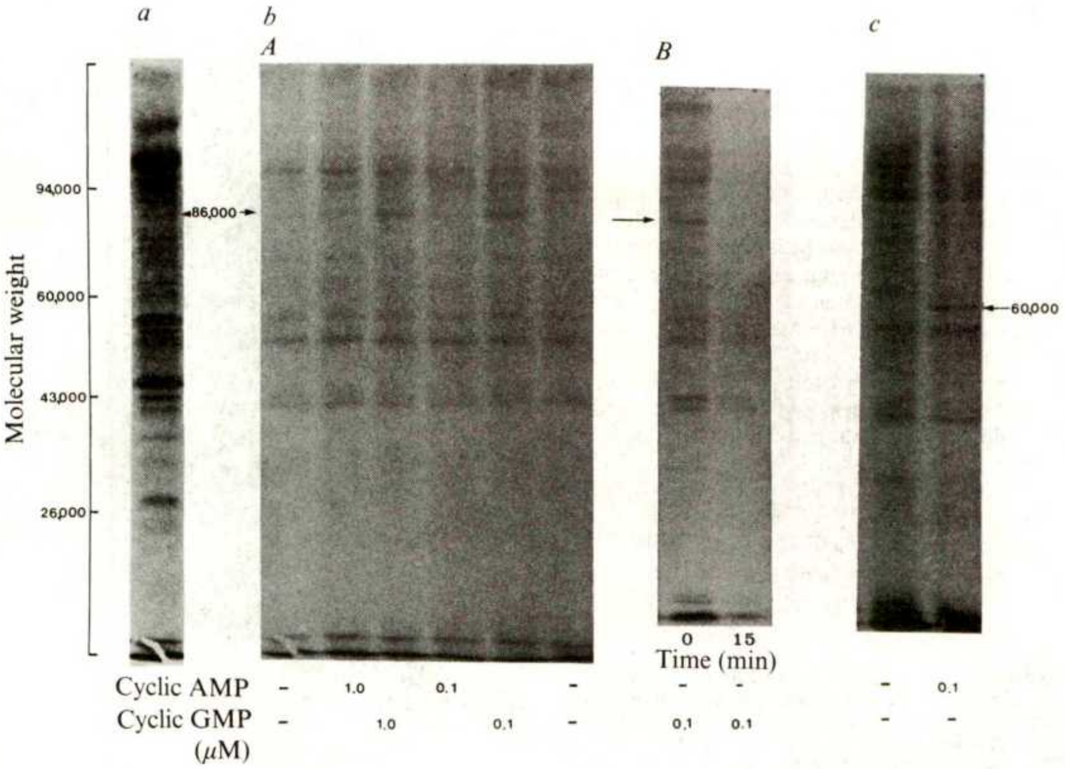

Fig. 1 *a*, Protein staining. *b* and *c*, Autoradiographs: Effects of cyclic GMP and cyclic AMP on endogenous phosphorylation of brush borders isolated from rat enterocytes. Intestinal brush borders (100–150 μg of protein) without (*b*) or with (*c*) cytosolic proteins (60 μg) were preincubated for 3 min at 30 °C in a volume of 50 μl containing 40 mM histidine buffer, 50 mM manitol, 10 mM Tris-HCl, 5 mM sodium-β-glycerophosphate (to diminish degradation of ATP by alkaline phosphatase), 5 mM theophylline, 10 mM $MgCl_2$ and cyclic nucleotide concentrations as indicated (final *p*H 6.8). Phosphorylation (*A* and *c*) started by addition of 2 μCi γ-^{32}P-ATP (final concentration 20 μM) and terminated after 10 s with 25 μl of a solution containing 60 mM Tris-HCl, 2 mM ATP, 3% SDS and 30% glycerol (*p*H 7.4). To stop the reaction the mixture was heated immediately in a boiling water bath, cooled and provided with 0.5% β-mercaptoethanol. 40 μl aliquots were loaded on 10% acrylamide–0.1% SDS slab gels (thickness 1 mm) with a 3% acrylamide stacking gel and run in the discontinuous buffer system of Laemmli[13] using a Slabophor apparatus (Pleuger, Wijnegem, Belgium). Electrophoresis was carried out for 6–8 h at 30 mA. For the procedures of gel staining, drying and autoradiography we refer to Ueda *et al.*[14]. In the dephosphorylation experiments (*B*) brush borders were labelled first for 2 min at 0 °C as described above, followed by rapid sedimentation in an Eppendorf 3200 centrifuge (30 s, 10,000 r.p.m.). The pellet was suspended in 50 μl of fresh medium prewarmed at 30 °C containing 10 mM $MgCl_2$, 5 mM ATP and 50 mM Tris-HCl (*p*H 7.0). After 5–15 min of incubation at 30 °C, dephosphorylation was terminated as described above. Molecular weight determinations were carried out according to Weber and Osborn[15] using phosphorylase *a*, catalase, ovalbumin and chymotrypsinogen as markers.

not shown). The phosphoprotein B caused one of the major peaks in optical density tracings of brush-border autoradiographs but corresponded with only a minor band in the protein staining pattern (Fig. 1). Densitometric analysis also showed that incorporation of label into protein B proceeded linearly with time for 10 s at 30 °C or 30 s at 0 °C. Incorporation was much lower in the presence of 10 mM Mn^{2+} or Ca^{2+} and was nearly absent in the presence of Zn^{2+} (5 mM) or γ-^{32}P-GTP instead of ATP (data not shown). The apparent K_a value for its phosphorylation by cyclic GMP (0.06 μM) was about 30-fold less than for cyclic AMP (2 μM; Fig. 2). The endogenous dephosphorylation of protein B was a relatively slow process. At 30 °C, half of the ^{32}P label was removed after 5 min whereas 20% of the initial label was left after 15 min (Fig. 1). Dephosphorylation rates did not change by addition of cytosolic proteins or cyclic nucleotides. The different turnover rates of the phosphoproteins on the autoradiograph (Fig. 1) suggest that the intrinsic phosphatase(s) in the brush border possess a certain degree of specificity towards their substrates.

A cyclic GMP-dependent phosphorylation could not be detected in villous cell fractions other than brush borders. Presumably, protein B is an integral and specific component of the microvillous membrane. Its phosphorylation was still manifest in brush-border preparations purified according to Hopfer *et al.*[17] with a relatively low content of core material (result not shown).

In spite of a wide variation in experimental conditions we were unable to show any specific effect of cyclic AMP on protein phosphorylation in isolated brush borders. If a cytosolic fraction was included in the system as a possible source of cyclic AMP-dependent protein kinase, a specific cyclic AMP-dependent phosphorylation of a 60,000 molecular weight protein was decided (Fig. 1*c*), but a similar radioactive peak of equal intensity appeared if the same amount of cytosolic protein was incubated alone (Fig. 3*c*). The corresponding apparent K_a for cyclic AMP was 0.04 μM (Fig. 2). A protein with similar properties was also found in microsomal membranes (Fig. 3*b*). This protein is probably identical to the so-called 'steroid and cyclic AMP regulated phosphoprotein'. (SCARP) detected by Greengard's group in cytosolic and membranous fractions from a large number of other rat tissues[18,19]: its molecular weight is comparable to that of SCARP (49,000–54,000); it is seen as the highest labelled band on autoradiographs of cytosolic fractions (Fig. 3); replacement of Mg^{2+} by Zn^{2+} 5 mM or Ca^{2+} 2 mM led to inhibition instead of stimulation of the phosphorylation rate by cyclic AMP, both in cytosolic and microsomal preparation (data not shown); and cyclic GMP up to 10 μM was entirely ineffective and was also unable to modify the cyclic AMP response (Figs 2 and 3). The only unusual property of the microsomal substrate protein was the strong stimulation of its phosphorylation by cyclic AMP in the presence of Mg^{2+}. In particulate fractions from most other tissues (synaptic membranes excepted[14]), cyclic AMP was hardly effective in this condition or even displayed an inhibitory action (toad bladder[5]).

The present discovery of cyclic GMP-dependent phosphorylation of a specific microvillous protein provides a possible mechanism by which cyclic GMP might change the properties of transport systems exclusively at the luminal membrane of the villous cell. Phosphorylation of protein B might exert a direct effect on the ion transport properties of the membrane or, alternatively, might work rather indirectly by changing the contractility of the microvillous core. The latter mechanism could then be quite analogous to the action of cyclic GMP on smooth muscle contractility, most probably also mediated by changes in the phosphorylation state of specific membrane-bound substrate proteins for cyclic GMP-dependent protein kinases[20].

Since high concentrations of cyclic AMP are able to promote the phosphorylation of protein B as efficiently as cyclic GMP (Fig. 2) it may be proposed that brush border phosphorylation could also be changed by cyclic AMP in pathological conditions characterised by high levels of this nucleotide (cholera) or during *in vitro* incubations with high concentrations (10^{-3}–10^{-2} M) of exogenously added cyclic AMP, dibutyryl cyclic AMP or theophylline[21,22]. Cyclic GMP levels might also be augmented in these conditions as a consequence of inhibitory or competitive effects on cyclic GMP phosphodiesterases (unpublished and refs 23–25). In contrast, phosphorylation of the SCARP-like protein—most probably absent in the brush border but enriched in microsomal preparations—could then be involved in cyclic AMP-dependent changes of ion transport across the basal–lateral plasma membrane. Direct measurements of the degree of phosphorylation of protein B and the SCARP-like protein in intact epithelium in different hormonal conditions and absorption or secretion states will be necessary to further substantiate this model.

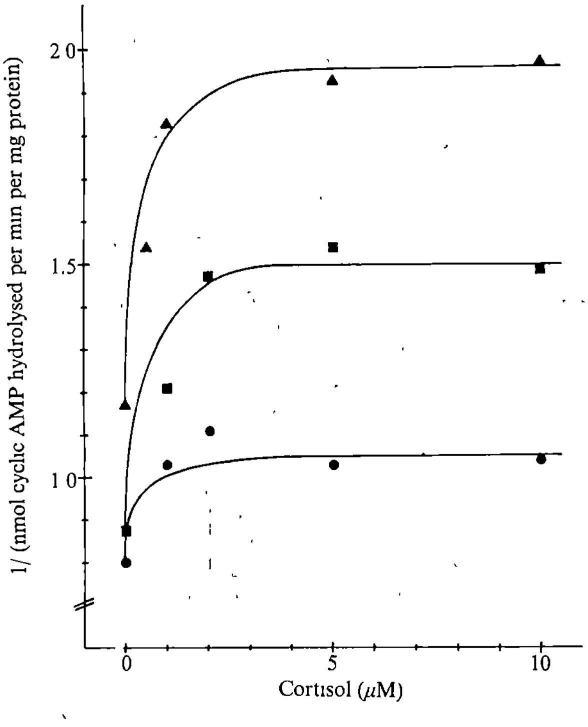
In vitro inhibition of cyclic AMP phosphodiesterase by cortisol

HORMONAL effects on cyclic nucleotide phosphodiesterase activity are assumed to play an important role in the regulation of intracellular cyclic nucleotide concentrations[1]. The respective hormones vary widely with respect to function and structure, and comprise polypeptides, biogenic amines, and steroids including the glucocorticoids[2–4]. In no case, however, has the mechanism of hormonal action on cyclic AMP phosphodiesterase clearly been established. It is not known whether the enzyme itself is the primary point of attack by the hormone or whether the observed changes in enzyme activity (for review, see ref. 1) are side-effects of hormonal action, since no conclusive *in vitro* studies have been undertaken so far.

In the course of experiments designed to elucidate the possible function of the adrenal glucocorticoids as stimulators of the cyclic AMP-mediated human chorionic gonadotropin (hCG) sensitivity of the postnatal Leydig cell in the rat[5], we have tested the influence of cortisol on cyclic AMP phosphodiesterase activity in crude testis homogenates. For comparison, we have examined the effect of cortisol on the activity of the commercially available enzyme purified from beef heart.

Fig. 1 Inhibition of cyclic AMP phosphodiesterase from rat testicular tissue. Dixon plot of the reciprocal of reaction velocity against cortisol concentration. Each point represents the mean of duplicate determinations. Cyclic AMP concentrations in the assay were 0.120 (●), 0.058 (■), and 0.036 (▲) mM. Pooled testes from 20-d-old SIV 50 rats were homogenised with a motor-driven glass pestle in 10.9% sucrose 1:10 (w/v). The homogenate was sonicated with a Branson B12 sonifier at setting 1 for 30 s. All steps were carried out in an ice bath. The homogenate was adjusted to *p*H 6.0 with 1 M acetic acid[6], and a clear supernatant was obtained by centrifugation at 20,000*g* at 4 °C for 20 min.



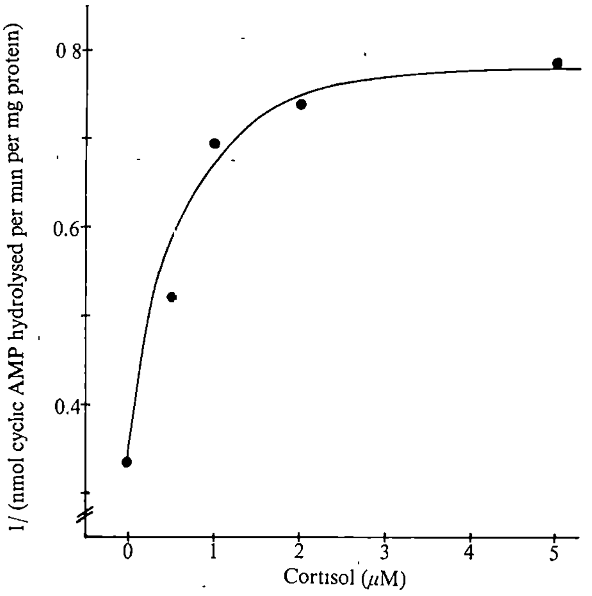


Fig. 2 Inhibition of cyclic AMP phosphodiesterase from beef heart. Dixon plot of the reciprocal of reaction velocity against cortisol concentration. Each point represents the mean of duplicate determinations. Cyclic AMP concentration in the assay was 0.0124 mM. The substrate was solved in 66 mM Tris-HCl buffer, *p*H 8.5, containing 1 mM $MgCl_2$.

Cyclic AMP phosphodiesterase was assayed as described by Rutten *et al.*[7]. The incubation medium contained 66 mM Tris-HCl, *p*H 8.5, 1 mM $MgCl_2$, 0.5 μM ^3H cyclic AMP (Amersham Buchler, specific activity 27 Ci $mmol^{-1}$), varying concentrations of unlabelled cyclic AMP (Boehringer, Mannheim, Germany), and 25 μl diluted tissue homogenate supernatant or enzyme solution in a final volume of 140 μl. Homogenate supernatant and enzyme concentrations were adjusted to a total substrate conversion not exceeding 10% of the initial concentrations. After 20 min incubation at 37 °C (the reaction was at least 2 h linear) the reaction was stopped by placing the tubes into boiling water for 2 min; 8 mU 5′ nucleotidase (Sigma) were added, the mixture was centrifuged (10 min at 10,000 *g*) and 100 μl of the supernatant were applied to a column (20×6 mm) filled with DOWEX 200–400 mesh (Serva). The column was eluted with 10 ml 0.1 M $NaHCO_3$, the eluate mixed with 10 ml scintillation fluor (Szintigel; Roth, Karlsruhe, Germany) and counted in a Tri-Carb scintillation counter. Inhibition experiments were carried out with homogenate supernatants as well as with enzyme solutions preincubated with 0.5–10 μM cortisol (Merck, Darmstadt, Germany) at 37 °C for 20 min. The ethanol, in which cortisol had been dissolved, was evaporated before addition of the enzyme solutions, since the presence of ethanol heavily interfered with the phosphodiesterase assay. The phosphodiesterase assay mixture was adjusted to the corresponding concentrations of cortisol. Controls, containing no cortisol, were preincubated and assayed in parallel.

The results of our experiments demonstrate that both testicular and beef heart cyclic AMP phosphodiesterase can be inhibited by cortisol at low concentrations. In Figs 1 and 2 the reciprocals of the reaction velocities are plotted against cortisol concentration[8]. The curves obtained can be easily interpreted as a partially competitive type of inhibition. This type of inhibition occurs when an intermediate complex of enzyme–substrate–inhibitor is formed, which then breaks down at the same rate as the enzyme–substrate complex, the inhibition therefore being purely an effect on affinity (Fig. 3). Assuming that product formation is rate-limiting and the enzyme, enzyme–substrate, enzyme–inhibitor, enzyme–inhibitor–substrate are rapidly equili-

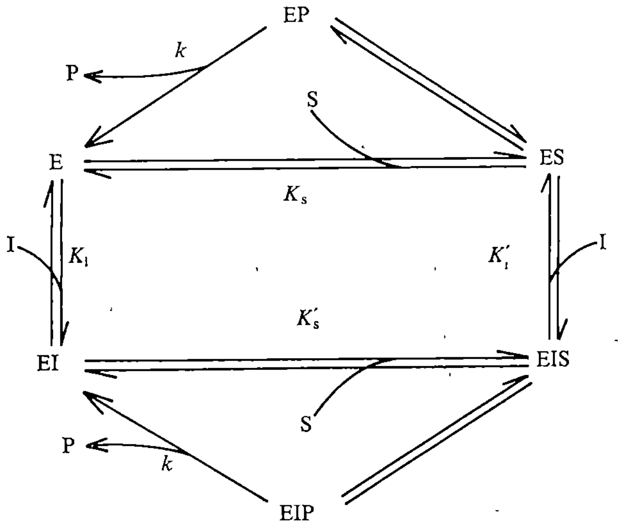

Fig. 3 Reaction scheme: partially competitive inhibition. E, Enzyme; EP, enzyme–product; EI, enzyme–inhibitor; EIP, enzyme–inhibitor–product; P, product; S, substrate; ES, enzyme–substrate; I, inhibitor.

brating, the 'rapid equilibrium treatment' easily leads to the rate equation[9]

$$v = \frac{V}{1+\dfrac{K_m(1+i/K_i)}{s(1+(i/K_i)(K_m/K'_s))}}$$

The plateau of the resulting curve is attained when all the enzyme is combined with inhibitor, and the degree of inhibition can increase no further.

Electrophoretic investigations of testis homogenates from 20-d-old rats revealed a single enzyme species possessing cyclic AMP phosphodiesterase activity. This enzyme exhibited true Michaelis–Menten behaviour in the range of substrate concentrations tested (0.6 mM–4.5 μM). Before the inhibition constants could be calculated, K_m and V had to be determined. We found the specific activity to be 1.5 mU per mg protein and the Michaelis constant to be 0.018 mM. Our results are largely consistent with the data reported by other workers[10]. The K_m and the specific activity of the commercially available phosphodiesterase purified from beef heart were 0.13 mM and 37 mU per mg protein, respectively. The range of substrate concentrations tested was 0.36 mM–2.9 μM.

K_i and K'_s were calculated by fitting a curve to the experimentally determined values of Figs 1 and 2 in an iterative procedure making use of an appropriate computer program. Subsequently the equilibrium constant K'_i was determined according to the equation

$$K_i/K'_i = K_s/K'_s$$

Values of K_m, K'_s, K_i and K'_i for the enzymes from rat testis and beef heart are summarised in Table 1.

Thus, high K_m cyclic AMP phosphodiesterases from two different sources, regardless of purity, seem to be inhibited by the same mechanism at low concentrations of cortisol. We have recently shown that low K_m cyclic AMP phosphodiesterase present in the testicular tissue of the 10-d-old rat can be inhibited by cortisol in a manner indicative of the partially competitive type of inhibition (W. E., M. F., J. Frowein and J. S., unpublished). It is tempting, therefore, to speculate that many of the so-called 'permissive effects' produced by glucocorticoids on cyclic AMP-mediated processes[11,12] reflect in fact a direct interaction of these hormones with cyclic AMP phosphodiesterase[8].

Table 1 Equilibrium constants for enzymes from rat testis and beef heart

	K_m (mM)	K'_s (mM)	K_i (μM)	K'_i (μM)
Rat testis	0.018	0.075	0.05	0.21
Beef heart	0.13	0.37	0.15	0.43

(−)-Propranolol inhibits the behavioural responses of rats to increased 5-hydroxytryptamine in the central nervous system

THERE are now several reports of the beneficial effect of large doses of (±)-propranolol in the treatment of various psychoses, particularly schizophrenia[1–3]. These reports prompted us to investigate whether propranolol had any effect on the behavioural syndrome produced in rats by increasing the functional activity of 5-hydroxytryptamine (5-HT) or dopamine (DA) in the central nervous system. Our results indicate that large doses of (−)-propranolol but not (+)-propranolol inhibit the behavioural responses resulting from increased functional activity of central 5-HT but not DA.

To investigate the action of propranolol on brain 5-HT function we used a behavioural model[4] reviewed elsewhere[5]. This involves the injection of tranylcypromine and L-tryptophan and measurement of the hyperactivity that results from the increased synthesis of 5-HT and its "spillover" into functional activity.

Rats were given (±)-propranolol (40 mg kg^{-1}) by intraperitoneal injection or saline and 45 min later given tranylcypromine followed by L-tryptophan (details in legend to Fig. 1). All aspects of the hyperactivity syndrome were almost totally inhibited by (±)-propranolol pretreatment (Table 1).

No evidence was found for alteration of the steady-state concentration of whole brain 5-HT, 45 min after (±)-propranolol (40 mg kg^{-1}). Both the rate of 5-HT synthesis and the rate of accumulation of 5-HT following administration of tranylcypromine and L-tryptophan were also unaltered by the single injection of (±)-propranolol. This demonstrated that propranolol was not exerting its effect on the hyperactivity syndrome by altering 5-HT biosynthetic mechanisms and suggested that the drug was in some way altering postsynaptic responses to 5-HT receptor stimulation.

This was examined indirectly by injection of the suggested 5-HT agonist 5-methoxy *N,N*-dimethyltryptamine (5-MeODMT). This compound produces a hyperactivity syndrome qualitatively identical to that seen when tranylcypromine and L-tryptophan are given but with a different time course and it has been suggested that this compound stimulates central 5-HT receptors[6].

Pretreatment of rats with (±)-propranolol (40 mg kg^{-1}) 45 min before tranylcypromine (20 mg kg^{-1}), with 5-MeODMT (2 mg kg^{-1}) given 30 min later resulted in almost complete abolition of the hyperactivity response. A similar reduction in the hyperactivity was seen in rats pretreated with (±)-propranolol (40 mg kg^{-1}) following subsequent administration of tranylcypromine and 5-methoxytryptamine, another suggested 5-HT agonist[7,8]. These results indicated therefore that propranolol inhibits the behavioural changes produced by central 5-HT stimulation and that it probably does so by means of a postsynaptic 5-HT receptor mechanism or through an effect on neuronal structures connected to these receptors.

The hyperactivity once established could be considerably reduced within 5 min by injection of (±)-propranolol (40 mg kg^{-1}) (Fig. 1). Furthermore, no inhibition was observed when (±)-propranolol (40 mg kg^{-1}) was given 3 h before the tranylcypromine administration. Since the half life of propranolol is about 40 min (ref. 9) these results suggested that the effect of propranolol was due to the parent compound rather than a metabolite. This view was strengthened by the observation that pretreatment of the rats with the drug metabolising enzyme inhibitor SKF525A, while not altering the hyperactivity seen when tranylcypromine and tryptophan were given, did make (±)-propranolol effective in inhibiting the hyperactivity at a dose (20 mg kg^{-1}) which is normally almost ineffective (Table 1).

The effect of the two isomers was next examined to determine whether both forms of the drug were equally active in inhibiting the 5-HT induced hyperactivity response. Injection of (−)-propranolol (20 mg kg^{-1}) 45 min before the tranylcypromine administration abolished the hyperactivity following subsequent tryptophan injection as effectively as when (±)-propranolol (40 mg kg^{-1}) had been given (Fig. 1 and Table 1) and the hyperactivity was inhibited by (−)-propranolol in a dose dependent manner (Fig. 1) Injection of (+)-propranolol (20 mg kg^{-1}) however was without effect on the hyperactivity (Fig. 1) suggesting that it is only the (−)-form of the drug in the racemate that is inhibiting the 5-HT induced behavioural changes.

To find out if propranolol had any effect on brain dopaminergic function we examined whether propranolol administration altered the locomotor activity produced by administration to rats of tranylcypromine and L-dopa since this activity seems to be almost solely the result of stimulation of dopaminergic systems in the brain[10]. Administration of (±)-propranolol (40 mg kg^{-1}) or (+) or (−)-propanolol (20 mg kg^{-1}) 45 min before the tranylcypromine did not alter the locomotor activity seen after subsequent L-dopa administration (Fig. 2). This indicated that propranolol has no inhibitory action on DA neurotransmission, a conclusion strengthened by two further observations. First (−)-propanolol (20 mg kg^{-1}) did not inhibit the rotation produced by amphetamine (5 mg kg^{-1}) in unilateral nigrostriatal lesioned rats and it is believed that turning produced in these animals by amphetamine is the result of dopaminergic stimulation[11,12]. Furthermore, propranolol is ineffective in inhibiting striatal dopamine sensitive adenylate cyclase[13], a finding confirmed in our current studies. It was also found that (±)-propranolol (40 mg kg^{-1}) had no effect on brain DA or noradrenaline concentration 45 min later.

The effect of other β-adrenergic receptor blocking drugs was also investigated. Propranolol is a β_1 and β_2 receptor blocking agent, and being lipid soluble enters the brain. The structurally related drug pronethalol (40 mg kg^{-1}) was almost ineffective in inhibiting the 5-HT mediated response, as was butoxamine (40 mg kg^{-1}) a lipid soluble β_2 antagonist (Table 1). Practolol (40 mg kg^{-1}) a β_2 receptor blocking agent that does not enter the brain in significant quantity[14] did not inhibit hyperactivity (Table 1). Thus propranolol

Fig. 1 Effect of (+)- and (−)-propranolol on the hyperactivity produced by administration of tranylcypromine and L-tryptophan. Groups of 3 rats (male Sprague–Dawley, 160–200 g, Anglia Laboratory Animals, Huntingdon) were injected with either saline (■), (−)-propranolol, 20 mg kg^{-1} (●), 15 mg kg^{-1} (○), 10 mg kg^{-1} (△) or (+)-propranolol, 20 mg kg^{-1} (▲). After 45 min all groups were injected with tranylcypromine (20 mg kg^{-1}) and L-tryptophan (L-Trp; 50 mg kg^{-1}) 30 min later. Fig. 1 shows subsequent changes in activity in each group using LKB Animex activity meters (sensitivity and tuning: 30 µA). The behavioural changes observed and method of measurement were exactly as described previously[4]. The effect of administration of (±)-propranolol (40 mg kg^{-1}) to rats already displaying hyperactivity is also shown (□), the drug being administered at the arrow.

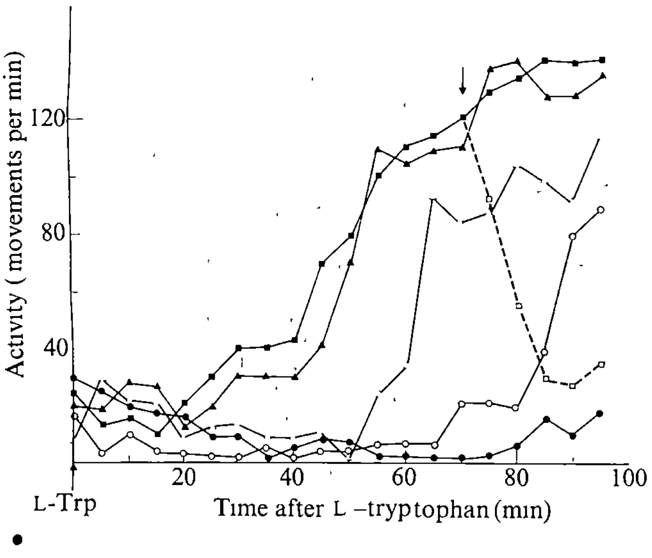

Table 1 Effect of (±)-propanolol pretreatment on hyperactivity induced by tranylcypromine and L-tryptophan

Injected	Total movements during 90 min following L-tryptophan (50 mg kg^{-1})
Saline	5,316± 598 (8)
(±)-Propranolol (40 mg kg^{-1})	886± 284 (3)*
(−)-Propranolol (20 mg kg^{-1})	1,041± 357 (3)*
(+)-Propranolol (20 mg kg^{-1})	4,558± 319 (3)
(±)-Propranolol (20 mg kg^{-1})	4,090± 759 (4)
(±)-Propranolol (20 mg kg^{-1}) +SKF 525A (2×10 mg kg^{-1})	1,740± 180 (3)‡
Pronethalol (40 mg kg^{-1})	3,631± 475 (4)†
Practolol (40 mg kg^{-1})	4,728± 920 (4)
Butoxamine (40 mg kg^{-1})	5,355±1,031 (3)
	Total movements during 60 min following L-dopa (50 mg kg^{-1})
Saline	3,140± 180 (3)
(−)-Propranolol (20 mg kg^{-1})	3,305± 110 (3)

Rats were injected with propranolol, pronethalol, practolol or butoxamine 45 min before tranylcypromine and activity measured following subsequent L-tryptophan or L-dopa administration as described in caption to Fig. 1. All drugs were dissolved in 0.9% saline except practolol which was suspended in 0.9% saline containing 1% carboxymethylcellulose and all these drugs were injected intraperitoneally. In the SKF 525A experiment rats were injected subcutaneously with SKF 525A (10 mg kg^{-1}) 30 min before and 30 min after the propranolol administration, tranylcypromine being given 45 min after propranolol as before. Results expressed as mean±s.e.m. with number of observations in brackets.

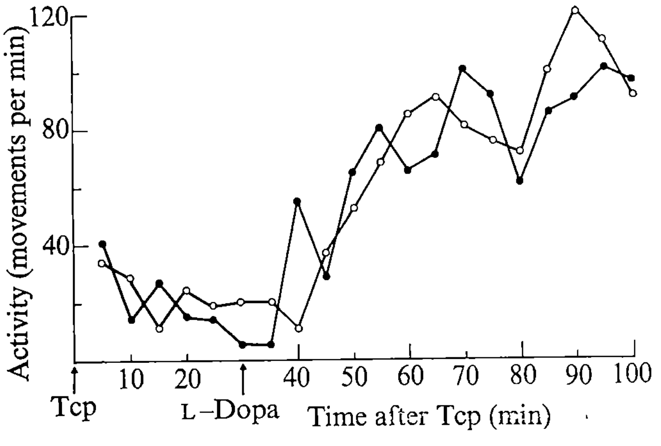

Fig. 2 Effect of (−)-propranolol on the locomotor activity produced by administration of tranylcypromine (Tcp) and L-dopa. Groups of 3 rats were injected with either saline (●) or (−)-propranolol, 20 mg kg^{-1} (○). After 45 min both groups were injected with tranylcypromine (20 mg kg^{-1}) with L-dopa (50 mg kg^{-1}) 30 min later. The figure shows subsequent changes in activity. The behavioural changes observed were as described previously[10].

was the only one of the β-adrenergic blocking drugs tested to inhibit 5-HT induced hyperactivity. Furthermore, this action cannot be ascribed to any tranquillising action of propranolol, since previous studies in rats have shown both isomers to be equipotent in this respect[15,16]

The results therefore all suggest that propranolol inhibits central 5-HT function, a finding that is analagous to the recent observation that (−)-propranolol (but not the (+)-isomer) blocks neurotransmission produced by 5-HT in the cat cervical ganglion[17].

If our conclusions are correct that propranolol inhibits central 5-HT neurotransmission and if future studies confirm its efficacy in the treatment of schizophrenia then there are several important implications.

Much interest has been focused on the dopamine receptor blocking action of neuroleptics as their mode of action, as anti-psychotic drugs[18,19] and indeed this has led to suggestions that increased activity of dopamine pathways may be involved in the aetiology of schizophrenia. If propranolol inhibits the central effects of 5-HT but not dopamine and if it is effective by this mechanism in schizophrenia then indirectly this points to an involvement of 5-HT as well as, or instead of, dopamine in this condition. Indeed, if 5-HT mechanisms were involved at a higher organisational level than dopaminergic mechanisms then the action of current neuroleptics could still be explained by their action on dopaminergic mechanisms. In rats inhibition of dopaminergic function either by use of neuroleptic drugs[6,20] or the decrease of brain dopamine concentration[21] blocks the behavioural responses to increasing 5-HT functional activity in the brain. Thus it seems that blocking dopaminergic activity can result in inhibition of certain aspects of central 5-HT function.

The demonstrated effect of propranolol on central 5-HT function, raises the question as to whether this is the mode of its action as an anti-schizophrenic drug and, if so, the role of 5-HT in schizophrenia.

We thank Ann F. C. Tordoff for technical assistance, Dr D. T. Greenwood of ICI Pharmaceuticals for propranolol and discussions and Burroughs Wellcome for butoxamine.

Decreased uptake of 5-hydroxytryptamine in blood platelets from depressed patients

THE search for biological aberrations in affective disorders has been intensified within the last few years[1]. Special attention has been given to the changes in the metabolites of 5-hydroxytryptamine (5-HT) and of catecholamines in the cerebrospinal fluid[2]. In this laboratory[3] as well as in several others[4,5] the blood platelet has been used as an easily obtainable model of 5-HT neurones. Studies on the storage, metabolism and uptake of 5-HT in various neurological and mental illnesses have been largely negative[1,6,7] except in Down's syndrome[8–10]. Neither in schizophrenia[6] nor in affective illness[7] have any changes been found. By using low substrate concentrations and measuring the initial uptake rate, both the uptake kinetics in platelets and the inhibitory potencies of antidepressant drugs were recently shown to correlate well with those found in synaptosomes[11]. It was therefore of considerable interest to examine the kinetics of 5-HT uptake anew, in the platelets of certain psychiatric patients, notably those with manic-depressive illness. This report indicates that in the platelets of depressed patients the uptake of 5-HT is clearly decreased.

The patients studied were newly hospitalised with a diagnosis of depression. None of them had used tricyclic antidepressants or any other drugs known to interfere with the amine transport mechanisms for at least two days before the study commenced and some of them had never used antidepressants. Nor were any differences observed between patients who had recently ingested drugs and those who had not. The controls were healthy laboratory personnel, and the sample was taken at the same time as that of the patient. Platelets from one patient and one control were usually examined simultaneously.

The experiments were performed essentially as described previously[11]. Blood platelets were isolated and incubated in Krebs–Henseleit bicarbonate buffer with tritiated 5-HT. The accumulation of radioactive 5-HT to platelets in 5 min was determined. After subtracting the portion taken up by non-active processes, the data were subjected to kinetic analysis[12].

A very clear and highly significant difference was found in the 5-HT uptake by platelets from patients as compared to those from the controls (Fig. 1). The initial uptake by the platelets of depressed patients was about half as active as that of the controls. This is also reflected in the V_{max} of the process (Fig. 2) On the other hand, no difference was noted in the K_m. This suggests that there are less of the hypothetical transport molecules or "amine carriers"[13,14] in the cell membranes, or that some of them are

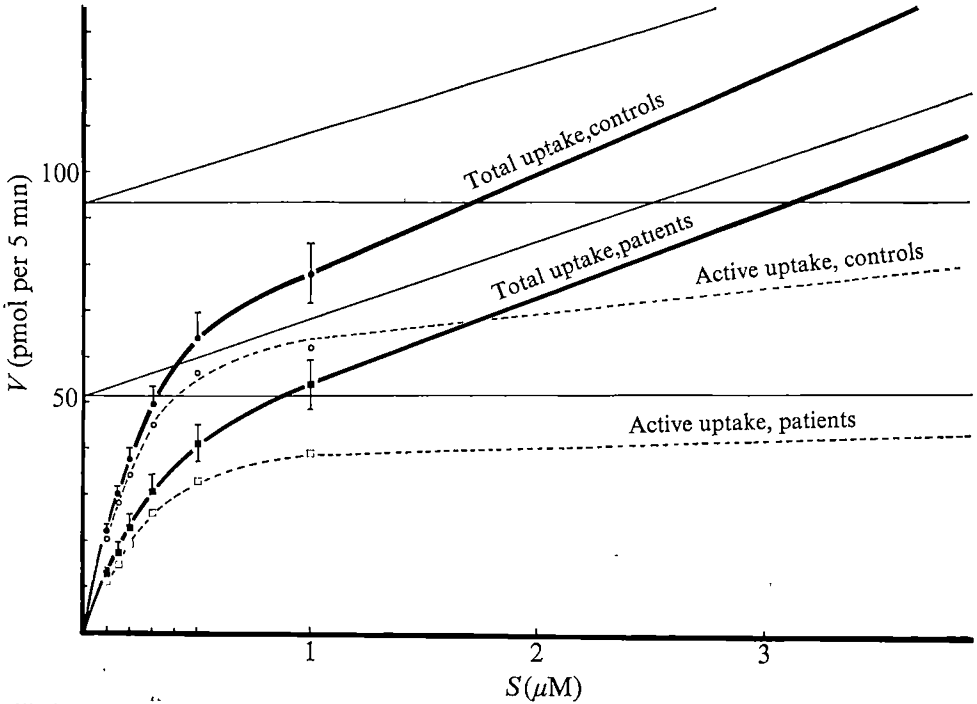

Fig. 1 Uptake of 5-HT by blood platelets of patients with depression (■) and controls (●) when the 5-HT concentration was varied from 10^{-7} to 10^{-4} M. The continuous thick lines show the total accumulation which continued linear to 10^{-4} M (thin lines indicate extrapolation from the highest concentrations). The dotted lines show the active uptake after subtraction of the linear part[11]. Before the incubation, the platelet-rich plasma was diluted with autologous platelet-free plasma to contain 200,000 platelets·mm^{-3}. An aliquot (100 μl) of diluted plasma (containing 0.15% EDTA) was added to 3.9 ml of prewarmed (37 °C) Krebs–Henseleit bicarbonate buffer (*p*H 7.4), containing 10^{-8}M ^{3}H-5-HT (5.66 Ci mmol^{-1}) and a necessary amount of cold 5-HT to make up total 5-HT concentrations of 10^{-7} to 10^{-4} M. After 5 min of incubation in a metabolic shaker, the platelets were separated by filtration (cellulose nitrate filters, pore size 0.2 μm) and washed with 10 ml of ice-cold saline. The radioactivity accumulated to the filters was assayed by liquid scintillation. Means±s.e.m. of duplicate experiments on 10 patients and 10 controls.

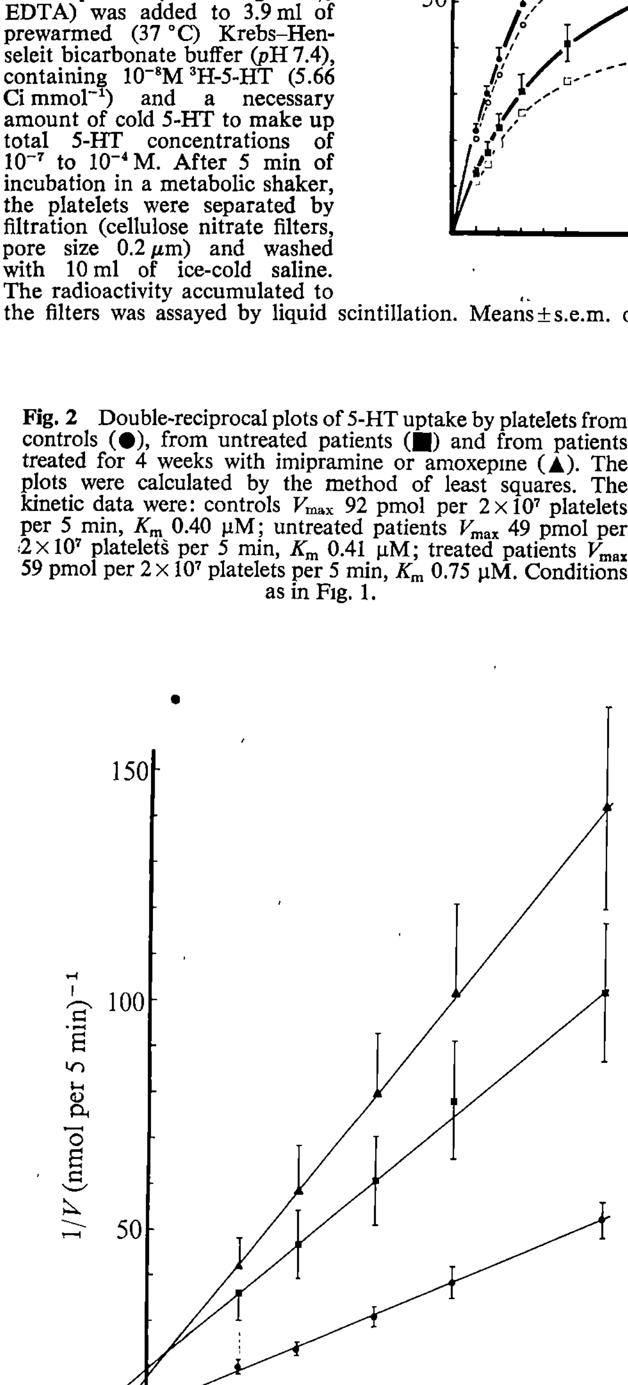
Fig. 2 Double-reciprocal plots of 5-HT uptake by platelets from controls (●), from untreated patients (■) and from patients treated for 4 weeks with imipramine or amoxepine (▲). The plots were calculated by the method of least squares. The kinetic data were: controls V_{max} 92 pmol per 2×10^7 platelets per 5 min, K_m 0.40 μM; untreated patients V_{max} 49 pmol per 2×10^7 platelets per 5 min, K_m 0.41 μM; treated patients V_{max} 59 pmol per 2×10^7 platelets per 5 min, K_m 0.75 μM. Conditions as in Fig. 1.



in an inactive state. Those which remain, however, are in a fully functional state as indicated by the unchanged K_m. The change is quite contrary to that seen in platelets or in brain synaptosomes after exposing them to tricyclic drugs[11]: they increase the K_m but the V_{max} remains the same, that is, the affinity to the transport is decreased, but the number of hypothetical carrier molecules remains the same. Also in the present study the V_{max} remained the same, but the K_m increased, when imipramine 10^{-8} M was added to the incubation medium. The same change was caused by imipramine both in the patients and in the controls. The different mode of kinetics rules out the possibility that the decrease in 5-HT uptake would be due to some tricyclic drug in the plasma and in the platelets of these patients.

After 4 weeks' treatment with antidepressants (either imipramine or amoxepine) a change in uptake characteristics was observed. The V_{max} had moved towards the control. At the same time, however, an increase in the K_m, apparently due to the antidepressant, was noted (Fig. 2). Patients under chronic lithium treatment, but at present without depressive symptoms, did not differ from the controls (J.T., E.T., Ahlfors and Levä, to be published).

We feel that these findings are most exciting and might be investigated along two lines: first, to find out whether it is feasible to use these aberrations as a basis for laboratory tests for certain subtypes of depression, and second, what these changes imply about the functioning of tryptaminergic neurones in the brain. If a similar change could be demonstrated in the neurones, the most crucial question would be whether this decrease in the 5-HT uptake is a constitutional change typical of the individual and common to both platelets and neurones, which seem to have the same or very similar mechanism to take up 5-HT[5,11]. On the other hand, the change could also be secondary and, possibly, compensatory to depression. In that case a question is how the change is transmitted to platelets. Perhaps hormonal or some other chemical regulatory mechanism might then be considered. Either way, these results may add a new dimension to the biological parameters in affective illness.

We thank Dr U. Ahlfors, Professor T. Pihkanen, and Mrs Sirkku Tuomikoski for help in obtaining the patient samples, Dr Leena Tuomisto for many consultations, and Mrs Anneli v. Behr for technical aid.

Reduction of quantum contents of synaptic potentials after postsynaptic axotomy

THE loss of synaptic transmission in the chick ciliary ganglion that is observed after the postganglionic section of the ciliary nerves is accompanied by both a decrease in acetylcholine (ACh) sensitivity of the axotomised cells and a change in the transmitter release characteristics of the presynaptic terminals[1,2]. Evidence for the presynaptic change included a decrease in the mean quantum content *m* of the excitatory postsynaptic potentials (e.p.s.p.s) and a greater susceptibility to fatigue during repetitive stimulation. The reduction in quantum content after axotomy was inferred from an increase in the coefficient of variation of the e.p.s p. amplitude distribution in the depressed state. In the experiments reported here it was possible to measure miniature synaptic potentials (m.e.p.p.s) in axotomised preparations so that more accurate estimates of the mean quantum content of e.p.s.p.s could be made .

Experiments were done on 3- and 4-d-old chickens. Axotomy of the ciliary nerves was performed within a few hours after hatching. Surgical and experimental procedures have been described before[1,3]. To ensure that transmission failure in axotomised preparations was not caused by disuse of the ganglionic synapses, in some chickens only the eyelids were sutured together and the animals were kept and fed in the dark for 4–5 d. No impairment of transmission was observed in ganglia taken from these control animals.

The *m* of the e.p.s.p.s was estimated by dividing their mean amplitude ($\bar{v}$) by the mean quantal size ($\bar{v}_1$). Mean e.p.s.p. amplitudes were determined from 5–15 measurements, taken at 10-s intervals to avoid synaptic depression. In the axotomised cells action potential initiation by the e.p.s.p.s could be blocked by hyperpolarising the cell (Fig. 1*a*). In some normal cells with large e.p.s.p.s it was not possible to pass sufficient hyperpolarising current to achieve such block. In such cases the e.p.s.p. amplitude was estimated from the inflexion at the onset of the action potential (Fig. 1*b*, arrow) or, if no such inflexion was present, from the residual synaptic depolarisation after the action potential (Fig. 1*c*, arrow). The latter two measurements represent underestimates of the true e.p.s.p. amplitudes. Quantal sizes were determined in two ways. In most experiments spontaneous release of quanta could be induced by stimulating the preganglionic nerve at 30–50 Hz for 30 s. The modal amplitude of the spontaneous m.e.p.s.p.s was taken as the quantal size. In some of the axotomised cells single quantal responses to nerve stimulation were obtained by perfusing the preparation with saline solution containing $\frac{1}{3}$ normal Ca^{2+} and 6×normal Mg^{2+}. Measurements of quantal size were corrected to correspond to the hyperpolarised level of membrane potential at which the e.p.s.p.s were measured; that is, *m* was determined from the relation: $\bar{v}_{hyp}/\bar{v}_{1hyp}$, where $\bar{v}_{1hyp}=\bar{v}_1(E_{hyp}-15)/(E_r-15)$. E_{hyp} is the membrane potential at which the e.p.s.p. was measured and E_r the resting membrane potential. The equation assumes the reversal potential for the e.p.s.p. is at −15 mV (refs 2 and 3). Input resistances (*R*) were determined routinely in all cells. The conductance (Δg) produced by a single quantum of ACh was calculated from the relation: $\Delta g=\bar{v}_1/R(E_r-15)^4$.

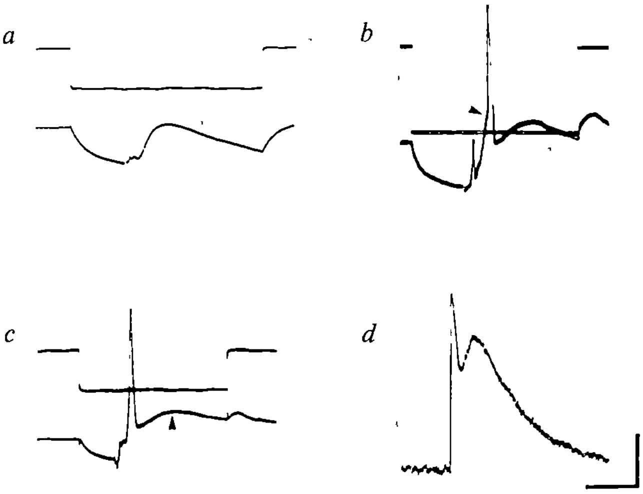

Fig. 1 Examples of e.p.s.p.s (used for calculation of mean quantum contents) from axotomised (*a* and *d*) and control cells (*b* and *c*). Amplitudes were corrected for nonlinear summation[9], neglecting the influence of membrane capacitance. The resulting overestimation of the mean quantum contents, *m*, were, at least partially, balanced by the underestimated measurements of e.p.s.p. amplitudes, when the generation of action potentials could not be blocked. Occasionally, e.p.s.p.s in such cells were large enough to initiate two action potentials. Calibration: 40 mV (*a*, *b* and *c*), 4 mV (*d*); 10 ms.

Table 1 summarises the mean quantal contents of e.p.s.p.s in which the signal-to-noise ratio was high enough for the average quantal amplitude of the m.e.p.s.p.s to be estimated with an accuracy of ±10%. The mean quantum contents of e.p.s.p.s recorded from axotomised cells were significantly lower than in control cells. The actual difference might be somewhat greater than indicated in Table 1 because of the underestimate of control e.p.s.p. amplitudes already mentioned in connection with Fig. 1*b* and *c*. The results summarised in Table 1 therefore confirm the observations obtained previously by more indirect measurements[1].

It could be argued that the lower quantum contents measured after axotomy were due to partial detachment of the presynaptic terminal from the postsynaptic cell so that the number of release sites apposed to the postsynaptic receptors was reduced. Detachment of presynaptic terminals after postsynaptic axo-

Table 1 Comparison of *m* of e.p.s.p. and of Δg produced by one quantum in control and axotomised cells

P (*t*-test)	<0.01	>0.1	

N, number of experiments.
For unknown reasons, *m* in control cells is significantly higher and Δg lower than found by Martin and Pilar[5].

tomy has indeed been found to be the major reason for loss of synaptic transmission in several preparations[6,7]. In the ciliary ganglion of chickens, synapses are electrically coupled[3] and detachment would be expected to reduce the coupling between presynaptic terminals and ganglion cells. The fact that the average amplitude of the coupling potentials was reduced after axotomy (6.6 mV compared with 18.3 mV in the control group) and that the percentage of cell profiles lacking synaptic contacts was increased[1], may therefore suggest partial detachment. As reported previously, however, the faster rate of fatigue of chemical transmission at synapses in axotomised preparations[1] cannot be explained on this basis. Moreover, in several axotomised cells, e.p.s.p.s smaller than ever observed in control cells were preceded by a coupling potential of normal amplitude (Fig. 1*d*). These findings suggest that the effects of axotomy on the parameters of synaptic transmission can occur before significant detachment. Similar observations have been made on axotomised cat spinal motoneurones[8].

Table 1 also indicates that the unit conductance change, Δg, produced in the postsynaptic membrane by the interaction with one quantum of transmitter substance, was lower in axotomised than in control cells. The difference in Δg, however, is not statistically significant. In fact, two out of three of the axotomised cells had values of Δg larger than the smallest Δg observed in the control cells. This suggests that a decrease in transmitter release can occur before, or in the absence of, a reduction in postsynaptic ACh sensitivity. The lack of significant reduction in Δg is in contrast to the reduced sensitivity of the axotomised cells to iontophoretically applied ACh[2].

In the present experiments described here, however, the axotomised cells were selected for particularly high miniature potential amplitudes. Many of the cells impaled, particularly those with small e.p.s.p. amplitudes, could not be used for calculations of *m* because m.e.p.s.p.s were absent or too small to be measured accurately. Such cells had resting potentials and input resistances similar to those of cells listed in Table 1 and therefore would have been expected to produce measurable m.e.p.s.p.s if the underlying unit conductances had been the same. The disparity between the reduced sensitivity to exogenous ACh and lack of a marked reduction in Δg can also be explained in another way, namely by supposing that single receptor sites are lost after axotomy one at a time, together with the release sites apposed to them. This would lead to a decrease in overall ACh sensitivity with no reduction in the quantal conductance change, Δg, at the remaining sites. The reduction in quantum content would then be due, at least in part, to loss of release sites. Alternatively, postsynaptic receptor sites might disappear without accompanying loss of corresponding presynaptic release sites. Quantal release in such regions would then be ineffective and there would be an apparent reduction in *m*. In this case the increased susceptibility of the e.p.s.p. to fatigue during repetitive stimulation[1] would be the only electrophysiologically identifiable presynaptic consequence of postsynaptic axotomy. At present it is not possible to decide between these mechanisms.

I thank Dr A. R. Martin for advice. This work was supported by grants from the USPHS and the Holderbank–Stiftung (Switzerland).

Re-examination of avian cochlear potentials

THE aim of this study is to provide a basic description of the cochlear receptor potentials, the cochlear microphonic (CM) and the summating potential (SP) of the bird. Although several workers have examined these avian potentials in limited aspects, a comprehensive survey of their frequency and intensity behaviour is long overdue. Moreover, a re-examination of the avian potentials has seemed necessary because the potentials are reported to differ vastly from the mammalian CM and SP and one is left with the baffling implication that the middle and/or inner ears of these classes operate with a degree of dissimilarity exceeding what might reasonably be expected on the basis of structural difference. For example, the avian CM sensitivity function has been reported[1] to be flatter than the middle ear transfer function in a comparable species[2] thus implicating an unknown sort of cochlear element in the frequency response of the avian system. Second, the slopes of avian CM input–output functions have been reported as considerably less than unity and thus less steep than in the mammal[1,3–7] leaving unanswered the question of whether the mechanics of the middle ear or basilar membrane, or peculiarities of the receptor cells *per se*, enforce the nonlinear intensity response in the bird. Third, if, as reported, the avian summating potential is appropriately described as a unitary negative response, manifest only at frequencies above 600 Hz (refs 4, 7–10), one can hardly reconcile this with the observation that the SP exists as both a positive and negative response in the mammal, and certainly occurs at even the lowest audible frequencies[11,12] in that class. While each of the above differences implies a fundamental dichotomy between the avian and mammalian cochleae, such differences were not found in the present study. We did however use a new intracochlear electrode configuration in the elucidation of the parametric behaviour of the CM and SP in the pigeon. Fine tungsten electrodes, flame-sealed in capillary tubing, were placed in the basal scala vestibuli (SV) and the scala tympani (ST) proper. This electrode configuration made differential recordings possible and avoided electroanatomical effects, believed to be inherent in previous recessus tympani or round window recordings in the bird. The following differentially measured avian functions are discussed: the 1-μV r.m.s. CM isopotential curve, CM isovelocity curves (relative to a constant footplate velocity of 10^{-6} mm s^{-1}), CM input–output functions, CM "degree of nonlinearity" functions and SP isovelocity functions. Our results show that these functions do not differ significantly from their mammalian counterparts.

Racing pigeons (*Columba livia*), generally less than three

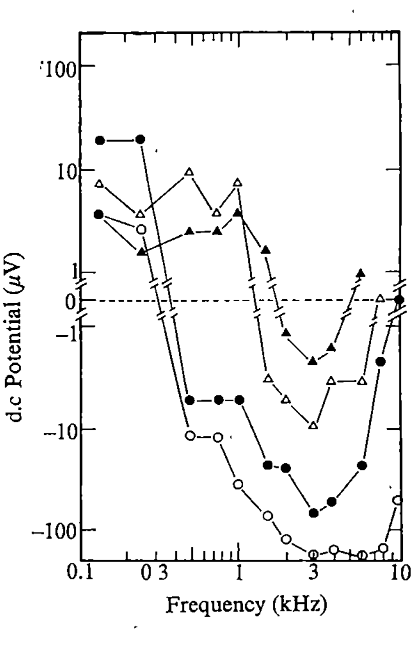
months old, were used. The birds were sedated with 20 mg kg^{-1} pentobarbital 15 min before anaesthetisation with 64 mg kg^{-1} ketamine. Supplemental half-doses of ketamine were administered every 90 min thereafter. A tracheostomy was performed and the pigeons were respirated throughout surgery and the data collection period. The animals were maintained at 107 °F with a feedback-controlled heating pad. The surgical approach used was a dorsolateral one described by Wever and Bray[1]. Figure 1 shows the electrode locations used. The wire of the SV electrode could be cut quite short since that scala is shallow in the bird[13,14]. By contrast the wire of the ST electrode had to traverse the recessus tympani before the tip could be appropriately positioned for differential recordings. It was therefore necessary to fuse a 1.5–2.0-mm glass insulating shoulder along the wire of that electrode. To assess whether damage occurred during the placement of this long electrode tip into the rather inaccessible scala tympani, the sensitivity of the CM and the magnitude of whole nerve action potential, both recorded from the SV electrode, were compared before and after the ST electrode was placed.

In Fig. 2*a*, a median, differentially measured 1-μV CM isopotential curve (that is, sound pressure levels (SPL) required to produce 1-μV r.m.s. CM) for 7 pigeons is presented in conjunction with a reciprocal form of an average middle ear transfer function measured in five Barbary doves[2]. The inversion of that middle ear function was achieved by expressing footplate velocity measurements[2] in dB relative to the maximum velocity obtained at a constant SPL (that is velocity at 1,000 Hz). In Fig. 2*a*, it should be noted that the contours of the inverted middle ear transfer function and the CM isopotential function are well matched below 4,000 Hz. This agreement corresponds well with other studies in suggesting that the CM sensitivity in a normal cochlea is proportional to the footplate velocity[15,18] up to a cutoff frequency that depends on electrode location. Moreover, the correspondence suggests that the influence of the middle ear on cochlear response could be minimised by referencing input levels to a constant footplate velocity. This has been shown to be the case in studies of mammalian cochlear function[18]. Consequently, in the parametric measurements being reported, the SPL at the eardrum was adjusted from frequency to frequency on the basis of the middle ear transfer function of the Barbary dove to produce an approximately constant footplate velocity across frequency. To this end a velocity of 10^{-6} mm s^{-1} (1 nm s^{-1}) was arbitrary called 0 dB in the present study and corresponds approximately to a 20 dB SPL signal at 1,000 Hz.

Figure 2*b* shows differentially measured CM isovelocity functions (that is, CM magnitude measured at constant footplate velocity) at 20-dB intervals in one pigeon. As expected using a constant footplate velocity, the functions are quite flat below the best frequency of the electrode pair. The notch seen at 2 kHz could be a consequence of the irregularity of the middle ear response (not manifested in the average transfer function) or a cochlear effect. Similar notches below the best frequency are also seen in guinea pig CM functions[17]. At the 40 dB level, the 3,000-Hz en-

Fig. 3 Differential SP isovelocity functions from one pigeon. Using averaged responses, measurements were made 25 ms after stimulus onset. The parameter is footplate velocity level expressed in dB relative to 1 nm s^{-1}. Symbols as for Fig. 2.



hancement indicated this to be the best frequency of the differential electrode location used in this, and most (see Fig. 2*a*) pigeons. Were input output functions to be derived at low frequencies from the data shown in Fig. 2*b*; they would have an initial slope of 1.0 in double logarithmic coordinates. This indicates that the avian middle ear, the basilar membrane, and the contributing receptor cells have an operating range characterised by simple linearity over at least some portion of their dynamic range.

Figure 2*c* was derived from the data contained in Fig. 2*b*. In the construction of Fig. 2*c*, the response magnitude of the curves in 2*b* was normalised by shifting each curve vertically by an amount equivalent to the expected linear increase in the CM (commensurate with the increase in input level). The "degree of nonlinearity"[18] functions shown in Fig 2*c* were then derived by converting to dB the deviations of each normalised curve from the 40-dB isovelocity output. In Fig. 2*c*, it is seen that a region of pronounced nonlinearity develops around the best frequency. As the input level increases, the region of nonlinearity spreads to increasingly lower frequencies. The coincidence of the best frequency and the frequency of earliest and most pronounced nonlinearity is noteworthy inasmuch as CM nonlinearities are most prominent $\frac{1}{3}$ to $\frac{1}{2}$ octave above the best frequency in the guinea pig[18]. Nonlinearities at frequencies below the region of early nonlinearity, although clearly present, do not seem to be frequency-dependent in their severity. This is suggestive that two mechanisms produce CM nonlinearities; one mechanism being simply dependent on input level and one being also influenced by frequency.

The frequency response pattern of the differential component (SV–ST potential difference) of the summating potential is shown in Fig. 3. The earliest (40 dB level) and most pronounced negative component occurs at the best frequency (3,000 Hz) of the electrode pair. Similar to the summating potential in the mammal, the negative response band spreads to increasingly lower frequencies as the input level is increased. It is apparent, contrary to earlier reports, that there is a positive SP component at lower frequencies in the pigeon.

One may conclude that the salient properties of both receptor potential components (CM and SP) are very similar in representative avian and mammalian cochleas. It is likely that the differences shown between the results of the present and earlier work on avian receptor potentials are accountable by the generally excellent physiological condition of our animals, the lack of prolonged or excessive sound exposure in the present work, and by the electroanatomical differences between the present differential electrode location and the previously used round window or recessus tympani sites.

The only significant discrepancy found between avian and mammalian receptor potentials is that the CM nonlinearities and the most pronounced negative differential SP component (itself a nonlinear phenomenon) occur at the best frequency in the pigeon, whereas these nonlinearities occur above the best frequency in the guinea pig[18]. In both classes the occurrence of these nonlinearities seems to correspond to the relative frequency at which noise-induced hearing loss occurs. In the parakeet, such losses occur at the centre frequency of the eliciting noise[19], while in the mammal, they appear at about $\frac{1}{2}$ octave above the centre frequency. A possible explanation, one suggested by Saunders and Dooling[19], relates to the observation that travelling wave envelopes are sharper in the bird than in the mammal.

Rod–cone mechanism underlying the Purkinje shift

TABLES have been published[1] of averaged brightness matches made by 16 observers who had compared 11 spectral lights (from 410 to 710 nm) with the CIE standard radiator in a 15° field set at various levels in the mesopic range. The scotopic and photopic luminances (S,P) of each light were calculated by multiplying the spectral radiant power for the match by the corresponding values of the CIE V' and $\bar{y}_{10}$ functions, with appropriate weighting factors. $\bar{y}_{10}$ was used because of the large field. The spectral data can readily be converted to the usual CIE system, and in fact the choice is immaterial in the following argument. As the matches were mesopic, neither S nor P alone can represent the luminance, and the Tables were used later[2] to define this quantity as a function of (S,P). Arithmetic manipulation of the data now suggests a simple rod–cone mechanism responsible for the sensation of brightness.

The first aim of my study was to refer the matches to an ideal light which would stimulate the cones preferentially. A deep red would fulfil this, as even at absolute threshold, redness is still visible[3], indicating a considerable cone response compared with the rod response. The S value for 680 nm is only 1/70 of the P value (P_{680}), and this wavelength was selected as the reference. Light at 710 nm would also be suitable, but the data were deficient at higher levels.

For shorter wavelengths, the ratio S/P gradually increases to a limit of about 10/1 at 440 nm. To compare the various values of (S,P) with the reference, the P value of each light was subtracted from P_{680} and this showed that the difference, ΔP, depended only on S (Fig. 1).

Although derived from experiments done at seven levels spanning an enormous luminance range, most of the points lie on a straight line with a slope of about 0.5. The obvious conclusion is that

$$\Delta P \simeq \sqrt{(M^*S)} \qquad (1)$$

where M^* is some constant with the dimensions of luminance. Thus a light with scotopic and photopic luminances, S and P respectively, is equivalent in brightness to a red light at 680 nm of photopic luminance P_{680}, where

$$P_{680} \simeq P + \sqrt{(M^*S)} \qquad (2)$$

Some points stray far from the line, especially those for long wavelengths. Here ΔP is the difference between similar quantities and is thus bound to fluctuate widely. But a more subtle explanation is required, because the points for 590 nm, 620 nm and 650 nm generally lie below the basic line of the graph (Fig. 1).

The points at variance can be brought into line, *ad hoc*, by reducing their S values, and to do this the CIE $V'\lambda$ curve from which S is calculated must also be reduced at long wavelengths. (Without some correction, equation (2) is bound to fail at 680 nm because the S contribution, although small, is finite.) More measurements are needed for an accurate estimation of the required factor, but inspection suggests a value of about 0.5 at 620 nm, dropping to about 0.25 beyond 680 nm. The equation could then be made to sum to a similar total for all lights of a given equivalent luminance, even for reds deeper than 680 nm, and it could be postulated to represent that combination of rod and cone responses which initiates the sensation of brightness, without reference to a standard.

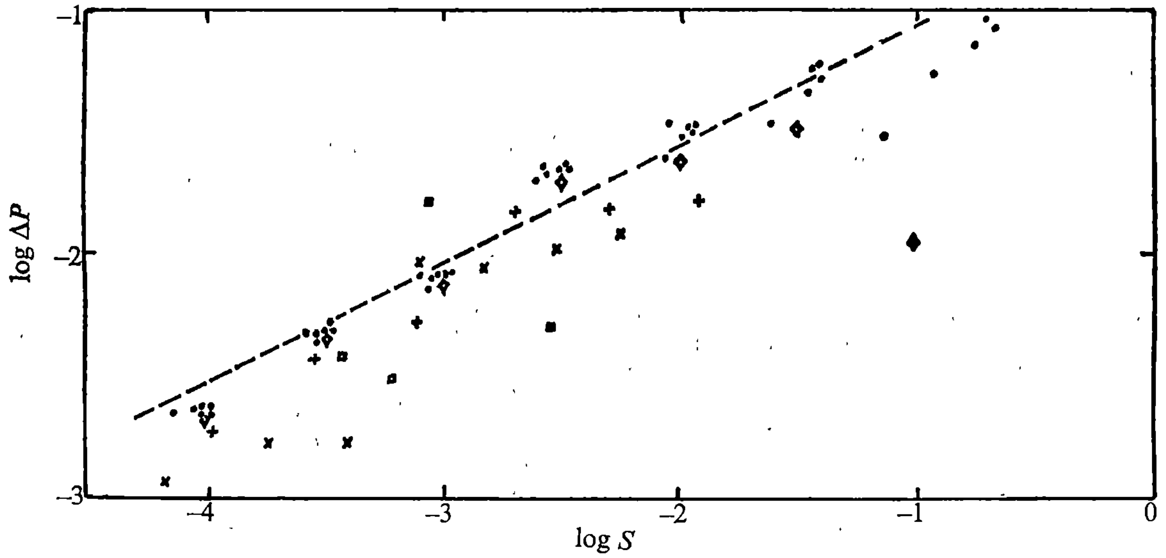

Fig. 1 Plot of ΔP against S on log scales. The quantities $\Delta P, S$ are in cd m^{-2}. +, 590 nm; ×, 620 nm; ▣, 650 nm; ●, 410–560 nm; ◇, standard radiator; — — — —, equation (2) with $M^* = 0.08$ cd m^{-2}.

The suggested modification to $V'\lambda$ is consistent with the initial assumption that, even at threshold, red lights still stimulate cone vision. The likely extrapolation of the graph in Fig. 1 is also intriguing in this respect, because if it continued at a slope of less than unity until it reached the threshold, which lies only one log unit below the lowest point, this would mean that the Purkinje shift is never completed.

For generality, the scheme must include non-monochromatic lights, which have been shown to behave photometrically like monochromatic lights with the same (S,P) coordinates[1,4]. The special case of the standard radiator (a black body at 2,043 K) can be derived from the Tables because its luminance L_v is by definition identical to its S and P values, and can be subtracted from P_{680} to yield ΔP, which is then plotted against L_v ($\equiv S$).

The resultant points (Fig. 1, ◇), follow the general trend through the mesopic range, except that the point at the highest level falls well below the graph. This apparently high discrepancy represents about 25% of P and is caused by additivity failure at high levels[1,4]. The problem is not directly relevant here, where the rod–cone mechanism, and not the cone–cone systems, is being analysed. It may be concluded that equation (2) is valid to a good approximation for a variety of lights throughout the mesopic range.

This general relationship invokes several considerations. It suggests first, a simple mechanism underlying the Purkinje shift. As there are no cross-product terms, neither inhibition of the rods by the cones at high levels, nor inhibition of the cones by the rods at low levels, needs to be postulated. The systems are independent, the rate of increase of the rod contribution diminishing progressively the higher the level. For this effect, a power function with an exponent less than unity is required, not necessarily exactly 0.5. Whether this represents any particular physiological feature in the retina or subsequent neural pathway is problematical, but at least one could search for a 'square-rooting' synapse involving the rod output.

Second, the formula suggests a simple mesopic photometer. This would require two photocells calibrated to the photopic and scotopic curves respectively, the scotopic signal being processed by a square-root circuit before addition to the photopic signal. Lights with the same luminance would therefore generate the same combined output in accordance with equation (2).

Third, intractable mesopic calculations are rendered relatively straightforward. The ideal reference stimulus may be used as a dummy, to convert to any other reference light. For example, for the CIE standard radiator, $S \equiv P \equiv L_v$ by definition. Thus for a light with components (S,P) the simultaneous equations are

$$P_{680} = P + \sqrt{(M^* S)} \qquad (3)$$

$$P_{680} = L_v + \sqrt{(M^* L_v)} \qquad (4)$$

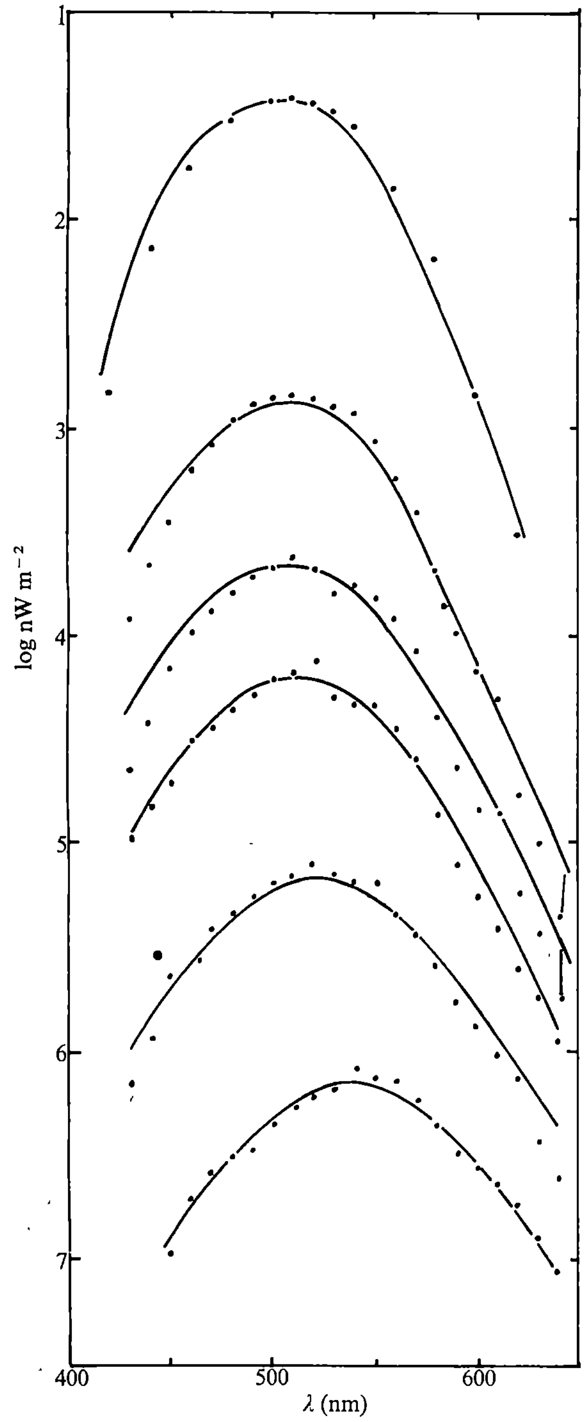
By elimination of P_{680}, L_v emerges as a quadratic solution in terms of S, P and M^*.

M^* is related to a parameter M, dependent on field size[2]. A value of 0.06 cd m^{-2} has been suggested for a 15° field; a somewhat higher figure of about 0.08 cd m^{-2} is needed to fit the data in Fig. 1, if the discrepant long wavelength points are ignored.

By an extension of this mathematical analysis 'mesopic spectral visibility curves' can be produced. Although these are somewhat misleading[4], since they cannot be used to calculate luminances from spectral power distributions, they are commonly used to display the results of spectral brightness matches. Observer D's results from Kinney's classic set[5], measured in a 2° field at a peripheral angle of 10°, are shown in Fig. 2, together with examples of curves calculated using equation (2). The agreement is close, except that the smooth theoretical curves do not reproduce the bumps ascribed by Kinney to cone activity.

Evidently, much information about brightness matching in

Fig. 2 Comparison of Kinney's mesopic visibility curves for subject D with curves calculated from equation (2). The radiant power for a match is plotted in nW m^{-2} on an inverted log scale against the wavelength (λ) in nm.



the mesopic range can be derived from equation (2). Even its inadequacies suggest plausible modifications to the CIE $V'\lambda$ curve, in order to represent the rod response to long wavelength light more accurately. I suggest therefore, that it expresses some fundamental rod–cone mechanism mediating the sensation of brightness.

I thank Dr Kinney for providing the data used in Fig. 2.

Effects of enkephalin and morphine on Renshaw cells in feline spinal cord

IT has been suggested that enkephalin is the endogenous ligand for the opiate receptor[1-3]. This substance is unevenly distributed throughout the brain[3,4] and occurs as two pentapeptides—met- and leu-enkephalin[5]. These substances have been shown to possess analgesic activity when injected intracerebroventricularly into rodents[6,7] and to depress the firing rate of single neurones in the brainstem of cats[8] and rats[9]. In the present experiments the effects of synthetic met-enkephalin have been compared with those of morphine on Renshaw cells in the feline spinal cord using the microelectrophoretic technique. This cholinoceptive interneurone is particularly suitable for such a comparison since it possesses stereospecific opiate receptor sites[10,11]. The results obtained show that both met-enkephalin and morphine directly excite Renshaw cells and that these actions are antagonised by naloxone.

Experiments were carried out on four cats anaesthetised with pentobarbitone sodium (35 mg kg^{-1} intraperitoneally initially). Blood pressure and temperature were monitored continuously. The spinal cord was exposed by lumber laminectomy and the central ends of S_1 and L_7 ventral roots were stimulated to identify Renshaw cells. Extracellular recordings were obtained with the centre barrel (4 M NaCl) of seven barrel microelectrodes (tip diameter 6 μm). The outer barrels contained aqueous solutions of the drugs to be ejected electrophoretically; these were: morphine sulphate (0.05 M), naloxone hydrochloride (0.1 M), L-glutamate sodium (0.5 M), acetylcholine chloride (0.5 M), glycine (0.5 M, *p*H 3) and met-enkephalin (0.018 M, *p*H 4). Action potentials were recorded and displayed using conventional techniques.

The effects of electrophoretic ejections of met-enkephalin were compared with those of morphine on 14 Renshaw cells. Met-enkephalin (50–80 nA for 15–40 s) ejected as a cation, directly excited eight neurones. The onset of and recovery from the excitatory action of met-enkephalin was rapid (3–8 s) and similar to that observed with morphine (50–100 nA), which directly excited eleven neurones including the eight excited by met-enkephalin (Fig. 1*a*). Desensitisation to the excitatory effects of met-enkephalin were not observed on repeated ejection of this substance. Compared with morphine, met-enkephalin was approximately equipotent as an excitant on the basis of equieffective ejecting currents (Fig. 1*a*).

The specific opiate antagonist, naloxone, has previously been shown to antagonise the excitatory effects of morphine and acetylcholine but not those of excitatory amino acids on Renshaw cells[10-13]. This effect of naloxone was also demonstrated in the present experiment (five tests on three cells). In addition, Figure 1*a* shows that naloxone (30 nA for 3–4 min) reversibly antagonised the excitatory effects of met-enkephalin. Similar effects were obtained in six tests on four more Renshaw cells.

Neither met-enkephalin nor morphine directly depressed the firing rate of any of the neurones studied in this investigation. When met-enkephalin (40–80 nA) was ejected for prolonged periods (2 min or more) however, the sensitivity of neurones to acetylcholine was decreased. This effect of met-enkephalin was observed on each of eight neurones, four of which were directly excited by a previous brief ejection of met-enkephalin. In contrast, prolonged ejections of morphine (25–40 nA) enhanced the excitatory effects of acetylcholine (five cells) and L-glutamate (two cells) in agreement with previous findings[10]. The reduction in acetylcholine sensitivity seemed to be a selective action of met-enkephalin in so far as the excitatory effects of morphine and L-glutamate were either unaffected (three neurones) or only slightly reduced (two neurones). Furthermore, the sensitivity of neurones to both morphine and amino acids recovered immediately on terminating the ejection of met-enkephalin, whereas recovery of the acetylcholine sensitivity was often prolonged, requiring up to 5 min or more. The effects of met-enkephalin on the acetylcholine- and morphine-induced excitation is illustrated in Fig. 1*b*.

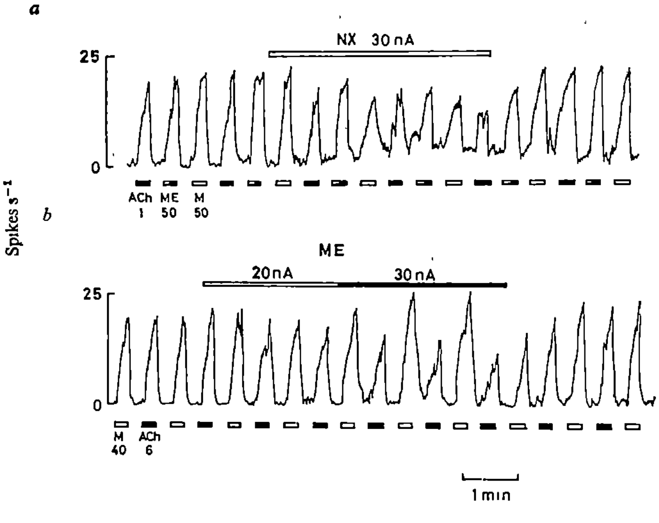
Met-enkephalin (40–100 nA) had no obvious effect on the depressant action of glycine in tests on five neurones whereas morphine (25–40 nA) reversibly reduced this action of glycine in tests on the same neurones. This action of morphine reported previously is not antagonised by naloxone[12,13].

In the present study it was significant that the only effect of met-enkephalin in common with that of morphine was an ability to excite Renshaw cells, an action which was also antagonised by naloxone. The excitatory action of morphine has previously been shown to be stereospecific at this site[11,12]. The present experiments therefore provide direct evidence that met-enkephalin acts on a central opiate receptor and supports the notion that enkephalin is the endogenous ligand for the stereospecific opiate receptor[1].

The enhancement of the excitatory responses to acetylcholine and amino acids excitants by morphine has been considered to be related to the excitatory properties of morphine on cholinoceptive neurones[12]. The apparent selective reduction in neuronal sensitivity to acetylcholine produced by met-enkephalin was therefore unexpected, since this substance also directly excited cholinoceptive neurones. The reasons for these different actions of met-enkephalin and morphine are not known. Note, however, that the active opiate levorphanol also causes a prolonged reduction in acetylcholine sensitivity of Renshaw cells[12].

Thus the present experiments indicate that enkephalin has complex actions on a central cholinoceptive neurone, including a specific opiate type effect. Preliminary results obtained on non-cholinoceptive interneurones suggest that the effects of met-enkephalin described here are confined to cholinoceptive neurones. More extensive experiments are necessary, however, to verify this point and to establish a possible physiological role for endogenous enkephalin.

Fig. 1 Ratemeter record. *a*, Excitatory effects of acetylcholine (ACh, 1 nA); met-enkephalin (ME, 50 nA) and morphine (M, 50 nA), and antagonism of these effects by naloxone (NX, 30 nA). *b*, Effects of a prolonged ejection of met-enkephalin on the excitatory responses induced by morphine (40 nA) and acetylcholine (6 nA). Both records are from the same Renshaw cell.



This work was supported by an MRC programme grant to Professor D. W. Straughan. We thank Dr B. A. Morgan (Reckitt and Colman Ltd, Hull) for gifts of met-enkephalin, and Endo Laboratories Inc., New York, for naloxone hydrochloride.

Depression of nociceptive and other neurones in the brain by iontophoretically applied met-enkephalin

IT has been suggested that enkephalin might act as a neurotransmitter or neuromodulator in the mammalian brain[1], and recent experiments[2,3] have shown that microiontophoretic application of enkephalin will depress brainstem neurones in both rat and cat. We have confirmed these observations on neurones in other regions of the rat brain and have extended the study to an investigation of the action of iontophoretic met-enkephalin on neurones activated by painful stimuli.

Experiments were carried out on adult male rats anaesthetised with 1% halothane in O_2 and prepared for single neurone recording from the cerebral cortex and thalamus (12 rats) or dorsal medulla (4 rats). Conventional techniques were used for single neurone recording and the iontophoretic application of drugs[4]. Five-barrelled micropipettes (tip-size about 6 μm) were used in most experiments with the outer barrels filled with solutions of L-glutamate (0.2 M, *p*H 8), GABA (0.2 M, *p*H 3.5), glycine (0.2 M, *p*H 3.5) and met-enkephalin (5 mg ml^{-1}, that is, about 8 mM in either 200 mM NaCl or in water; no adjustment of *p*H). In 7 of the 12 experiments some microelectrodes were double-barrelled and the only drug tested was met-enkephalin. NaCl 4 M was used in the recording barrel of all electrodes.

In a preliminary survey, in the cerebral cortex, thalamus and dorsal medulla, met-enkephalin applied with positive (0–400 nA), but not negative current, was found to inhibit 59 out of 88 neurones considered to be adequately tested. On 4 of the 88 neurones the action of enkephalin seemed to be excitatory. Appropriate controls to exclude current artefacts were carried out. The action of short applications (< 60 s) of met-enkephalin was uniformly rapid in onset and offset, typically taking less than 10 s to develop and this is similar to the time course of GABA's action in our experimental conditions, although extended application of enkephalin had effects which persisted for several minutes (Fig. 1). Desensitisation to the depressant actions of met-enkephalin was not observed when repeated short applications at intervals of 90–120 s were made to many neurones, sometimes over a period of 1 h or more. This is in contrast

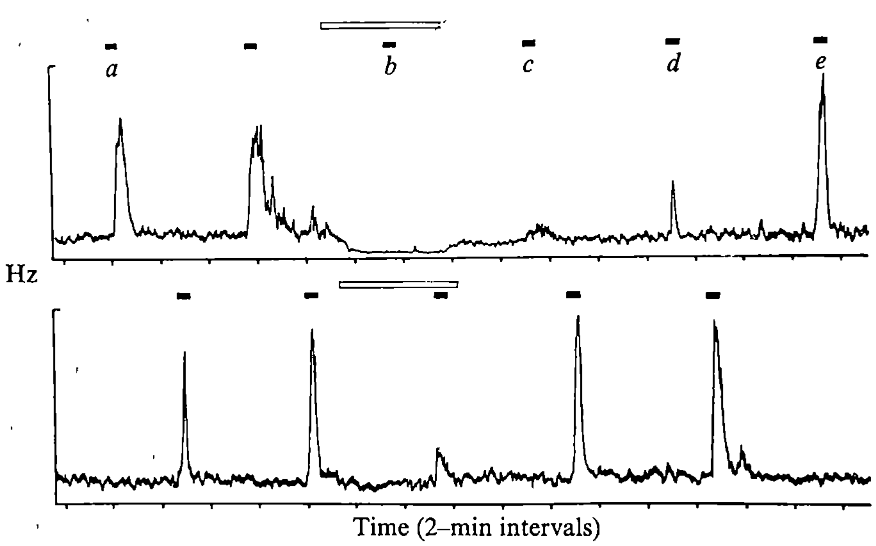

Fig. 1 Analogue ratemeter record of spontaneous firing of a nociceptive neurone (located at a depth of 4,430 μm below the cortical surface) in the rat thalamus. Lower section continuous with upper section. Short horizontal filled bars above record indicate immersion of rat's tail in water at 50 °C for 30 s; this treatment resulted in a brisk discharge of the neurone. For the duration of the first open bar over the record met-enkephalin was applied to the neurone with a current of 100 nA; this completely depressed the spontaneous firing and abolished the response to tail warming. The response to hot water was substantially recovered 16 min after removing the met-enkephalin. The second open bar above the record indicates removal of a 10 nA negative retaining current from the met-enkephalin barrel; although this had no detectable effect on the spontaneous firing rate, it markedly reduced the response to tail warming. The response was fully recovered within 5 min. The firing of this neurone was also depressed by GABA at 50 nA and the response to tail warming was partially blocked by GABA at 10 nA (not shown). *a–e*, Photographic records from the same experiment shown in Fig. 2.

to the action of morphine, in which case desensitisation has been reported after iontophoretic application to central neurones[5,6], but is consistent with the lack of desensitisation to the effects of enkephalin on peripheral tissues[1].

Met-enkephalin has also been tested on thalamic neurones thought to be excited by noxious stimuli[7,8]. The position of the micropipette in the thalamus at the stereotaxic coordinates AP+3, L3, H 4 to 7 (ref. 9) was confirmed both histologically and by recording field potentials[10,11] evoked by electrical stimulation of the limbs and tail. In the present study neurones excited by either a strong tail pinch with a thermometer clamp or immersion of the tail in hot (50 °C) water were considered to be nociceptive in nature. Such nociceptive neurones were very sensitive to met-enkephalin, and this observation is supported by the reduction in the evoked excitation shown in the latter part of Fig. 1 produced simply by removing the 10-nA retaining current from the met-enkephalin-containing barrel of the pipette. The photographic traces in Fig. 2 show that high currents (50–100 nA) of met-enkephalin completely abolished both the background spontaneous activity of this neurone and its response to noxious stimulation. This reduction in the response to noxious stimulation persisted for at least 12 min after the end of the met-enkephalin application (Figs 1 and 2). On seven other nociceptive neurones similar responses to met-enkephalin were obtained.

On eight unidentified neurones tested the depressant action of enkephalin was antagonised by intravenous naloxone (80–320 μg) on only two. This finding in the central nervous system is consistent with the results of experiments on isolated peripheral tissues[3], in which it was discovered that the depressant action of enkephalin was less sensitive to reversal by naloxone than was the similar action of morphine.

The implications of the observations reported here can only be fully explored by further experiments, but it is evident that met-enkephalin will depress many neurones in the mammalian brain and, most interestingly, those located in the thalamus and which are excited by noxious inputs. The observations of Hughes[12] and others[13] that enke-

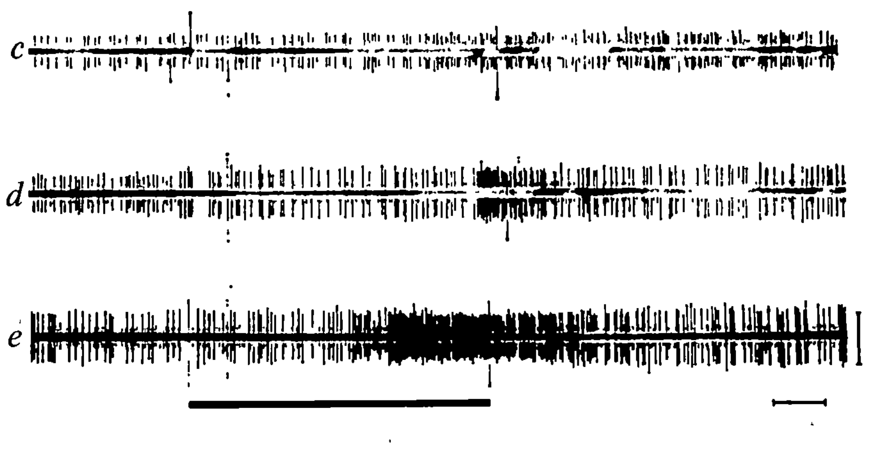

Fig. 2 Continuous photographic records of the firing of the same nociceptive neurone illustrated in Fig. 1. *a–e*, Similarly marked ratemeter traces in Fig. 1. Each vertical deflection on the filmed record represents a burst of 4 or 5 action potentials, the larger deflections visible on some records (for example, *b*) are artefacts caused by touching the animal to apply a heat stimulus. The solid black bar beneath the records indicates the 30-s period over which the animal's tail was immersed in hot (50 °C) water. This produced a sharp increase in firing shown by the increase in density of record *a*. Before record *b*, met-enkephalin was applied at a current of 100 nA and completely abolished the spontaneous firing of the neurone and its response to tail warming. Before record *c*, this met-enkephalin application was terminated; although spontaneous firing had returned, the response to tail warming was still virtually absent. Records *d* and *e* illustrate the gradual recovery of the response to tail warming over the next 12 min. Horizontal bar, 5 s; vertical bar, 0.4 mV.

phalin is found in many areas of the brain not yet implicated in the organism's responses to pain, suggests that this substance may be an important inhibitory transmitter candidate at both nociceptive and other sites.

We thank the MRC for financial support, and Dr Morgan (Reckitt & Colman) for met-enkephalin. C.M.P. is an MRC Scholar.

Changes in amino acid sensitivity during polypeptide 'desensitisation'

CURRENT interest in polypeptides as neurotransmitter substances in the central nervous system (CNS) has been focused on their ability to depolarise motoneurones[1] and to excite single cells in various parts of the brain[2–6]. An additional feature of their actions on nervous tissue, however, is the development of 'tachyphylaxis' or 'desensitisation' to their effects during repeated administration. This phenomenon has been reported with two structurally related undecapeptides in particular, substance P and eledoisin, both in spinal cord[7] and in brain[3–5]. We report here that in the substantia nigra additional changes in amino acid sensitivity occur during such a period of desensitisation to eledoisin.

Albino rats (220–270 g), anaesthetised with urethane 1.4 g kg^{-1}, were used during this study. Multibarrelled glass micropipettes (tip diameter 6 μm) were used to record action potentials extracellularly and to administer substances by electrophoresis on to spontaneously firing neurones in the substantia nigra. Micropipettes were filled immediately before use by a glass-fibre method or by centrifugation. The recording barrel contained 3 M sodium chloride and another containing 1 M sodium chloride was used to balance the net current at the electrode tip to zero or to test for electrophoretic current effects. Other barrels contained eledoisin dihydrochloride (Calbiochem) 24 mM, *p*H 4.5; sodium glutamate 0.2 M, *p*H 7.2; GABA 0.2 M, *p*H 3.5; glycine 0.2 M, *p*H 3.5; taurine 0.2 M, *p*H 4.0; and acetylcholine chloride 0.5 M *p*H 4.5.

Action potentials were recorded and displayed using conventional techniques. Substantia nigra neurones were identified histologically after pontamine-blue dye ejection or by their response after stimulation of the ipsilateral caudate nucleus[8].

Short lasting application (30–60 s) of eledoisin ejected as a cation (50–100 nA; mean 77.3 nA) excited the majority of substantia nigra neurones tested (50 out of 55 cells). One neurone was depressed. The time course of these effects was similar to that described previously[5]. When brief applications of eledoisin were repeated at short intervals the excitatory response became progressively smaller until it could no longer be distinguished from the spontaneous activity. A progressive reduction in the excitation also occurred when a single administration of eledoisin with rather less current (25–75 nA; mean 45.6 nA) was prolonged for 3.5–17 min.

Prolonged applications of eledoisin also reversibly reduced the inhibitory responses to GABA (11 out of 20 cells), glycine (5 out of 13 cells) and taurine (9 out of 20 cells). Such effects, however, were not always observed on the same neurones, since glycine or GABA responses could be depressed without changes in taurine sensitivity occurring (Fig. 1); or taurine responses were depressed without any significant changes in GABA sensitivity. In only 4 of the 13 cells tested with all three inhibitory amino acids, were the responses to each compound entirely unaffected. In addition the excitatory effects of glutamate could be reversibly reduced (10 out of 11 cells), although on one occasion glutamate excitation was potentiated. Acetylcholine excitation was also reduced (2 out of 2 cells), although relatively fewer neurones were tested. These interactions during prolonged applications of eledoisin were not usually accompanied by changes in background firing rate; neither

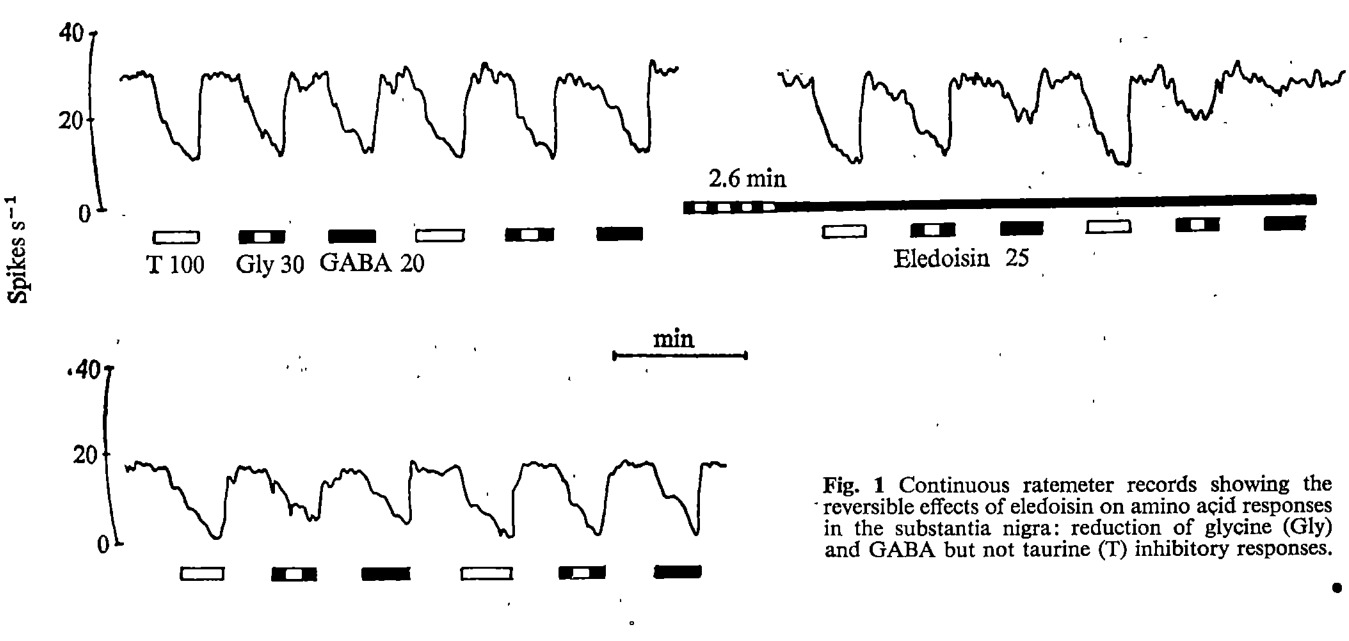

Fig. 1 Continuous ratemeter records showing the reversible effects of eledoisin on amino acid responses in the substantia nigra: reduction of glycine (Gly) and GABA but not taurine (T) inhibitory responses.

were there any alterations in neuronal spike size, although occasionally this was slightly decreased.

Recovery of the responses to amino acids, after termination of eledoisin administration sometimes occurred within about 5 min, but more commonly was considerably prolonged (up to 25.6 min). After recovery of neuronal sensitivity to these agonists, however, a repeated administration of eledoisin produced the same pattern of interactions as observed previously. This suggested that on individual cells the observed interactions were reproducible and could indeed be selective.

Our results, in agreement with previous observations[8], show that substantia nigra neurones are more sensitive to exogenously administered GABA than glycine and are more sensitive to glutamate than acetylcholine. Taurine, which occurs in significant amount in the substantia nigra[9], also exhibits significant inhibitory actions, although it is less potent than either GABA or glycine. In addition the undecapeptide eledoisin excited most substantia nigra neurones, confirming our previous observations[5]. Moreover, repeated or prolonged administration of eledoisin produced desensitisation. During such a period of desensitisation the sensitivity of neurones to exogenously applied GABA, glycine, taurine, glutamate or acetylcholine was reduced. Overall, eledoisin reduced neuronal sensitivity to inhibitory compounds less consistently than to excitatory ones. It is not clear why selectivity to one or more neuronally active substance could be observed on some neurones but not others. Note, however, that a reduction in the sensitivity of central neurones to exogenously administered glutamate or acetylcholine occurs after administration of the naturally occurring and structurally related undecapeptide, substance P (ref. 4).

Attention has been drawn to the potent excitant actions of polypeptides in the spinal cord[1] and in other areas of the brain[2–4,6] but it is possible that such effects may be an artefact resulting from the exogenous administration of non-physiological concentrations of these substances. Many active polypeptides including eledoisin and substance P have a common C-terminal amino acid sequence[1]. This property may be related to their depolarising properties as well as to the production of desensitisation and the modification of endogenous neurotransmission.

Although little is known concerning the precise mechanism of action or physiological role of polypeptides in the CNS their excitation of single neurones may be related to a neurotransmitter function. The modification of neuronal sensitivity to other putative neurotransmitters, however, suggests a more complex function which requires further elucidation.
